### Library

Valve Actuators

### Description

The 2-Position Valve Actuator block represents an actuator that you can use with directional valves to control their position. This actuator can drive a two-position valve. The block is developed as a data-sheet-based model and all its parameters are generally provided in catalogs or data sheets. The key parameters are the stroke, switch-on, and switch-off times.

The block accepts a physical input signal and produces a physical output signal that can be associated with a mechanical translational or rotational push-pin motion. Connect the block output to the directional valve control port.

The actuator is represented as an ideal transducer, where output does not depend on the load exerted on the push-pin and the push-pin motion profile remains the same under any loading conditions. The motion profile represents a typical transition curve for electromagnetic actuators and is shown in the following figure:

The push-pin is actuated when the input signal value crosses the threshold of 50% of the nominal input signal, where **Nominal signal value** is a block parameter. The motion is divided into three phases, equal in time: delay ( $t_1$ ), motion at constant acceleration ( $t_2$ ), and motion at constant velocity ( $t_3$ ). The motion stops when the switch-on time ( $t_{on}$ ) elapses. At this moment, the push-pin reaches the specified stroke value ( $x_{str}$ ). To return the push-pin into initial position, the control signal must cross back through the threshold of 50% of the nominal input signal, which causes the push-pin to retract. The retract motion follows exactly the same profile but “stretches” over the switch-off time. **Switching-on time** and **Switching-off time** are the block parameters.

The transition in any direction can be interrupted at any time by changing the input signal. If motion is interrupted, the switch-on or switch-off times are proportionally decreased depending on the instantaneous push-pin position.

The push-pin is actuated only by positive signal, similar to the AC or DC electromagnets. The direction of push-pin motion is controlled by the **Actuator orientation** parameter, which can have one of two values: **Acts in positive direction** or **Acts in negative direction**.

## Basic Assumptions and Limitations

Push-pin loading, such as inertia, spring, hydraulic forces, and so on, is not taken into account.

## Parameters

### Push-pin stroke

The push-pin stroke. The default value is 0.01 m.

**Switching-on time**

Time necessary to fully extend the push-pin after the control signal is applied. The default value is 0.1 s.

**Switching-off time**

Time necessary to retract push-pin from fully extended position after the input signal is removed. The default value is 0.1 s.

**Nominal signal value**

Sets the value of the nominal input signal. The output motion is initiated as the input signal crosses 50% value of the nominal signal. Other than that, the input signal has no effect on the motion profile. This parameter is meant to reproduce the rated voltage feature of an electromagnet. The default value is 24.

**Initial position**

Specifies the initial position of the push-pin. The parameter can have one of two values: `Extended` or `Retracted`. The default value is `Retracted`.

In selecting the initial position, consider the following:

- The steady-state push-pin position always corresponds to the control signal. In other words, zero or negative signal keeps the push-pin at `Retracted`, and positive signal — at `Extended`.
- At the start of simulation, if there is a discrepancy between the initial position of the push-pin, as specified by the **Initial position** parameter, and the control signal, the push-pin immediately starts moving towards the steady-state position designated by the control signal.

**Actuator orientation**

Parameter controls the direction of the push-pin motion and can have one of two values: `Acts in positive direction` or `Acts in negative direction`. The first value causes the push-pin to move in positive direction, similarly to the action of electromagnet A attached to a directional valve. If the parameter is set to `Acts in negative direction`, the control signal causes the push-pin to move in negative direction from the initial position. The default value is `Acts in positive direction`.

**Restricted Parameters**

When your model is in Restricted editing mode, you cannot modify the following parameters:

- **Initial position**
- **Actuator orientation**

All other block parameters are available for modification.

**Ports**

The block has one physical signal input port, associated with the input signal, and one physical signal output port, associated with the output signal (push-pin displacement).

**Examples**

In the “2-Position Valve Actuator” example, the hydraulic circuit contains two actuators. The first one is set to start from the retracted position, while the second one starts from the extended position.

Both actuators are driven with a Pulse Generator. The actuators start extending at 1 s, but the second actuator first retracts from 0.01 m to zero, since it was initially extended and there was no signal keeping it there.

In the “Single-Acting Cylinder with 3-Way Valve” example, the 2-Position Valve Actuator block is used along with a 3-Way Directional Valve block to simulate an electrically operated 3-way directional valve.

## Version History

### Library

Directional Valves

### Description

The 2-Way Directional Valve block represents a continuous, 2-way directional valve, also referred to as a shut-off valve. It is the device that controls the connection between two lines. The block has two hydraulic connections, corresponding to inlet port (A) and outlet port (B), and one physical signal port connection (S), which controls the spool position. The block is built based on a Variable Orifice block, where the **Orifice orientation** parameter is set to **Opens in positive direction**. This means that positive signal  $x$  at port S opens the orifice, and its instantaneous opening  $h$  is computed as follows:

$$h = x_0 + x$$

where

$h$	Orifice opening
$x_0$	Initial opening
$x$	Control member displacement from initial position

Because the block is based on a variable orifice, you can choose one of the following model parameterization options:

- **By maximum area and opening** — Use this option if the data sheet provides only the orifice maximum area and the control member maximum stroke.
- **By area vs. opening table** — Use this option if the catalog or data sheet provides a table of the orifice passage area based on the control member displacement  $A=A(h)$ .
- **By pressure-flow characteristic** — Use this option if the catalog or data sheet provides a two-dimensional table of the pressure-flow characteristics  $q=q(p, h)$ .

In the first case, the passage area is assumed to be linearly dependent on the control member displacement, that is, the orifice is assumed to be closed at the initial position of the control member (zero displacement), and the maximum opening takes place at the maximum displacement. In the second case, the passage area is determined by one-dimensional interpolation from the table  $A=A(h)$ . Flow rate is determined analytically, which additionally requires data such as flow discharge coefficient, critical Reynolds number, and fluid density and viscosity. The computation accounts for the laminar and turbulent flow regimes by monitoring the Reynolds number and comparing its value with the critical Reynolds number. See the Variable Orifice block reference page for details. In both cases, a small leakage area is assumed to exist even after the orifice is completely closed. Physically, it represents a possible clearance in the closed valve, but the main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. An isolated or “hanging” part of the system could affect computational efficiency and even cause simulation to fail.

In the third case, when an orifice is defined by its pressure-flow characteristics, the flow rate is determined by two-dimensional interpolation. In this case, neither flow regime nor leakage flow rate is taken into account, because these features are assumed to be introduced through the tabulated data. Pressure-flow characteristics are specified with three data sets: array of orifice openings, array of pressure differentials across the orifice, and matrix of flow rate values. Each value of a flow rate corresponds to a specific combination of an opening and pressure differential. In other words, characteristics must be presented as the Cartesian mesh, i.e., the function values must be specified at vertices of a rectangular array. The argument arrays (openings and pressure differentials) must be strictly increasing. The vertices can be nonuniformly spaced. You have a choice of three interpolation methods and two extrapolation methods.

The block positive direction is from port A to port B. This means that the flow rate is positive if it flows from A to B and the pressure differential is determined as  $p = p_A - p_B$ . Positive signal at the physical signal port S opens the valve.

## Basic Assumptions and Limitations

- Fluid inertia is not taken into account.
- Spool loading, such as inertia, spring, hydraulic forces, and so on, is not taken into account.

## Parameters

### Model parameterization

Select one of the following methods for specifying the valve:

- **By maximum area and opening** — Provide values for the maximum valve passage area and the maximum valve opening. The passage area is linearly dependent on the control member displacement, that is, the valve is closed at the initial position of the control member (zero displacement), and the maximum opening takes place at the maximum displacement. This is the default method.
- **By area vs. opening table** — Provide tabulated data of valve openings and corresponding valve passage areas. The passage area is determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.
- **By pressure-flow characteristic** — Provide tabulated data of valve openings, pressure differentials, and corresponding flow rates. The flow rate is determined by two-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.

**Valve passage maximum area**

Specify the area of a fully opened valve. The parameter value must be greater than zero. The default value is  $5e-5 \text{ m}^2$ . This parameter is used if **Model parameterization** is set to By maximum area and opening.

**Valve maximum opening**

Specify the maximum displacement of the control member. The parameter value must be greater than zero. The default value is  $5e-3 \text{ m}$ . This parameter is used if **Model parameterization** is set to By maximum area and opening.

**Tabulated valve openings**

Specify the vector of input values for valve openings as a one-dimensional array. The input values vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in meters, are  $[-0.002 \ 0 \ 0.002 \ 0.005 \ 0.015]$ . If **Model parameterization** is set to By area vs. opening table, the **Tabulated valve openings** values will be used together with **Tabulated valve passage area** values for one-dimensional table lookup. If **Model parameterization** is set to By pressure-flow characteristic, the **Tabulated valve openings** values will be used together with **Tabulated pressure differentials** and **Tabulated flow rates** for two-dimensional table lookup.

**Tabulated valve passage area**

Specify the vector of output values for valve passage area as a one-dimensional array. The valve passage area vector must be of the same size as the valve openings vector. All the values must be positive. The default values, in  $\text{m}^2$ , are  $[1e-09 \ 2.0352e-07 \ 4.0736e-05 \ 0.00011438 \ 0.00034356]$ . This parameter is used if **Model parameterization** is set to By area vs. opening table.

**Tabulated pressure differentials**

Specify the vector of input values for pressure differentials as a one-dimensional array. The vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in Pa, are  $[-1e+07 \ -5e+06 \ -2e+06 \ 2e+06 \ 5e+06 \ 1e+07]$ . This parameter is used if **Model parameterization** is set to By pressure-flow characteristic.

**Tabulated flow rates**

Specify the flow rates as an  $m$ -by- $n$  matrix, where  $m$  is the number of valve openings and  $n$  is the number of pressure differentials. Each value in the matrix specifies flow rate taking place at a specific combination of valve opening and pressure differential. The matrix size must match the dimensions defined by the input vectors. The default values, in  $\text{m}^3/\text{s}$ , are:

```
[-1e-07 -7.0711e-08 -4.4721e-08 4.4721e-08 7.0711e-08 1e-07;
-2.0352e-05 -1.4391e-05 -9.1017e-06 9.1017e-06 1.4391e-05 2.0352e-05;
-0.0040736 -0.0028805 -0.0018218 0.0018218 0.0028805 0.0040736;
-0.011438 -0.0080879 -0.0051152 0.0051152 0.0080879 0.011438;
-0.034356 -0.024293 -0.015364 0.015364 0.024293 0.034356;]
```

This parameter is used if **Model parameterization** is set to By pressure-flow characteristic.

**Interpolation method**

Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- **Linear** — Select this option to get the best performance.
- **Smooth** — Select this option to produce a continuous curve (By area vs. opening table) or surface (By pressure-flow characteristic) with continuous first-order derivatives.

For more information on interpolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

### Extrapolation method

Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- **Linear** — Select this option to produce a curve or surface with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.
- **Nearest** — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

### Flow discharge coefficient

Semi-empirical parameter for valve capacity characterization. Its value depends on the geometrical properties of the valve, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.7.

### Initial opening

Orifice initial opening. The parameter can be positive (underlapped orifice), negative (overlapped orifice), or equal to zero for zero lap configuration. The default value is 0.

### Laminar transition specification

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

### Laminar flow pressure ratio

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

### Critical Reynolds number

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12, which corresponds to a round orifice in thin material with sharp edges. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

### Leakage area

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system

from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is  $1e-12 \text{ m}^2$ .

### **Restricted Parameters**

When your model is in Restricted editing mode, you cannot modify the following parameters:

- **Model parameterization**
- **Interpolation method**
- **Extrapolation method**

All other block parameters are available for modification. The actual set of modifiable block parameters depends on the value of the **Model parameterization** parameter at the time the model entered Restricted mode.

### **Global Parameters**

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

### **Ports**

The block has the following ports:

A

Hydraulic conserving port associated with the valve inlet.

B

Hydraulic conserving port associated with the valve outlet.

S

Physical signal port to control spool displacement.

### **Examples**

In the “Closed-Loop Actuator with 2-Way Valve” example, the 2-Way Directional Valve block is used to control the position of a double-acting cylinder. At the start of simulation, the valve is open by 0.42 mm to make the circuit initial position as close as possible to its neutral position.

## **Version History**

**Introduced in R2006a**

**R2023a: To be removed**

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## **Extended Capabilities**

### **C/C++ Code Generation**

Generate C and C++ code using Simulink® Coder™.

### **See Also**

3-Way Directional Valve | 4-Way Directional Valve

## 2-Way Directional Valve (IL)

2-way flow control valve in an isothermal liquid systems

### Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Directional Control Valves

### Description

The 2-Way Directional Valve (IL) block represents a two-way valve, such as a shut-off valve. Use this block to simulate a flow-reducing control element that responds to pressures in another part of the system.

The block uses a variable orifice to control the flow between ports **A** and **B**. The physical signal at port **S** triggers the spool motion to open or shut the valve. For more details about how the block calculates flow rate through a variable orifice, see Orifice (IL).

### Orifice Parameterizations

You can parameterize the valve opening linearly or by using tabulated data.

#### Linear

When you set **Orifice parameterization** to Linear - Area vs. spool travel, the opening area is a linear function of the spool travel distance.

$$A_{orifice} = \frac{(A_{max} - A_{leak})}{\Delta S_{max}} \Delta S + A_{leak},$$

where

- $A_{orifice}$  is the opening area.
- $\Delta S$  is the spool travel distance input at port **S**.  $\Delta S = S - S_{max} + \Delta S_{max}$ .
- $\Delta S_{max}$  is the value of the **Spool travel between closed and open orifice** parameter.
- $A_{Leak}$  is the value of the **Leakage area** parameter.
- $A_{max}$  is the value of the **Maximum orifice area** parameter.

Note the linear scaling from  $A_{Leak}$  to  $A_{max}$  in the figure.

When the valve is in a near-open or near-closed position in the linear parameterization, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If

the **Smoothing factor** parameter is nonzero, the block smoothly saturates the opening area between  $A_{leak}$  and  $A_{max}$ . For more information, see “Numerical Smoothing”.

### Tabulated

When you set **Orifice parameterization** to Tabulated data - Area vs. spool travel, the block uses the **Spool travel vector** and **Orifice area vector** parameters to define the relationship between  $A_{orifice}$  and  $\Delta S$  by interpolation.  $A_{leak}$  and  $A_{max}$  are the first and last parameters of the **Orifice area vector** parameter, respectively.

When you set **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop, the block uses the **Volumetric flow rate table**,  $q(\mathbf{ds}, \mathbf{dp})$ , **Pressure drop vector**,  $\mathbf{dp}$ , and **Spool travel vector**,  $\mathbf{ds}$  parameters to define the volumetric flow rate,  $q(\Delta S, p)$ .

### Visualize Orifice Openings

To visualize the spool offsets and displacement, right-click the block and select **Fluids > Plot Valve Characteristics**. The plot shows the valve open area or volumetric flow rate as a function of spool position.

To update the data after changing the block parameters, click **Reload Data** in the figure window.

This figure shows the valve configuration with:

- **Spool position at maximum orifice area** set to  $2e-3$  m.
- **Spool travel between closed and open orifice** set to  $6e-3$  m.

All other parameters are at the default values.

### Faults

When you set **Enable faults** to On, the valve opening stops at a specified spool position in response to how you set the **Fault trigger** parameter:

- Temporal — Fault occurs at the time you specify in the **Simulation time for fault event** parameter.
- External — Faults occur in response to an external trigger from port **Tr**.

You can choose the type of fault by using the **Spool position when faulted** parameter:

- Negative — The block freezes the valve at its smallest value. The table shows which value the block uses depending on the setting of the **Orifice parameterization** parameter.

Orifice parameterization Parameter Setting	Freeze Position Value
Linear - Area vs. spool travel	<b>Leakage area</b> parameter
Tabulated data - Area vs. spool travel	First element of the <b>Orifice area vector</b> parameter
Tabulated data - Volumetric flow rate vs. spool travel and pressure drop	First row of the <b>Volumetric flow rate table, q(ds,dp)</b> parameter

- Positive — The valve freezes at its largest value. The table shows which value the block uses depending on the setting of the **Orifice parameterization** parameter.

Orifice parameterization Parameter Setting	Freeze Position Value
Linear - Area vs. spool travel	<b>Maximum opening area</b> parameter
Tabulated data - Area vs. spool travel	Last element of the <b>Orifice area vector</b> parameter
Tabulated data - Volumetric flow rate vs. spool travel and pressure drop	Last row of the <b>Volumetric flow rate table, <math>q(ds,dp)</math></b> parameter

- **Maintain last value** — The valve freezes at its last value. The table shows which value the block uses depending on the setting of the **Orifice parameterization** parameter.

Orifice parameterization Parameter Setting	Freeze Position Value
Linear - Area vs. spool travel	The valve open area when the trigger occurred
Tabulated data - Area vs. spool travel	The valve open area when the trigger occurred
Tabulated data - Volumetric flow rate vs. spool travel and pressure drop	Current position

Note that when you set **Orifice parameterization** to **Tabulated data - Volumetric flow rate vs. spool travel and pressure drop**, the volumetric flow rate continues to change according to pressure changes in the valve after the valve freezes.

Due to numerical smoothing at the extremes of the valve area, the block applies a minimum area that is larger than the **Leakage area**, and a maximum that is smaller than the **Maximum orifice area**, in proportion to the **Smoothing factor** value.

After the fault triggers, the valve remains at the faulted area for the rest of the simulation.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Isothermal liquid conserving port.

**B** — Liquid port  
isothermal liquid

Isothermal liquid conserving port.

### Input

**S** — Spool displacement, m  
physical signal

Physical signal associated with the spool displacement, in m. A positive value causes the valve to open.

**Tr** — External fault trigger  
physical signal

Physical signal port associated with the external fault trigger. Triggering occurs when the value is greater than 0.5.

#### **Dependencies**

To enable this port, set **Enable faults** to On and **Fault trigger** to External.

## **Parameters**

### **Model Parameterization**

**Orifice parameterization** — Opening area relationship

Linear - area vs. spool travel (default) | Tabulated data - Area vs. spool travel |  
Tabulated data - Volumetric flow rate vs. spool travel and pressure drop

Method the block uses to calculate the valve flow area. To learn more, see “Orifice Parameterizations” on page 1-12.

**Spool position at maximum orifice area** — Spool offset at maximum area

5e-3 m (default) | positive scalar

Position of the spool travel member when the valve is fully open. The default value represents a zero-lapped system. A positive, nonzero value represents an underlapped, or partially closed, system. A negative, nonzero value represents an overlapped system where the valve remains open over a range of displacements.

**Spool travel between closed and open orifice** — Maximum spool stroke

5e-3 m (default) | positive scalar

Spool offset at the maximum valve opened area.

#### **Dependencies**

To enable this parameter, set **Orifice parametrization** to Linear - area vs. spool travel.

**Maximum orifice area** — Area of fully open valve

1e-4 m<sup>2</sup> (default) | positive scalar

Maximum valve area experienced during simulation.

#### **Dependencies**

To enable this parameter, set **Orifice parametrization** to Linear - area vs. spool travel.

**Leakage area** — Valve gap area when in fully closed position

1e-10 m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the valve is in the fully closed position. The block maintains any area smaller than this value at the specified leakage area. This parameter contributes to numerical stability by maintaining continuity in the flow.

**Dependencies**

To enable this parameter, set **Orifice parametrization** to Linear - area vs. spool travel.

**Spool travel vector** — Spool opening distance values  
[0, .002, .004, .007, .017] m (default) | vector

Vector of control member travel distances. A positive value opens the valve. The values in this vector correspond one-to-one to values in the **Orifice area vector** parameter. The values must ascend from 0. The block interpolates the points linearly.

**Dependencies**

To enable this parameter, set **Orifice parametrization** to Tabulated data - Area vs. spool travel.

**Orifice area vector** — Valve opening area values  
[1e-09, 2.0352e-07, 4.0736e-05, .00011438, .00034356] m<sup>2</sup> (default) | vector

Vector of valve area values for the tabular parametrization of opening area. The values in this vector correspond one-to-one with the elements in the **Spool travel vector** parameter. The first element of this vector is the leakage area, and the last element is the maximum valve area. The block interpolates the points linearly.

**Dependencies**

To enable this parameter, set **Orifice parametrization** to Tabulated data - Area vs. spool travel.

**Spool travel vector, ds** — Tabular spool opening distance values  
[0, .002, .004, .007, .017] m (default) | vector

Vector of control member travel distances. The spool travel vector forms an independent axis with the **Pressure drop vector, dp** parameter for the 3-D dependent **Volumetric flow rate table, q(ds,dp)** parameter. A positive displacement corresponds to valve opening. The values ascend from 0. The block interpolates the points linearly.

**Dependencies**

To enable this parameter, set **Orifice parametrization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**Pressure drop vector, dp** — Tabular pressure drop values  
[.3, .5, .7] MPa (default) | vector

Vector of pressure drop values for the volumetric flow rate. The pressure drop vector forms an independent axis with the **Spool travel vector, ds** parameter for the 3-D dependent **Volumetric flow rate table, q(ds,dp)** parameter. The values must be positive and ascending. The block interpolates the points linearly.

**Dependencies**

To enable this parameter, set **Orifice parametrization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**Volumetric flow rate table,  $q(ds,dp)$**  — Volumetric flow rate for given spool travel and pressure drop

[1.7e-05, 2e-05, 2.6e-05; .0035, .0045, .0053; .7, .9, 1.06; 1.96, 2.5, 3; 6, 7.7, 9.13] m<sup>3</sup>/s (default) | matrix

$M$ -by- $N$  matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance.  $M$  and  $N$  are the sizes of the correlated vectors:

- $M$  is the number of elements in the **Pressure drop vector,  $dp$**  parameter.
- $N$  is the number of elements in the **Spool travel vector,  $ds$**  parameter.

#### Dependencies

To enable this parameter, set **Orifice parametrization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Discharge loss for a hydraulic structure. The default discharge coefficient for an valve in Simscape Fluids is 0.64.

#### Dependencies

To enable this parameter, set **Orifice parametrization** to either:

- Tabulated data - Area vs. spool travel
- Linear - area vs. spool travel

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

#### Dependencies

To enable this parameter, set **Orifice parametrization** to either:

- Tabulated data - Area vs. spool travel
- Linear - area vs. spool travel

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change based to the flow response when the valve is in near-open and near-closed positions. To increase the stability of your simulation in these regimes, set this parameter to a nonzero value less than one.

#### Dependencies

To enable this parameter, set **Orifice parametrization** to Linear - area vs. spool travel.

**Pressure recovery** — Whether to account for pressure increase in area expansions

on (default) | off

Whether to account for pressure increase when the fluid flows from a region of smaller cross-sectional area to a region of larger cross-sectional area.

**Cross-sectional area at ports A and B** — Valve area at conserving ports

inf m<sup>2</sup> (default) | positive scalar

Cross-sectional area at ports **A** and **B**. The block uses this area in the pressure-flow rate equation to determine the volumetric flow rate through the valve.

#### Dependencies

To enable this parameter, set **Orifice parametrization** to either:

- Tabulated data - Area vs. spool travel
- Linear - area vs. spool travel

#### Faults

**Enable faults** — Fault option

Off (default) | On

Enable externally or temporally triggered faults. When a fault occurs, the block sets the valve area to the value specified in the **Spool position when faulted** parameter.

**Spool position when faulted** — Set faulted characteristics

Positive (default) | Negative | Maintain last value

Sets the faulted valve spool position. You can choose for the valve to seize when the spool is in the positive position, negative position, or at the position when the fault triggers.

#### Dependencies

To enable this parameter, set **Enable faults** to On.

**Fault trigger** — External or temporal trigger option

Temporal (default) | External

Whether a fault occurs due to an external event or at a specified time.

- External — A physical signal at port **Tr** that is greater than 0.5 triggers a fault.
- Temporal — The block sets the valve area to the value specified in the **Spool position when faulted** parameter once the simulation reaches the time specified in the **Simulation time for fault event** parameter.

#### Dependencies

To enable this parameter, set **Enable faults** to On.

**Simulation time for fault event** — Time at which faulting is triggered

5 s (default) | positive scalar

Simulation time when fault occurs.

#### Dependencies

To enable this parameter, set **Enable faults** to On and **Fault trigger** to Temporal.

## 2-Way Directional Valve (G)

Controlled valve with two ports in a gas network

### Libraries:

Simscape / Fluids / Gas / Valves & Orifices / Directional Control Valves

### Description

The 2-Way Directional Valve (G) block represents a valve with two ports, **A** and **B**, and one flow path, **A-B**. The path runs through an orifice of variable width. The input signal specified at port **S** controls the position of the spool. The valve closes when the spool covers the orifice opening.

The flow can be laminar or turbulent, and it can reach up to sonic speeds. The maximum velocity happens at the throat of the valve where the flow is narrowest and fastest. The flow chokes and the velocity saturates when a drop in downstream pressure can no longer increase the velocity. Choking occurs when the back-pressure ratio reaches the critical value characteristic of the valve. The block does not capture supersonic flow.

### Valve Positions

The valve is continuously variable and it shifts smoothly between one normal and one working position.

When the instantaneous displacement of the spool at port **S** is zero, the valve reverts to the normal position where it is no longer operating. Unless the land of the spool is at an offset to the valve orifice, the valve is fully closed. The working position is the position the valve moves to when the spool is maximally displaced, in the positive direction, from the normal position. The orifice is then fully open.

The spool displacement that puts the valve in its working position depends on the offset of the land on the spool. The **Valve opening fraction offset** parameter specifies the block constant for the spool displacements of the ports.

### Orifice Opening Fractions

Between valve positions, the opening of the **A-B** orifice depends on where the land of the spool is, relative to the rim. This distance is the orifice opening, and the block normalizes this distance so that its value is a fraction of the maximum distance at which the orifice is fully open. The normalized variable is the orifice opening fraction.

The orifice opening fraction can range from 0, in the normal position, to 1, in the working position. The block calculates the opening fractions from the spool displacement and opening fraction offset. The displacement and offset are unitless fractions of the maximum land-orifice distance. The orifice opening fraction is:

$$h_{AB} = H_{AB} + \chi,$$

where:

- $h$  is the opening fraction of the **A-B** orifice. If the calculation returns a value outside of the range  $0 - 1$ , the block uses the nearest limit.
- $H$  is the value of the **Valve opening fraction offset** parameter. To allow for unusual valve configurations, the block imposes no limit on their values, although generally these will fall between  $-1$  and  $+1$ .
- $x$  is the normalized instantaneous displacement of the spool, specified by a physical signal at port **S**. To compensate for extreme opening fraction offsets, there is no limit on the signal value. The value is typically between  $0$  and  $+1$ .

**Opening Fraction Offsets**

By default, the valve is fully closed when its control displacement is zero. In this state, the valve is zero-lapped.

You can offset the lands of the spool to model an underlapped or overlapped valve. Underlapped valves are partially open in the normal position. Overlapped valves are fully closed slightly beyond the normal position. The figure shows how the orifice opening fractions vary with the instantaneous spool displacement:

- **Image I:** A zero-lapped valve. The opening fraction offset is zero. When the valve is in the normal position, the land of the spool completely covers the orifice.
- **Image II:** An underlapped valve. The opening fraction offset is positive. When the valve is in the normal position, the land of the spool partially covers the orifice.
- **Image III:** An overlapped valve. The opening fraction offset is negative. The land of the spool completely covers the orifice not only in the normal position but also over a small region of spool displacements around it.

**I.**

**II.**

**III.**

**Control Position in Zero-Lapped, Underlapped, and Overlapped valves**

### Leakage Flow

The leakage flow ensures that no section of a fluid network becomes isolated. Isolated fluid sections can reduce the numerical robustness of the model, slow the rate of simulation and, in some cases, cause the simulation to fail. The **Leakage flow fraction** parameter represents the leakage flow area in the block as a small number greater than zero.

### Composite Structure

This block is a composite component comprising a single Orifice (G) block connected between ports **A**, **B**, and **S**. Refer to the Orifice (G) block for more detail on the valve parameterizations and block calculations.

### Valve Parameterizations

The block behavior depends on the **Valve parametrization** parameter:

- **Cv flow coefficient** — The flow coefficient  $C_v$  determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential. [2][3]
- **Kv flow coefficient** — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential. [2][3]
- **Sonic conductance** — The sonic conductance of the resistive element at steady state determines the block parameterization. The sonic conductance measures the ease with which a gas can flow when *choked*, which is a condition in which the flow velocity is at the local speed of sound. Choking occurs when the ratio between downstream and upstream pressures reaches a critical value known as the *critical pressure ratio*. [1]
- **Orifice area** — The size of the flow restriction determines the block parametrization. [4]

### Opening Characteristics

The flow characteristic relates the opening of the valve to the input that produces it, which is often the spool travel. The block expresses the opening as a sonic conductance, flow coefficient, or restriction area, depending on the setting of the **Valve parameterization** parameter. The control input is the orifice opening fraction, a function of the spool displacement specified at port **S**.

The flow characteristic is normally given at steady state, with the inlet at a constant, carefully controlled pressure. The flow characteristic depends only on the valve and can be linear or nonlinear. To capture the flow characteristics, use the **Opening characteristic** parameter:

- **Linear** — The measure of flow capacity is a linear function of the orifice opening fraction. As the opening fraction rises from 0 to 1, the measure of flow capacity scales from the specified minimum to the specified maximum.

- **Tabulated** — The measure of flow capacity is a general function, which can be linear or nonlinear, of the orifice opening fraction. The function is specified in tabulated form, with the independent variable specified by the **Opening fraction vector**

## Numerical Smoothing

When the **Opening characteristic** parameter is **Linear**, and the **Smoothing factor** parameter is nonzero, the block applies numerical smoothing to the orifice opening fraction. Enabling smoothing helps maintain numerical robustness in your simulation.

For more information, see “Numerical Smoothing”.

## Assumptions and Limitations

- The **Sonic conductance** setting of the **Valve parameterization** parameter is for pneumatic applications. If you use this setting for gases other than air, you may need to scale the sonic conductance by the square root of the specific gravity.
- The equation for the **Orifice area** parameterization is less accurate for gases that are far from ideal.
- This block does not model supersonic flow.

## Ports

### Input

**S** — Valve control signal, unitless  
physical signal

Instantaneous displacement of the control member against its normal unactuated position, specified as a physical signal. The block normalizes the displacement against the maximum position of the control member that required to open the orifice fully. The signal is unitless and its instantaneous value is typically in the range between 0 and 1.

### Conserving

**A** — Valve opening  
gas

Gas conserving port associated with the opening through which the flow enters or exits the valve.

**B** — Valve opening  
gas

Gas conserving port associated with the opening through which the flow enters or exits the valve.

## Parameters

**Valve parameterization** — Parameterization used to specify flow characteristics of orifice  
Cv flow coefficient (default) | Kv flow coefficient | Sonic conductance | Orifice area

Method to calculate the mass flow rate.

- **Cv flow coefficient** — The flow coefficient  $C_v$  determines the block parameterization.
- **Kv flow coefficient** — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization.
- **Sonic conductance** — The sonic conductance of the resistive element at steady state determines the block parameterization.
- **Orifice area** — The size of the flow restriction determines the block parameterization.

**Opening characteristic** — Method to calculate the opening characteristics of the valve  
Linear (default) | Tabulated

Method the block uses to calculate the opening area of the valve. The linear setting treats the opening area as a linear function of the orifice opening fraction. The tabulated setting allows for a general, nonlinear relationship you can specify in tabulated form.

**Opening fraction vector** — Control signal values at which to specify tabulated parameter data  
 $0 : 0.2 : 1$  (default) | vector of positive numbers

Vector of control signal values at which to specify the chosen measure of flow capacity: **Sonic conductance vector**, **Cv coefficient vector**, **Kv coefficient vector**, or **Orifice area vector**. The control signal is between 0 and 1, with each value corresponding to an opening fraction of the resistive element. The greater the value, the greater the opening and easier the flow.

The opening fractions must increase monotonically across the vector from left to right. The size of this vector must be the same as the **Sonic conductance vector**, **Cv coefficient vector**, **Kv coefficient vector**, or **Orifice area vector** parameter.

#### Dependencies

To enable this parameter, set **Opening characteristic** to Tabulated.

**Maximum Cv flow coefficient** — Cv coefficient that corresponds to maximally open component  
4 (default) | positive scalar

Value of the  $C_v$  flow coefficient when the restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Cv flow coefficient, and **Opening characteristic** to Linear.

**xT pressure differential ratio factor at choked flow** — Ratio of pressure differentials  
0.7 (default) | positive scalar

Ratio between the inlet pressure,  $p_{in}$ , and the outlet pressure,  $p_{out}$ , defined as  $(p_{in} - p_{out})/p_{in}$  where choking first occurs. If you do not have this value, look it up in table 2 in ISA-75.01.01 [3]. Otherwise, the default value of 0.7 is reasonable for many valves.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Cv flow coefficient or Kv flow coefficient.

**Leakage flow fraction** — Ratio of flow rates

1e-6 (default) | positive scalar

Ratio of the flow rate of the orifice when it is closed to when it is open.

**Dependencies**

To enable this parameter, set **Opening characteristic** to Linear.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the orifice is in near-open or near-closed positions. Set this parameter to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Dependencies**

To enable this parameter, set **Opening characteristic** to Linear.

**Cv flow coefficient vector** — Cv coefficients corresponding to values in opening fraction vector

[1e-06, .8, 1.6, 2.4, 3.2, 4] (default) | vector of positive numbers

Vector of  $C_v$  flow coefficients. Each coefficient corresponds to a value in the **Opening fraction vector** parameter. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential. The flow coefficients must increase monotonically from left to right, with greater opening fractions representing greater flow coefficients. The size of the vector must be the same as the **Opening fraction vector**.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Cv flow coefficient, and **Opening characteristic** to Tabulated.

**Maximum Kv flow coefficient** — Kv coefficient that corresponds to maximally open component

3.6 (default) | positive scalar

Value of the  $K_v$  flow coefficient when the restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Kv flow coefficient, and **Opening characteristic** to Linear.

**Kv flow coefficient vector** — Kv coefficients corresponding to values in opening fraction vector

[1e-06, .72, 1.44, 2.16, 2.88, 3.6] (default) | vector of positive numbers

Vector of  $K_v$  flow coefficients. Each coefficient corresponds to a value in the **Opening fraction vector** parameter. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential. The flow coefficients must increase monotonically from left to right, with greater opening fractions representing greater flow coefficients. The size of the vector must be the same as the **Opening fraction vector** parameter.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Kv flow coefficient, and **Opening characteristic** to Tabulated.

**Maximum sonic conductance** — Sonic conductance corresponding to maximally open component  
 $12 \text{ l}/(\text{bar}\cdot\text{s})$  (default) | positive scalar

Value of the sonic conductance when the cross-sectional area available for flow is at a maximum.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance, and **Opening characteristic** to Linear.

**Critical pressure ratio** — Ratio of downstream and upstream pressures at which the flow first chokes  
 $0.3$  (default) | positive scalar

Pressure ratio at which flow first begins to choke and the flow velocity reaches its maximum, given by the local speed of sound. The pressure ratio is the outlet pressure divided by inlet pressure.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance, and **Opening characteristic** to Linear.

**Subsonic index** — Exponent used to characterize mass flow in subsonic flow regime  
 $0.5$  (default) | positive scalar

Empirical value used to more accurately calculate the mass flow rate in the subsonic flow regime.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**ISO reference temperature** — ISO 8778 reference temperature  
 $293.15 \text{ K}$  (default) | scalar

Temperature at standard reference atmosphere, defined as 293.15 K in ISO 8778.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**ISO reference density** — ISO 8778 reference density  
 $1.185 \text{ kg}/\text{m}^3$  (default) | positive scalar

Density at standard reference atmosphere, defined as 1.185 kg/m<sup>3</sup> in ISO 8778.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**Sonic conductance vector** — Sonic conductances corresponding to values in opening fraction vector  
 $[1\text{e-}05, 2.4, 4.8, 7.2, 9.6, 12] \text{ l}/(\text{bar}\cdot\text{s})$  (default) | vector of positive values

Vector of sonic conductances inside the resistive element. Each conductance corresponds to a value in the **Opening fraction vector** parameter. The sonic conductances must increase monotonically

from left to right, with greater opening fractions representing greater sonic conductances. The size of the vector must be the same as the **Opening fraction vector** parameter.

**Dependencies**

To enable this parameter, set **Valve parameterization** to `Sonic conductance`, and **Opening characteristic** to `Tabulated`.

**Critical pressure ratio vector** — Critical pressure ratios corresponding to values in opening fraction vector

0.3 \* ones(1,6) (default) | vector of positive numbers

Vector of critical pressure ratios at which the flow first chokes, with each critical pressure ratio corresponding to a value in the **Opening fraction vector** parameter. The critical pressure ratio is the fraction of downstream-to-upstream pressures at which the flow velocity reaches the local speed of sound. The size of the vector must be the same as the **Opening fraction vector** parameter.

**Dependencies**

To enable this parameter, set **Valve parameterization** to `Sonic conductance`, and **Opening characteristic** to `Tabulated`.

**Maximum orifice area** — Flow area corresponding to maximally open component

1e-4 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the orifice opening when the cross-sectional area available for flow is at a maximum.

**Dependencies**

To enable this parameter, set **Valve parameterization** to `Orifice area`, and **Opening characteristic** to `Linear`.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar in the range of [0,1]

Correction factor that accounts for discharge losses in theoretical flows.

**Dependencies**

To enable this parameter, set **Valve parameterization** to `Orifice area`.

**Orifice area vector** — Vector of orifice opening area values

[1e-10, 2e-05, 4e-05, 6e-05, 8e-05, .0001] m<sup>2</sup> (default) | vector

Vector of cross-sectional areas of the orifice opening. The values in this vector correspond one-to-one with the elements in the **Opening fraction vector** parameter. The first element of this vector is the orifice leakage area and the last element is the maximum orifice area.

**Dependencies**

To enable this parameter, set **Valve parameterization** to `Orifice area`, and **Opening characteristic** to `Tabulated`.

**Valve opening fraction offset** — Opening fraction of the valve at a zero displacement signal

0 (default) | unitless scalar

Opening fraction of the valve when the value of the input signal **S** is zero. The valve is then in the normal position. The opening fraction measures the distance between the land of the spool and the orifice of the valve, normalized by the maximum allowed.

**Laminar flow pressure ratio** — Pressure ratio at which flow transitions between laminar and turbulent regimes

0.999 (default) | positive scalar

Pressure ratio at which flow transitions between laminar and turbulent flow regimes. The pressure ratio is the outlet pressure divided by inlet pressure. Typical values range from 0.995 to 0.999.

**Cross-sectional area at ports A and B** — Flow area at gas ports

0.01 m<sup>2</sup> (default) | positive scalar

Area normal to the flow path at each port. The ports are equal in size. The value of this parameter should match the inlet area of the components to which the resistive element connects.

## Version History

Introduced in R2018b

### R2022b: Model gas systems using improved flow computations

In previous versions, the blocks in the gas library used a conversion factor to implement different orifice parameterizations in terms of sonic conductance. You can use the **Valve parameterization** parameter to specify the parameterization.

The new parameterizations also include new parameters:

- **xT pressure differential ratio factor at choked flow**
- **Discharge coefficient**
- **Leakage flow fraction.** This parameter replaces the **Cv coefficient (USCS) at leakage flow**, **Kv coefficient (SI) at leakage flow**, **Sonic conductance at leakage flow**, and **Restriction area at leakage flow** parameters.

To improve clarity:

- The **Opening parameterization** parameter has been renamed to **Opening characteristic**.
- The **Reference temperature** and **Reference density** parameters have been renamed to **ISO reference temperature** and **ISO reference density**, respectively.
- The **Cv coefficient (USCS) at maximum flow** and **Kv coefficient (USCS) at maximum flow** parameters have been renamed to **Maximum Cv coefficient** and **Maximum Kv coefficient**, respectively.
- The **Sonic conductance at maximum flow** parameter has been renamed to **Maximum sonic conductance**.

## **Extended Capabilities**

### **C/C++ Code Generation**

Generate C and C++ code using Simulink® Coder™.

### **See Also**

Orifice (G) | 3-Way Directional Valve (G) | 4-Way 3-Position Directional Valve (G)

## 2-Way Directional Valve (TL)

2-way directional valve in a thermal liquid network

### Libraries:

Simscape / Fluids / Thermal Liquid / Valves & Orifices / Directional Control Valves

## Description

The 2-Way Directional Valve (TL) block represents a two-way valve, such as a shut-off valve. Use this block to simulate a flow-reducing control element that responds to pressures in another part of the system.

The block uses a variable orifice to control the flow between ports **A** and **B**. The physical signal at port **S** triggers the spool motion to open or shut the valve. For more details about how the block calculates flow rate through a variable orifice, see Orifice (TL).

### Orifice Parameterizations

You can parameterize the valve opening linearly or by using tabulated data.

#### Linear

When you set **Orifice parameterization** to Linear - Area vs. spool travel, the opening area is a linear function of the spool travel distance.

$$A_{orifice} = \frac{(A_{max} - A_{leak})}{\Delta S_{max}} \Delta S + A_{leak},$$

where

- $A_{orifice}$  is the opening area.
- $\Delta S$  is the spool travel distance input at port **S**.  $\Delta S = S - S_{max} + \Delta S_{max}$ .
- $\Delta S_{max}$  is the value of the **Spool travel between closed and open orifice** parameter.
- $A_{Leak}$  is the value of the **Leakage area** parameter.
- $A_{max}$  is the value of the **Maximum orifice area** parameter.

Note the linear scaling from  $A_{Leak}$  to  $A_{max}$  in the figure.

When the valve is in a near-open or near-closed position in the linear parameterization, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the opening area between  $A_{leak}$  and  $A_{max}$ . For more information, see “Numerical Smoothing”.

### Tabulated

When you set **Orifice parameterization** to Tabulated data - Area vs. spool travel, the block uses the **Spool travel vector** and **Orifice area vector** parameters to define the relationship between  $A_{orifice}$  and  $\Delta S$  by interpolation.  $A_{leak}$  and  $A_{max}$  are the first and last parameters of the **Orifice area vector** parameter, respectively.

When you set **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop, the block uses the **Volumetric flow rate table,  $q(ds,dp)$** , **Pressure drop vector,  $dp$** , and **Spool travel vector,  $ds$**  parameters to define the volumetric flow rate,  $q(\Delta S, p)$ .

When you set **Orifice parameterization** to Tabulated data - Mass flow rate vs. opening and pressure drop the block calculates the mass flow rate directly from the spool position and the pressure drop across the valve. The relationship between the three variables can be nonlinear and it is given by the tabulated data in the **Spool travel vector,  $ds$** , **Pressure drop vector,  $dp$** , and **Mass flow rate table,  $\dot{m}(ds,dp)$**  parameters.

### Visualize Orifice Openings

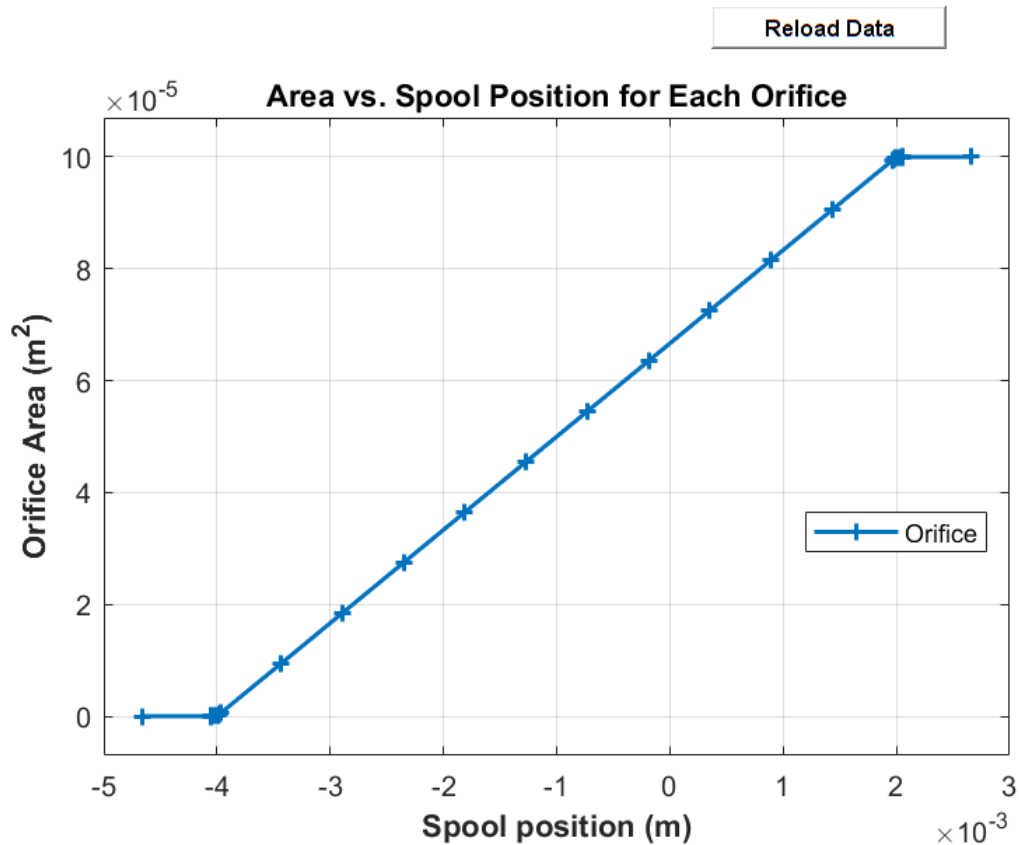

To visualize the spool offsets and displacement, right-click the block and select **Fluids > Plot Valve Characteristics**. The plot shows the valve open area or volumetric flow rate as a function of spool position.

To update the data after changing the block parameters, click **Reload Data** in the figure window.

This figure shows the valve configuration with:

- **Spool position at maximum orifice area** set to  $2 \times 10^{-3}$  m.
- **Spool travel between closed and open orifice** set to  $6 \times 10^{-3}$  m.

All other parameters are at the default values.

## Ports

### Conserving

**A** — Liquid port  
thermal liquid

Thermal liquid conserving port.

**B** — Liquid port  
thermal liquid

Thermal liquid conserving port.

## Input

**S** — Spool displacement, m  
physical signal

Physical signal associated with the spool displacement, in m. A positive value causes the valve to open.

## Parameters

### Model Parameterization

**Orifice parameterization** — Opening area relationship

Linear - Area vs. spool travel (default) | Tabulated data - Area vs. spool travel |  
Tabulated data - Volumetric flow rate vs. spool travel and pressure drop |  
Tabulated data - Mass flow rate vs. spool travel and pressure drop

Method the block uses to calculate the valve flow area.

**Spool position at maximum orifice area** — Spool offset at maximum area  
5e-3 m (default) | positive scalar

Position of the spool travel member when the valve is fully open.

**Spool travel between closed and open orifice** — Maximum spool stroke  
5e-3 m (default) | positive scalar

Spool offset at the maximum valve opened area.

### Dependencies

To enable this parameter, set **Orifice parameterization** to Linear - area vs. spool travel.

**Maximum orifice area** — Area of fully open valve  
1e-4 m<sup>2</sup> (default) | positive scalar

Maximum valve area experienced during simulation.

### Dependencies

To enable this parameter, set **Orifice parameterization** to Linear - area vs. spool travel.

**Leakage area** — Valve gap area when in fully closed position  
1e-10 m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the valve is in the fully closed position. The block maintains any area smaller than this value at the specified leakage area. This parameter contributes to numerical stability by maintaining continuity in the flow.

### Dependencies

To enable this parameter, set **Orifice parameterization** to Linear - area vs. spool travel.

**Smoothing factor** — Numerical smoothing factor  
0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change based to the flow response when the valve is in near-open and near-closed positions. To increase the stability of your simulation in these regimes, set this parameter to a nonzero value less than one.

#### Dependencies

To enable this parameter, set **Orifice parametrization** to Linear - area vs. spool travel.

**Spool travel vector** — Spool opening distance values  
[0, .002, .004, .007, .017] m (default) | vector

Vector of control member travel distances. A positive value opens the valve. The values in this vector correspond one-to-one to values in the **Orifice area vector** parameter. The values must ascend from 0. The block interpolates the points linearly.

#### Dependencies

To enable this parameter, set **Orifice parametrization** to Tabulated data - Area vs. spool travel.

**Orifice area vector** — Valve opening area values  
[1e-09, 2.0352e-07, 4.0736e-05, .00011438, .00034356] m<sup>2</sup> (default) | vector

Vector of valve area values for the tabular parametrization of opening area. The values in this vector correspond one-to-one with the elements in the **Spool travel vector** parameter. The first element of this vector is the leakage area, and the last element is the maximum valve area. The block interpolates the points linearly.

#### Dependencies

To enable this parameter, set **Orifice parametrization** to Tabulated data - Area vs. spool travel.

**Discharge coefficient** — Discharge coefficient  
0.64 (default) | positive scalar

Discharge loss for a hydraulic structure.

#### Dependencies

To enable this parameter, set **Orifice parametrization** to either:

- Tabulated data - Area vs. spool travel
- Linear - area vs. spool travel

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

#### Dependencies

To enable this parameter, set **Orifice parametrization** to either:

- Tabulated data - Area vs. spool travel
- Linear - area vs. spool travel

**Pressure recovery** — Whether to account for pressure increase in area expansions  
on (default) | off

Whether to account for pressure increase when the fluid flows from a region of smaller cross-sectional area to a region of larger cross-sectional area.

**Spool travel vector, ds** — Tabular spool opening distance values  
[0, .002, .004, .007, .017] m (default) | vector

Vector of control member travel distances. The spool travel vector forms an independent axis with the **Pressure drop vector, dp** parameter for the 3-D dependent **Volumetric flow rate table, q(ds,dp)** parameter. A positive displacement corresponds to valve opening. The values ascend from 0. The block interpolates the points linearly.

#### Dependencies

To enable this parameter, set **Orifice parametrization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**Pressure drop vector, dp** — Tabular pressure drop values  
[.3, .5, .7] MPa (default) | vector

Vector of pressure drop values for the volumetric flow rate. The pressure drop vector forms an independent axis with the **Spool travel vector, ds** parameter for the 3-D dependent **Volumetric flow rate table, q(ds,dp)** parameter. The values must be ascending. The block interpolates the points linearly

#### Dependencies

To enable this parameter, set **Orifice parametrization** to Tabulated data -Volumetric flow rate vs. spool travel and pressure drop.

**Volumetric flow rate table, q(ds,dp)** — Volumetric flow rate for given spool travel and pressure drop  
[1.7e-05, 2e-05, 2.6e-05; .0035, .0045, .0053; .7, .9, 1.06; 1.96, 2.5, 3; 6, 7.7, 9.13] m<sup>3</sup>/s (default) | matrix

*M*-by-*N* matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the correlated vectors:

- *M* is the number of elements in the **Spool travel vector, ds** parameter.
- *N* is the number of elements in the **Pressure drop vector, dp** parameter.

#### Dependencies

To enable this parameter, set **Orifice parametrization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**Mass flow rate table, mdot(ds,dp)** — Mass flow rate for given spool travel and pressure drop  
[1.7e-05, 2e-05, 2.6e-05; .0035, .0045, .0053; .7, .9, 1.06; 1.96, 2.5, 3; 6, 7.7, 9.13] kg/s (default) | matrix

*M*-by-*N* matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the correlated vectors:

- $M$  is the number of elements in the **Spool travel vector,  $ds$**  parameter.
- $N$  is the number of elements in the **Pressure drop vector,  $dp$**  parameter.

#### Dependencies

To enable this parameter, set **Orifice parametrization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop.

**Reference inflow temperature** — Temperature at which mass flow rate data is specified  
293.15 K (default) | positive scalar

Temperature at which the tabulated mass flow rate data is specified.

#### Dependencies

To enable this parameter, set **Orifice parameterization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop.

**Reference inflow pressure** — Pressure at which mass flow tabulated data is specified  
0.101325 MPa (default) | positive scalar

Pressure at which the tabulated mass flow rate data is specified. The block uses this parameter to calculate a third reference parameter, the reference density.

#### Dependencies

To enable this parameter, set **Orifice parameterization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop.

**Cross-sectional area at ports A and B** — Valve area at conserving ports  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area at ports **A** and **B**. The block uses this area in the pressure-flow rate equation to determine the volumetric flow rate through the valve.

#### Dependencies

To enable this parameter, set **Orifice parametrization** to either:

- Tabulated data - Area vs. spool travel
- Linear - area vs. spool travel

## Version History

Introduced in R2016a

### R2022b: Right-click blocks to view opening characteristic plots

You can view the plot of the area or volumetric flow rate with respect to spool position for each orifice by right-clicking the block and selecting **Fluids > Plot Valve Characteristics**.

### Library

Valve Actuators

### Description

The 3-Position Valve Actuator block represents an actuator that you can use with directional valves to control their position. This actuator can drive a three-position valve. The block is developed as a data-sheet-based model and all its parameters are generally provided in catalogs or data sheets. The key parameters are the stroke, switch-on, and switch-off times.

The block has two signal inputs associated with the activation signals for electromagnets A or B. It produces a physical output signal that can be associated with a mechanical translational or rotational push-pin motion. Connect the block output to the directional valve control port.

The actuator is represented as an ideal transducer, where output does not depend on the load exerted on the push-pin and the push-pin motion profile remains the same under any loading conditions. The motion profile represents a typical transition curve for electromagnetic actuators. The following figure shows the motion profile for a case when the input signal is applied long enough for the push-pin to reach the end of the stroke ( $x_{str}$ ), and then the input signal is removed, causing the push-pin to return to initial position:

The push-pin is actuated when the input signal value crosses the threshold of 50% of the nominal input signal, where **Nominal signal value** is a block parameter. The motion is divided into three phases, equal in time: delay ( $t_{de}$ ), motion at constant acceleration ( $t_{ae}$ ), and motion at constant velocity ( $t_{ve}$ ). The motion stops when the switch-on time ( $t_{on}$ ) elapses. At this moment, the push-pin reaches the specified stroke value ( $x_{str}$ ). To return the push-pin into initial position, the control signal must be removed, which causes the push-pin to retract. The retract motion also consists of three phases, equal in time: delay ( $t_{dr}$ ), motion at constant acceleration ( $t_{ar}$ ), and motion at constant velocity ( $t_{vr}$ ). It follows exactly the same profile but “stretches” over the switch-off time. **Switching-on time** and **Switching-off time** are the block parameters.

The signal applied to port A causes the output to move in positive direction. To shift the push-pin in negative direction, you must apply the signal to port B. Only one control signal can be applied at a time. This means that if the actuator is being controlled by the signal at port A, the push-pin must be allowed to return to initial position before the control signal at port B can be processed. The transition in any direction can be interrupted at any time by changing the input signal. If motion is interrupted, the switch-on or switch-off times are proportionally decreased depending on the instantaneous push-pin position.

Only positive signals activate the actuator. In other words, negative signals at ports A and B have no effect on the actuator, which is similar to the behavior of electromagnetically controlled 3-position directional valves.

## Basic Assumptions and Limitations

Push-pin loading, such as inertia, spring, hydraulic forces, and so on, is not taken into account.

## Parameters

### Push-pin stroke

The push-pin stroke. The default value is 0.01 m.

### Switching-on time

Time necessary to fully extend the push-pin after the control signal is applied. The default value is 0.1 s.

**Switching-off time**

Time necessary to retract push-pin from fully extended position after the input signal is removed. The default value is 0.1 s.

**Nominal signal value**

Sets the value of the nominal input signal. The output motion is initiated as the input signal crosses 50% value of the nominal signal. Other than that, the input signal has no effect on the motion profile. This parameter is meant to reproduce the rated voltage feature of an electromagnet. The default value is 24.

**Initial position**

Specifies the initial position of the push-pin. The parameter can have one of three values: `Extended positive`, `Extended negative`, or `Neutral`. The default value is `Neutral`.

In selecting the initial position, consider the following:

- The steady-state push-pin position always corresponds to the control signal. In other words, zero signal keeps the push-pin at `Neutral`, positive signal — at `Extended positive`, and negative signal — at `Extended negative`.
- At the start of simulation, if there is a discrepancy between the initial position of the push-pin, as specified by the **Initial position** parameter, and the control signal, the push-pin immediately starts moving towards the steady-state position designated by the control signal.

**Restricted Parameters**

When your model is in Restricted editing mode, you cannot modify the following parameter:

- **Initial position**

All other block parameters are available for modification.

**Ports**

The block has the following ports:

A

Physical signal input port associated with the port A input signal.

B

Physical signal input port associated with the port B input signal.

The block also has one physical signal output port, which is associated with the output signal (push-pin displacement).

**Examples**

In the “3-Position Valve Actuator” example, all three actuators are set to different strokes, switch-on and switch-off times, and initial positions. If the initial position is not `Neutral` and the control signal at the beginning of simulation equals zero, the push-pin starts moving towards neutral position, as the actuators A and C show in the example.

### Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Valves / Directional Valves

### Description

The 3-Way Directional Valve block represents a directional control valve with three ports and two positions, or flow paths. The ports connect to what in a typical model are a hydraulic pump (port **P**), a storage tank (port **T**), and a single-acting actuator (port **A**). Fluid can flow from the pump to the actuator via path **P-A** and from the actuator to the tank via path **A-T**.

### Typical Valve Setup

In the default configuration, one valve position corresponds to the **A-T** flow path maximally open and the **P-A** flow path maximally closed (position **I** in the figure). The second valve position corresponds

to the **P-A** flow path maximally open and the **A-T** flow path maximally closed (position **II** in the figure). A translating spool serves as the valve control member and determines the position that the valve is in—I, **II**, or in between.

I.

II.

### Valve Positions

Physical signal port **S** controls the spool displacement. In the default configuration, a zero displacement corresponds to a fully closed valve between positions **I** and **II**. A negative displacement shifts the spool toward valve position **I**. A positive displacement signal shifts the spool toward valve position **II**. The spool displacement acts indirectly by setting the spool position relative to each flow path—a length known here as the *orifice opening*. The orifice opening in turn determines the opening area of the respective flow path.

### Orifice Openings and Offsets

The orifice opening of a flow path depends partly on its *opening offset*—the orifice opening of a flow path at zero spool displacement. The block models only the dynamic effects of the opening offsets. An offset can be due to a change in distance between ports or spool lands—the thick disks built into the spool to obstruct flow. It can also be due to a change in the thicknesses of the spool lands. The orifice openings are computed separately for each flow path in terms of the respective opening offset:

$$h_{PA} = h_{PA0} + x,$$

$$h_{AT} = h_{AT0} - x,$$

where:

- $h_{PA}$  and  $h_{AT}$  are the orifice openings of the **P-A** and **A-T** flow paths. The orifice openings are computed during simulation.
- $h_{PA0}$  and  $h_{AT0}$  are the opening offsets of the **P-A** and **A-T** flow paths. The opening offsets are specified in the **Valve opening offsets** tab.

- $x$  is the spool displacement relative to what in the zero-offset case is a fully closed valve. The spool displacement is specified through physical signal port **S**.

The figure shows the effects of the opening offsets on the orifice openings. Plot **I** corresponds to the default configuration with both opening offsets equal to zero. Plot **II** corresponds to a valve with both opening offsets greater than zero and plot **III** to a valve with both opening offsets smaller than zero. These cases are similar in behavior to zero-lapped (**I**), underlapped (**II**) and overlapped (**III**) valves. The valve schematics to the right show what the offsets might look like for the **A-T** flow path.

### Zero (I), Positive (II), and Negative (III) Opening Offsets

An underlapped valve is always partially open and allows some flow at all spool displacements. An overlapped valve is fully closed over an extended range of spool displacements and requires longer spool travel to open. The table summarizes the opening offsets for zero-lapped, underlapped, and overlapped valves. Other configurations are possible—e.g., with one opening offset positive and the other negative.

Valve Lapping	Opening Offsets
Zero-lapped (default)	Both zero
Underlapped	Both positive
Overlapped	Both negative

## Opening Area Parameterizations

The **Model parameterization** setting determines the calculations used for the opening areas of the flow paths—or, in the **Pressure-flow characteristic** case, the volumetric flow rates. The calculations are based on orifice parameters or tabulated data sets specified in the **Model Parameterization** tab. The block uses the same data for both flow paths if the **Area characteristics** parameter in the **Basic Parameters** tab is set to **Identical** for all flow paths and different data otherwise. Model parameterizations that you can select include:

- **Maximum area and opening** — Specify the maximum opening area and the corresponding orifice opening. The opening area is a linear function of the orifice opening,

$$A_{AT} = \frac{A_{AT,Max}}{h_{AT,Max}} h_{AT} + A_{Leak},$$

where  $A$  is the opening area and  $h$  the orifice opening of a given flow path. The subscript **Max** refers to a fully open orifice and the subscript **Leak** to a fully closed orifice—one with internal leakage flow area only. The figure shows a plot of the linear function  $A(h)$ .

- **Area vs. opening table** — Specify the opening area at discrete orifice openings as a 1-D lookup table. The opening area is computed for a given orifice opening by interpolation or extrapolation of the tabulated data. The figure shows a conceptual plot of the tabulated function  $A(h)$ .

- **Pressure-flow characteristic** — Specify the volumetric flow rate at discrete orifice openings and pressure differentials as a 2-D lookup table. The opening area is computed for a given orifice opening and pressure differential by interpolation or extrapolation of the tabulated data. The figure shows a conceptual plot of the tabulated function  $q(h, p)$ .

### Flow Regime and Internal Leakage

Volumetric flow rates are computed analytically in the **Maximum area and opening** and **Area vs. opening table** parameterizations. The calculations are based on additional block parameters such as the flow discharge coefficient and account for the effects of flow regime—laminar or turbulent. Regime transition occurs at the specified critical laminar flow ratio or critical Reynolds number.

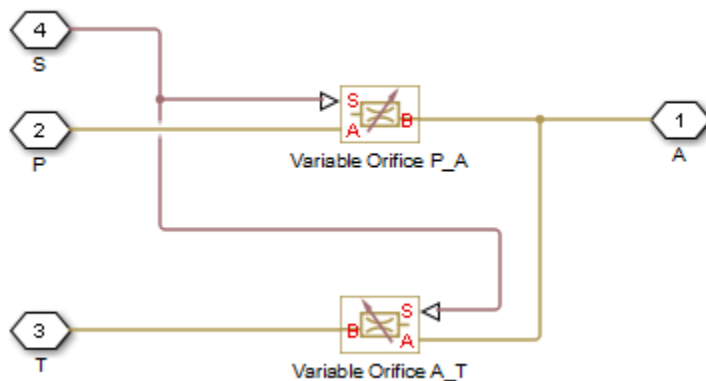

The **Maximum area and opening** and **Area vs. opening table** parameterizations also account for a small leakage area associated with the valve spool-to-bore clearance. The leakage area ensures that portions of the hydraulic network never become isolated when a flow path is closed. Isolated, or “hanging”, network portions affect computational efficiency and can cause simulation to fail.

The effects of flow regime and internal leakage are assumed to be reflected in the tabulated flow rate data specified directly in the **Pressure-flow characteristic** parameterization.

### Structural Component Diagram

The block is a composite component with two **Variable Orifice** blocks driven by a single physical signal. Block **Variable Orifice P\_A** represents the **P-A** flow path. Block **Variable orifice A\_T** represents the **A-T** flow path. The physical signal is specified through **Connection Port block S**.

The **Orifice orientation** block parameters are set so that a positive signal acts to open **Variable Orifice P\_A** while closing **Variable Orifice A\_T**. A negative signal has the opposite effect, acting to open **Variable Orifice A\_T** while closing **Variable Orifice P\_A**.

### Valve Structural Diagram

#### Assumptions

- Fluid inertia is ignored.
- Spool loading due to inertial, spring, and other forces is ignored.
- All valve orifices are assumed identical in size unless otherwise specified.

### Ports

#### Input

**S** — Spool displacement, m  
physical signal

Physical signal input port for the spool displacement.

### **Conserving**

**P** — Supply line orifice  
hydraulic (isothermal liquid)

Hydraulic (isothermal liquid) port associated with the supply line orifice.

**T** — Return line orifice  
hydraulic (isothermal liquid)

Hydraulic (isothermal liquid) port associated with the return line orifice.

**A** — Actuation line orifice  
hydraulic (isothermal liquid)

Hydraulic (isothermal liquid) port associated with the actuation orifice.

## **Parameters**

### **Basic Parameters**

**Area characteristics** — Symmetry of the flow path opening characteristics  
Identical for all flow paths (default) | Different for each flow path

Choice of different or identical flow path opening characteristics. Select **Different** for each flow path to specify flow path parameters or tabulated data separately for each flow path.

**Model parameterization** — Types of valve parameters to use as input  
Maximum area and opening (default) | Area vs. opening table | Pressure-flow characteristic

Parameterization of the valve model. Options include:

- **By maximum area and opening** — Specify the maximum orifice opening and opening area. The opening area varies linearly with the spool displacement specified at physical signal port **S**.
- **By area vs. opening table** — Specify the flow path opening area at discrete orifice openings as a 1-D lookup table. The opening area is computed by interpolation or extrapolation of the tabulated data.
- **By pressure-flow characteristic** — Specify the flow path volumetric flow rates at discrete orifice openings and pressure differentials. The flow rate is computed by interpolation or extrapolation of the tabulated data.

**Interpolation method** — Method of computing values inside the lookup table range  
Linear (default) | Smooth

Method of computing values inside the tabulated data range. The **Linear** method joins adjacent data points with straight line or surface segments with generally discontinuous slope at the segment boundaries. Surface segments are used in the 2-D lookup table specified in the **Pressure-flow characteristic** model parameterization.

The Smooth method replaces the straight segments with curved versions that have continuous slope everywhere inside the tabulated data range. The segments form a smooth line or surface passing through all of the tabulated data points without the discontinuities in first-order derivatives characteristic of the Linear interpolation method.

**Dependencies**

This parameter is active when the **Model Parameterization** parameter is set to By area vs. opening table or Pressure-flow characteristic.

**Extrapolation method** — Method of computing values outside of the lookup table range  
Linear (default) | Nearest

Method of computing values outside of the tabulated data range. The Linear method extends the line segment drawn between the last two data points at each end of the data range outward with a constant slope.

The Nearest method extends the last data point at each end of the data range outward as a horizontal line with constant value.

**Dependencies**

This parameter is active when the **Model Parameterization** parameter is set to `By area vs. opening table` or `Pressure-flow characteristic`.

**Flow discharge coefficient** — Semi-empirical parameter for valve capacity characterization  
0.7 (default) | unitless scalar between 0 and 1

Ratio of the actual and theoretical flow rates through the valve. This parameter depends on the geometrical properties of the valve. Values are usually provided in textbooks and manufacturer data sheets.

**Dependencies**

This parameter is active when the **Model Parameterization** parameter is set to `By maximum area and opening` or `By area vs. opening table`.

**Leakage area** — Internal leakage area between valve inlets  
1e-12 m<sup>2</sup> (default) | positive scalar in units of area

Total area of internal leaks in the completely closed state. The purpose of this parameter is to maintain the numerical integrity of the fluid network by preventing a portion of that network from becoming isolated when the valve is completely closed.

**Dependencies**

This parameter is active when the **Model Parameterization** parameter is set to `By maximum area and opening` or `By area vs. opening table`.

**Laminar transition specification** — Choice of parameter used to define the laminar-turbulent transition  
`Pressure ratio` (default) | `Reynolds number`

Select the parameter to base the laminar-turbulent transition on. Options include:

- `Pressure ratio` — Flow transitions between laminar and turbulent at the pressure ratio specified in the **Laminar flow pressure ratio** parameter. Use this option for the smoothest and most numerically robust flow transitions.
- `Reynolds number` — The transition occurs at the Reynolds number specified in the **Critical Reynolds number** parameter. Flow transitions are more abrupt and can cause simulation issues at near-zero flow rates.

**Dependencies**

This parameter is active when the **Model Parameterization** parameter is set to `By maximum area and opening` or `By area vs. opening table`.

**Laminar flow pressure ratio** — Pressure ratio at the laminar-turbulent flow transition  
0.999 (default) | unitless scalar between 0 and 1

Pressure ratio at which the flow transitions between the laminar and turbulent regimes. The pressure ratio is the fraction of the outlet pressure over the inlet pressure.

**Dependencies**

This parameter is active when the **Model Parameterization** parameter is set to **By maximum area and opening** or **By area vs. opening table** and the **Laminar transition specification** parameter is set to **Pressure ratio**.

**Critical Reynolds number** — Reynolds number at the laminar-turbulent flow transition  
12 (default) | unitless positive scalar

Maximum Reynolds number for laminar flow. This parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value, 12, corresponds to a round orifice in thin material with sharp edges.

**Dependencies**

This parameter is active when the **Model Parameterization** parameter is set to **By maximum area and opening** or **By area vs. opening table** and the **Laminar transition specification** parameter is set to **Reynolds number**.

**Model Parameterization: Maximum area and opening**

**Maximum opening** — Orifice opening at which the opening area is a maximum  
0.005 m (default) | positive scalar with units of length

Orifice opening at which the opening area of a flow path is a maximum. The maximum opening is the same for all flow paths when this parameter is exposed. For the orifice opening definitions, see “Orifice Openings and Offsets” on page 1-44.

**Dependencies**

This parameter is active when the **Area characteristics** parameter is set to **Identical for all flow paths** and the **Model parameterization** parameter is set to **Maximum area and opening**.

**Maximum opening area** — Maximum cross-sectional area of a flow path  
0.5e-4 m<sup>2</sup> (default) | positive scalar with units of area

Maximum cross-sectional area of a flow path. The maximum opening areas are the same for all paths when this parameter is exposed. For the opening area calculations, see “Opening Area Parameterizations” on page 1-46.

**Dependencies**

This parameter is active when the **Area characteristics** parameter is set to **Identical for all flow paths** and the **Model parameterization** parameter is set to **Maximum area and opening**.

**P-A, maximum opening** — P-A orifice opening at which the opening area is a maximum  
0.005 m (default) | positive scalar with units of length

Spool position relative to the **P-A** flow path at which the **P-A** opening area is equal to the **P-A, maximum opening area** parameter.

**Dependencies**

This parameter is active when the **Area characteristics** parameter is set to **Different for each flow path** and the **Model parameterization** parameter is set to **Maximum area and opening**.

**P-A, maximum opening area** — Maximum flow area of the P-A flow path

0.5e-4 m<sup>2</sup> (default) | positive scalar with units of area

Maximum cross-sectional area of the **P-A** flow path. The maximum opening areas are different for each flow path when this parameter is exposed. For the opening area calculations, see “Opening Area Parameterizations” on page 1-46.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to **Different for each flow path** and the **Model parameterization** parameter is set to **Maximum area and opening**.

**A-T, maximum opening** — A-T Orifice opening at which the opening area is a maximum

0.005 m (default) | positive scalar with units of length

Spool position relative to the **A-T** flow path at which the **A-T** opening area is equal to the **A-T, maximum opening area** parameter.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to **Different for each flow path** and the **Model parameterization** parameter is set to **Maximum area and opening**.

**A-T, maximum opening area** — Maximum flow area of the A-T flow path

0.5e-4 m<sup>2</sup> (default) | positive scalar with units of area

Maximum cross-sectional area of the **P-A** flow path. The maximum opening areas are different for each flow path when this parameter is exposed. For the opening area calculations, see “Opening Area Parameterizations” on page 1-46.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to **Different for each flow path** and the **Model parameterization** parameter is set to **Maximum area and opening**.

#### Model Parameterization: Area vs. opening table

**Opening vector** — Orifice openings at which to specify the flow path opening areas

[-0.002, 0.0, 0.002, 0.005, 0.015] m (default) | numerical array with units of length

Array of orifice openings used to construct the opening area 1-D lookup table for all flow paths. The opening characteristics are identical for all flow paths when this parameter is exposed. The number of elements in the array determines the number of columns in the table.

The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for **Linear** interpolation and three elements for **Smooth** interpolation.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to **Identical for all flow paths** and the **Model parameterization** parameter is set to **Area vs. opening table**.

**Opening area vector** — Opening areas corresponding to the orifice openings specified in the **Opening vector** parameter

[1.0e-9, 2.0352e-7, 4.0736e-5, 0.00011438, 0.00034356] m<sup>2</sup> (default) | numerical array with units of area

Array of flow path opening areas corresponding to the specified orifice openings. The number of elements in the array must match the number of elements in the **Opening vector** parameter.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to **Identical** for all flow paths and the **Model parameterization** parameter is set to **Area vs. opening table**.

**P-A, opening vector** — P-A orifice openings at which to specify the P-A opening area  
[-0.002, 0.0, 0.002, 0.005, 0.015] m (default) | numerical array with units of length

Array of **P-A** orifice openings used to construct the opening area 1-D lookup table for the **P-A** flow path. The number of elements in the array determines the number of elements in the table.

The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for **Linear** interpolation and three elements for **Smooth** interpolation.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to **Different** for each flow path and the **Model parameterization** parameter is set to **Area vs. opening table**.

**P-A, opening area vector** — P-A opening areas corresponding to the orifice openings specified in the P-A, opening vector parameter  
[1.0e-9, 2.0352e-7, 4.0736e-5, 0.00011438, 0.00034356] m<sup>2</sup> (default) | numerical array with units of area

Array of **P-A** opening areas corresponding to the specified **P-A** orifice openings. The number of elements in the array must match the number of elements in the **P-A, opening vector** parameter.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to **Different** for each flow path and the **Model parameterization** parameter is set to **Area vs. opening table**.

**A-T, opening vector** — A-T orifice openings at which to specify the A-T opening area  
[-0.002, 0.0, 0.002, 0.005, 0.015] m (default) | numerical array with units of length

Array of **A-T** orifice openings used to construct the opening area 1-D lookup table for the **A-T** flow path. The number of elements in the array determines the number of elements in the table.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to **Different** for each flow path and the **Model parameterization** parameter is set to **Area vs. opening table**.

**A-T, opening area vector** — A-T opening areas corresponding to the orifice openings specified in the A-T, opening vector parameter  
[1.0e-9, 2.0352e-7, 4.0736e-5, 0.00011438, 0.00034356] m<sup>2</sup> (default) | numerical array with units of area

Array of **A-T** opening areas corresponding to the specified **A-T** orifice openings. The number of elements in the array must match the number of elements in the **A-T, opening vector** parameter.

**Dependencies**

This parameter is active when the **Area characteristics** parameter is set to **Different** for each flow path and the **Model parameterization** parameter is set to **Area vs. opening table**.

**Model Parameterization: Pressure-flow characteristic**

**Opening vector, s** — Orifice openings at which to specify the flow rate tabulated data  
 $[-0.002, 0.0, 0.002, 0.005, 0.015]$  m (default) | numerical array with units of length

Array of orifice openings used to construct the volumetric flow rate 2-D lookup table. The number of elements in the array determines the number of rows in the table. The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for **Linear** interpolation and three elements for **Smooth** interpolation.

**Dependencies**

This parameter is active when the **Area characteristics** parameter is set to **Identical** for all flow paths and the **Model parameterization** parameter is set to **Pressure-flow characteristic**.

**Pressure differential vector, dp** — Pressure differentials at which to specify the flow rate data  
 $[-10000000.0, -5000000.0, -2000000.0, 2000000.0, 5000000.0, 10000000.0]$  Pa (default) | numerical array with units of pressure

Array of pressure differentials used to construct the volumetric flow rate 2-D lookup table. The number of elements in the array determines the number of columns in the table. The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for **Linear** interpolation and three elements for **Smooth** interpolation.

**Dependencies**

This parameter is active when the **Area characteristics** parameter is set to **Identical** for all flow paths and the **Model parameterization** parameter is set to **Pressure-flow characteristic**.

**Volumetric flow rate table, q(s,dp)** — Volumetric flow rates at the specified orifice openings and pressure differentials

5-by-6 matrix with elements between  $-0.0344$  and  $0.0344$  m<sup>3</sup>/s (default) | numerical array with units of length

Matrix with the volumetric flow rates corresponding to the specified orifice openings and pressure differentials. The number of rows must match the number of elements in the **Opening vector, s** parameter. The number of columns must match the number of elements in the **Pressure differential vector, dp** parameter.

**Dependencies**

This parameter is active when the **Area characteristics** parameter is set to **Identical** for all flow paths and the **Model parameterization** parameter is set to **Pressure-flow characteristic**.

**P-A, opening vector, s** — Orifice openings at which to specify the P-A flow rate data  
 $[-0.002, 0.0, 0.002, 0.005, 0.015]$  m (default) | numerical array with units of length

Array of **P-A** orifice openings used to construct the **P-A** volumetric flow rate 2-D lookup table. The number of elements in the array determines the number of rows in the table. The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for Linear interpolation and three elements for Smooth interpolation.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to **Different** for each flow path and the **Model parameterization** parameter is set to **Pressure-flow** characteristic.

**P-A, pressure differential vector, dp** — Pressure differentials at which to specify the P-A flow rate data

[-10000000.0, -5000000.0, -2000000.0, 2000000.0, 5000000.0, 10000000.0] Pa (default) | numerical array with units of pressure

Array of pressure differentials used to construct the volumetric flow rate 2-D lookup table for the **P-A** flow path. The number of elements in the array determines the number of columns in the table.

The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for Linear interpolation and three elements for Smooth interpolation.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to **Different** for each flow path and the **Model parameterization** parameter is set to **Pressure-flow** characteristic.

**P-A, volumetric flow rate table, q(s,dp)** — Volumetric flow rates at the specified P-A orifice openings and pressure differentials

5-by-6 matrix with elements between -0.0344 and 0.0344 m<sup>3</sup>/s (default) | numerical array with units of length

Matrix with the volumetric flow rates through the **P-A** flow path at the **P-A** orifice openings and pressure differentials. The number of rows must match the number of elements in the **P-A, opening vector, s** parameter. The number of columns must match the number of elements in the **P-A, pressure differential vector, dp** parameter.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to **Different** for each flow path and the **Model parameterization** parameter is set to **Pressure-flow** characteristic.

**A-T, opening vector, s** — Orifice openings at which to specify the A-T flow rate data

[-0.002, 0.0, 0.002, 0.005, 0.015] m (default) | numerical array with units of length

Array of **A-T** orifice openings used to construct the **A-T** volumetric flow rate 2-D lookup table. The number of elements in the array determines the number of rows in the table.

The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for Linear interpolation and three elements for Smooth interpolation.

**Dependencies**

This parameter is active when the **Area characteristics** parameter is set to **Different** for each flow path and the **Model parameterization** parameter is set to **Pressure-flow characteristic**.

**A-T, pressure differential vector, dp** — Pressure differentials at which to specify the A-T flow rate data

`[-10000000.0, -5000000.0, -2000000.0, 2000000.0, 5000000.0, 10000000.0]` Pa (default) | numerical array with units of pressure

Array of pressure differentials used to construct the volumetric flow rate 2-D lookup table for the **A-T** flow path. The number of elements in the array determines the number of columns in the table.

The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for **Linear** interpolation and three elements for **Smooth** interpolation.

**Dependencies**

This parameter is active when the **Area characteristics** parameter is set to **Different** for each flow path and the **Model parameterization** parameter is set to **Pressure-flow characteristic**.

**A-T, volumetric flow rate table, q(s,dp)** — Volumetric flow rates at the specified A-T orifice openings and pressure differentials

5-by-6 matrix with elements between  $-0.0344$  and  $0.0344$  m<sup>3</sup>/s (default) | numerical array with units of length

Matrix with the volumetric flow rates through the **A-T** flow path at the **A-T** orifice openings and pressure differentials. The number of rows must match the number of elements in the **A-T, opening vector, s** parameter. The number of columns must match the number of elements in the **A-T, pressure differential vector, dp** parameter.

**Dependencies**

This parameter is active when the **Area characteristics** parameter is set to **Different** for each flow path and the **Model parameterization** parameter is set to **Pressure-flow characteristic**.

**Valve Opening Offsets**

**Between P-A** — P-A orifice opening at zero spool displacement

$0$  m (default) | scalar number with units of length

Orifice opening of the **P-A** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $0$  corresponds to a zero-lapped valve.

**Between A-T** — A-T orifice opening at zero spool displacement

$0$  m (default) | scalar number with units of length

Orifice opening of the **A-T** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $0$  corresponds to a zero-lapped valve.

## Version History

**Introduced in R2017a**

### **R2023a: To be removed**

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Extended Capabilities

### **C/C++ Code Generation**

Generate C and C++ code using Simulink® Coder™.

### **See Also**

2-Way Directional Valve | 4-Way Directional Valve

## 3-Way Directional Valve (IL)

3-way flow control valve in an isothermal liquid system

### Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Directional Control Valves

### Description

The 3-Way Directional Valve (IL) block models a valve with three openings in an isothermal liquid network, typically between an actuator, pump, and tank. The valve operation is controlled by a single spool displaced according to the signal at port **S**. You can set the baseline configuration of your valve by specifying the orifices that are open when the spool moves in the positive direction and negative directions in the **Positive spool position open connections** and **Negative spool position open connections** parameters, respectively.

You can set the model for valve opening in the **Orifice parameterization** parameter as a linear relationship or function of user-provided data, which can be applied to one or all flow paths in the valve.

In this configuration, **Positive spool position open connections** is set to A-T only. When the signal at port **S** moves the spool to a positive position, the path between ports **A** and **T** is open to flow. The paths between ports **P** and **A** and between ports **P** and **T** are closed:

In this configuration, **Negative spool position open connections** is set to P-A only. When the signal at port **S** moves the spool to a negative position, the path between ports **P** and **A** is open to flow and the paths between ports **T** and **A** and between ports **P** and **T** are closed:

You can open the path between ports **P** and **T** by setting either **Positive spool position open connections** or **Negative spool position open connections** to P-T only or P-A, A-T, and P-T.

A flow path can be open in either the positive or negative spool positions, but not both.

### Valve Orifice Parameterizations

The **Orifice parameterization** sets the method for calculating the valve open area. The calculations are based either on the orifice parameters or tabulated data sets specified in the **Model Parameterization** tab. The block uses the same data for all flow paths if **Area characteristics** is set to **Identical for all flow paths**; otherwise, individual values are applied in the **Different for all flow paths** setting. The orifice parameterizations are:

- Linear - area vs. spool travel

The opening area is a linear function of the spool travel distance and the signal received at port **S**:

$$A_{orifice} = \frac{(A_{max} - A_{leak})}{\Delta S_{max}} \Delta S + A_{leak},$$

where:

- $A_{max}$  is the **Maximum orifice area**.
- $A_{leak}$  is the **Leakage area**.
- $\Delta S_{max}$  is the **Spool travel between closed and open orifice**.
- $\Delta S$  is the spool travel distance. For flow paths that are open in the positive position:

$$\Delta S = S_{orifice\_max} - \Delta S_{max} + S,$$

and for flow paths that are open in the negative position:

$$\Delta S = S_{orifice\_max} + \Delta S_{max} - S,$$

where  $S_{orifice\_max}$  is the **Spool position at maximum orifice area**.

When the valve is in a near-open or near-closed position in the linear parameterization, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the opening area between  $A_{leak}$  and  $A_{max}$ . For more information, see “Numerical Smoothing”.

- Tabulated data - Area vs. spool travel

Provide spool travel vectors for your system or for individual flow paths between ports **P** and **A**, **A** and **T**, and **P** and **T**. This data will be used to calculate the relationship between the orifice opening area and spool travel distance. Interpolation is used to determine the opening area between given data points.  $A_{leak}$  and  $A_{max}$  are the first and last parameters of the **Opening area vector**, respectively.

- Tabulated data - Volumetric flow rate vs. spool travel and pressure drop

Provide spool travel and pressure drop vectors. The volumetric flow rate is calculated based on the relationship between pressure change and the spool travel distance. Interpolation is used to determine flow rate between given data points. The mass flow rate is the product of the volumetric flow rate and the local density.

### Visualize Orifice Openings

To visualize spool offsets and displacement, right-click the block and select **Fluids > Plot Valve Characteristics**. The plot shows the orifices selected in the **Valve Configuration** settings. The parameterization selection sets the axes, which are either:

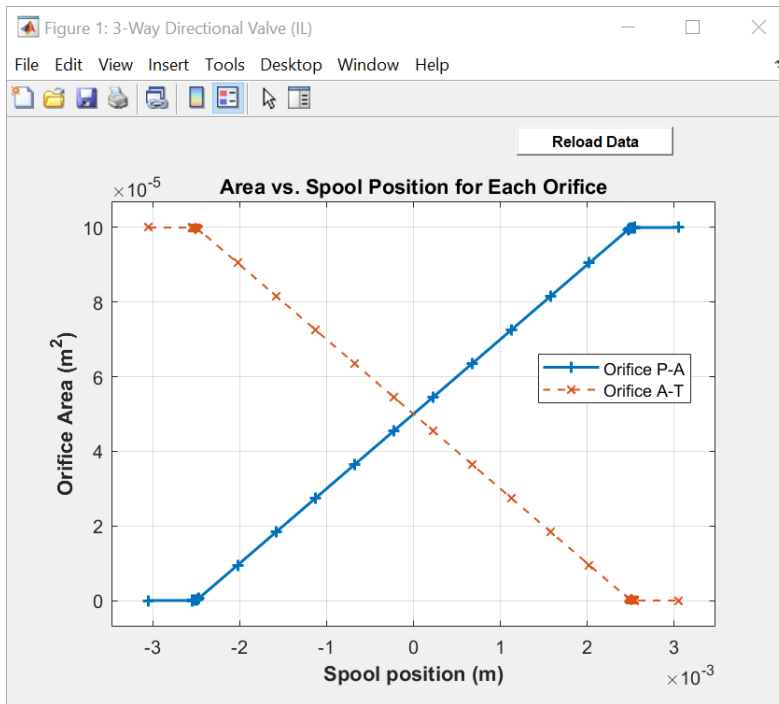

- Orifice area versus spool position
- Volumetric flow rate versus spool position, queried at a specific pressure differential

To update the data after changing the block parameters, click **Reload Data** on the figure window.

This image shows an example valve configuration. In the **Valve Configuration** settings:

- **Positive spool position open connections** is P-A only.
- **Negative spool position open connections** is A-T only.

All other spool positions are at the default values.

## Faults

When faults are enabled, the valve open area becomes stuck at a specified spool position in response to one of these triggers:

- Simulation time — Faulting occurs at a specified time.
- Simulation behavior — Faulting occurs in response to an external trigger. This exposes port **Tr**.

Three fault options are available in the **Spool position when faulted** parameter:

- **Positive** — The spool position freezes in the positive position, opening the **Positive spool position open connections** flow paths to their maximum value. The flow paths that are only open in the **Negative spool position open connections** and **Neutral spool position open connections** are closed.
- **Negative** — The spool position freezes in the negative position, opening the **Negative spool position open connections** flow paths to their maximum value. The flow paths that are only open in the **Positive spool position open connections** and **Neutral spool position open connections** are closed.

- **Maintain last value** — The valve freezes at the spool position when the trigger occurs.

Due to numerical smoothing at the extremes of the valve area, in the linear parameterization, the minimum area applied is larger than the **Leakage area**, and the maximum is smaller than the **Maximum orifice area**, in proportion to the **Smoothing factor** value.

Once triggered, the valve remains at the faulted area for the rest of the simulation.

### **Predefined Parameterization**

Pre-parameterization of the 3-Way Directional Valve (IL) block with manufacturer data is available. This data allows you to model a specific supplier component.

To load a predefined parameterization,

- 1 Click the "Select a predefined parameterization" hyperlink in the 3-Way Directional Valve (IL) block dialog description.
- 2 Select a part from the drop-down menu and click **Update block with selected part**.
- 3 If you change any parameter settings after loading a parameterization, you can check your changes by clicking **Compare block settings with selected part**. Any difference in settings between the block and pre-defined parameterization will display in the MATLAB command window.

Note that it is not possible to set different values for the same orifice for both positive and negative displacement of the control member. Additionally, the opening area is mirrored around the neutral position.

---

**Note** Predefined parameterizations of Simscape components use available data sources for supplying parameter values. Engineering judgement and simplifying assumptions are used to fill in for missing data. As a result, deviations between simulated and actual physical behavior should be expected. To ensure requisite accuracy, you should validate simulated behavior against experimental data and refine component models as necessary.

---

### **Assumptions**

- Fluid inertia is ignored.
- Spool loading due to inertial, spring, and other forces is ignored.
- All valve orifices are assumed to be identical in size unless otherwise specified.

### **Ports**

#### **Conserving**

**A** — Liquid port  
isothermal liquid

Exit point of the valve.

**P** — Liquid port  
isothermal liquid

Entry point to the valve.

**T** — Liquid port  
isothermal liquid

Entry or exit point to the valve.

### Input

**S** — Control member displacement, m  
physical signal

Spool position displacement in m, received as a physical signal. For flow paths that open in the positive spool position, a positive signal opens the orifice. For flow paths that open in the negative spool position, a negative signal opens the orifice.

**Tr** — External fault trigger  
physical signal

Physical signal port for an external fault trigger. Triggering occurs when the value is greater than 0.5. There is no unit associated with the trigger value.

### Dependencies

This port is visible when **Enable faults** is set to On and **Fault trigger** is set to External.

## Parameters

### Model Parameterization

**Positive spool position open connections** — Flow paths open when the spool is in a positive position

P-T only (default) | All closed | P-A, A-T, and P-T | P-A only | A-T only

Flow paths open when the spool is in a positive position. This parameter sets the valve configuration and defines the direction of spool movement according to the signal received at port **S**.

**Negative spool position open connections** — Flow paths open when the spool moves in the negative direction

P-A only (default) | All closed | P-A, A-T, and P-T | A-T only | P-T only

Flow paths open when the spool moves in the negative direction. This parameter sets the valve configuration and defines the direction of spool movement according to the signal received at port **S**.

**Area characteristics** — Flow equations for orifices

Identical for all flow paths (default) | Different for each flow path

Applies uniform or individual flow equations for the valve orifice area. **Identical for all flow paths** uses the same orifice and spool geometries, flow rates, pressure, and area vectors for all valve orifices. When using **Different for each flow path**, different spool offsets and tabulated data are assigned to the orifices between ports **P** and **A**, ports **A** and **T**, and ports **P** and **T**. In both cases, ports **A**, **P**, and **T** have the same cross-sectional areas, discharge coefficients, and Reynolds numbers. The same **Orifice parameterization** is also applied to all flow paths.

**Orifice parameterization** — Method of calculating opening area

Linear area vs. spool travel (default) | Tabulated data - Area vs. spool travel |  
Tabulated data - volumetric flow rate vs. spool travel and pressure drop

Method of calculating the valve opening area. In the tabulated data parameterizations, you can provide your own valve area and spool travel data for nonlinear valve opening profiles, or you can provide data in terms of volumetric flow rate, spool travel, and pressure drop over the flow path.

**Spool travel between closed and open orifice** — Maximum spool stroke

0.005 m (default) | positive scalar

Maximum distance of spool travel. This value provides an upper limit to calculations so that simulations do not return unphysical values.

**Dependencies**

To enable this parameter, set **Area characteristics** to `Identical` for all flow paths.

**Maximum orifice area** — Maximum orifice opening area

1e-4 m<sup>2</sup> (default) | positive scalar

Largest open area during operation of valve.

**Dependencies**

To enable this parameter, set **Area characteristics** to `Identical` for all flow paths.

**Cross-sectional area at ports A, P and T** — Area at valve entry or exit

inf m<sup>2</sup> (default) | positive scalar

Cross-sectional area at the entry and exit ports **A**, **P**, and **T**. These areas are used in the pressure-flow rate equation that determines volumetric flow rate through the valve.

**Leakage area** — Gap area when in fully closed position

1e-10 m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the valve is in its fully closed position. Any area smaller than this value is maintained at the specified leakage area. This contributes to numerical stability by maintaining continuity in the flow.

**Dependencies**

To enable this parameter, set **Area characteristics** to `Identical` for all flow paths and **Orifice parameterization** to `Linear - area vs. spool travel`.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Correction factor that accounts for discharge losses in theoretical flows.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change based to the flow response when the valve is in near-open and near-closed positions. To increase the stability of your simulation in these regimes, set this parameter to a nonzero value less than one.

**Pressure recovery** — Whether to account for pressure increase in area expansions  
on (default) | off

Select to account for pressure increase when fluid flows from a region of a smaller cross-sectional area to a region of larger cross-sectional area.

**Spool travel vector** — Vector of valve opening distance  
[0, .00125, .0025, .00375, .005] m (default) | 1-by-n vector

Vector of control member travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **Orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Tabulated data - Area vs. spool travel.

**Orifice area vector** — Vector of valve opening areas  
[1e-10, 1e-05, 4e-05, 8e-05, .0001] m<sup>2</sup> (default) | 1-by-n vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **Spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

#### Dependencies

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Opening parameterization** to Tabulated data - Area vs. spool travel.

**Spool travel vector, ds** — Vector of valve opening distances  
[0, .00125, .0025, .00375, .005] m (default) | 1-by-n vector

Vector of control member travel distances for tabular parametrization of volumetric flow rate. The spool travel vector forms an independent axis with the **Pressure drop vector, dp** parameter for the 3-D dependent **Volumetric flow rate table, q(ds,dp)** parameter. A positive displacement corresponds to valve opening. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Volumetric flow rate vs. spool travel and pressure drop.

**Pressure drop vector, dp** — Vector of valve pressure drop values  
[-.1, .3, .5, .7] MPa (default) | 1-by-n vector

Vector of pressure drop values for tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **Spool travel vector, s** parameter for the 3-D dependent **Volumetric flow rate table, q(ds,dp)** parameter. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

### Dependencies

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Volumetric flow rate vs. spool travel and pressure drop.

**Volumetric flow rate table,  $q(ds,dp)$**  — Array of volumetric flow rates

```
[-9.05e-10, 1.57e-09, 2.02e-09, 2.39e-09;
-9.05e-05, .000157, .000202, .000239; -.000362, .000627, .00081, .000958;
-.000724, .00125, .00162, .00192; -.000905, .00156, .002, .00239] m^3/s
(default) |  $M$ -by- $N$  matrix
```

$M$ -by- $N$  matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of elements in the **Pressure drop vector,  $dp$**  parameter.
- $N$  is the number of elements in the **Spool travel vector,  $ds$**  parameter.

### Dependencies

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

### P-A Orifice

**Spool position at maximum P-A orifice area** — Spool offset at maximum area between ports P and A

4.5e-3 m (default) | scalar

Initial orifice opening distance between ports **P** and **A**. The default represents an underlapped system.

- If the magnitude of **Spool position at maximum orifice area** is less than the value of **Spool travel between closed and open orifice**, the orifice is underlapped, or partially open when the spool position equals 0 m.
- If the magnitude of **Spool position at maximum orifice area** is greater than the value of **Spool travel between closed and open orifice**, the orifice is overlapped. This means the valve remains closed over a range of spool positions.
- If the magnitude of **Spool position at maximum orifice area** is equal to the value of **Spool travel between closed and open orifice**, the orifice is zero-lapped. This means the valve is closed when the spool position equals 0 and begins to open as soon as the spool position changes.

**P-A spool travel between closed and open orifice** — Maximum stroke for the spool between ports P and A

0.005 m (default) | positive scalar

Maximum distance of spool travel for the orifice between ports **P** and **A**. This value provides an upper limit to calculations so that simulations do not return unphysical values.

### Dependencies

To enable this parameter, set **Area characteristics** to Different for each flow path.

**P-A maximum orifice area** — Maximum area between ports P and A  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the orifice between ports **P** and **A** in its fully open position.

#### Dependencies

To enable this parameter, set **Area characteristics** to Different for each flow path and **Orifice parameterization** to Linear - area vs. spool travel.

**P-A orifice spool travel vector** — Vector of valve opening distance  
 $[0, .00125, .0025, .00375, .005] \text{ m}$  (default) | 1-by-n vector

Vector of control member travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **P-A orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Area characteristics** to Different for each flow path and **Orifice parameterization** to Tabulated data - Area vs. spool travel.

**P-A orifice area vector** — Vector of valve opening areas  
 $[1e-10, 1e-05, 4e-05, 8e-05, .0001] \text{ m}^2$  (default) | 1-by-n vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **P-A orifice spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

#### Dependencies

To enable this parameter, set **Area characteristics** to Different for each flow path and **Opening parameterization** to Tabulated data - Area vs. spool travel.

**P-A orifice spool travel vector, ds** — Vector of valve opening distances  
 $[0, .00125, .0025, .00375, .005] \text{ m}$  (default) | 1-by-n vector

Vector of control member travel distances for tabular parametrization of volumetric flow rate. The spool travel vector forms an independent axis with the **P-A orifice pressure drop vector, dp** parameter for the 3-D dependent **P-A orifice volumetric flow rate table, q(s,dp)** parameter. A positive displacement corresponds to valve opening. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Area characteristics** to Different for each flow path and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**P-A orifice pressure drop vector, dp** — Vector of pressure drop values over the valve  
 $[-.1, .3, .5, .7] \text{ MPa}$  (default) | 1-by-n vector

Vector of pressure drop values for tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **P-A orifice spool travel vector, s** parameter for the 3-D dependent **P-A orifice volumetric flow rate table, q(s,dp)** parameter. The values are listed in

ascending order and must be greater than 0. Linear interpolation is employed between table data points.

### Dependencies

To enable this parameter, set **Area characteristics** to Different for each flow path and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**P-A orifice volumetric flow rate table,  $q(ds,dp)$**  — Vector of valve volumetric flow rates  
 $[-9.05e-10, 1.57e-09, 2.02e-09, 2.39e-09;$   
 $-9.05e-05, .000157, .000202, .000239; -.000362, .000627, .00081, .000958;$   
 $-.000724, .00125, .00162, .00192; -.000905, .00156, .002, .00239]$  m<sup>3</sup>/s  
 (default) | *M*-by-*N* matrix

*M*-by-*N* matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the corresponding vectors:

- *M* is the number of elements in the **P-A orifice pressure drop vector,  $dp$**  parameter.
- *N* is the number of elements in the **P-A orifice spool travel vector,  $s$**  parameter.

### Dependencies

To enable this parameter, set **Area characteristics** to Different for each flow path and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

### A-T Orifice

**Spool position at maximum A-T orifice area** — Spool offset at maximum area between ports A and T  
 $-4.5e-3$  m (default) | scalar

Initial orifice opening distance between ports **A** and **T**. The default represents an underlapped system.

- If the magnitude of **Spool position at maximum orifice area** is less than the value of **Spool travel between closed and open orifice**, the orifice is underlapped, or partially open when the spool position equals 0 m.
- If the magnitude of **Spool position at maximum orifice area** is greater than the value of **Spool travel between closed and open orifice**, the orifice is overlapped. This means the valve remains closed over a range of spool positions.
- If the magnitude of **Spool position at maximum orifice area** is equal to the value of **Spool travel between closed and open orifice**, the orifice is zero-lapped. This means the valve is closed when the spool position equals 0 and begins to open as soon as the spool position changes.

**A-T spool travel between closed and open orifice** — Maximum stroke for the spool between ports A and T  
 $0.005$  m (default) | positive scalar

Maximum distance of spool travel for the orifice between ports **A** and **T**. This value provides an upper limit to calculations so that simulations do not return unphysical values.

**Dependencies**

To enable this parameter, set **Area characteristics** type to **Different** for each flow path.

**A-T maximum orifice area** — Maximum area between ports A and T  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the orifice between ports **A** and **T** in its fully open position.

**Dependencies**

To enable this parameter, set **Area characteristics** to **Different** for each flow path and **Orifice parameterization** to **Linear - area vs. spool travel**.

**A-T orifice spool travel vector** — Vector of valve opening distances  
 $[0, .00125, .0025, .00375, .005] \text{ m}$  (default) | 1-by-*n* vector

Vector of control member travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **A-T orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Area characteristics** to **Different** for each flow path and **Orifice parameterization** to **Tabulated data - Area vs. spool travel**.

**A-T orifice area vector** — Vector of valve opening areas  
 $[1e-10, 1e-05, 4e-05, 8e-05, .0001] \text{ m}^2$  (default) | 1-by-*n* vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **A-T orifice spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

**Dependencies**

To enable this parameter, set **Area characteristics** to **Different** for each flow path and **Opening parameterization** to **Tabulated data - Area vs. spool travel**.

**A-T orifice spool travel vector, ds** — Vector of valve opening distances  
 $[0, .00125, .0025, .00375, .005] \text{ m}$  (default) | 1-by-*n* vector

Vector of control member travel distances for tabular parametrization of volumetric flow rate. The spool travel vector forms an independent axis with the **A-T orifice pressure drop vector, dp** parameter for the 3-D dependent **A-T orifice volumetric flow rate table, q(ds,dp)** parameter. A positive displacement corresponds to valve opening. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Area characteristics** to **Different** for each flow path and **Orifice parameterization** to **Tabulated data - Volumetric flow rate vs. spool travel and pressure drop**.

**A-T orifice pressure drop vector, dp** — Vector of pressure drop values over the valve  
 $[-.1, .3, .5, .7] \text{ MPa}$  (default) | 1-by-*n* vector

Vector of pressure drop values for tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **A-T orifice spool travel vector, *s*** parameter for the 3-D dependent **A-T orifice volumetric flow rate table, *q(ds,dp)*** parameter. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Area characteristics** to Different for each flow path and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**A-T orifice volumetric flow rate table, *q(ds,dp)*** — Vector of volumetric flow rate for tabular parameterization - different flow paths

```
[-9.05e-10, 1.57e-09, 2.02e-09, 2.39e-09;
-9.05e-05, .000157, .000202, .000239; -.000362, .000627, .00081, .000958;
-.000724, .00125, .00162, .00192; -.000905, .00156, .002, .00239] m^3/s
(default) | M-by-N matrix
```

M-by-N matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the corresponding vectors:

- *M* is the number of elements in the **A-T orifice pressure drop vector, *dp*** parameter.
- *N* is the number of elements in the **A-T orifice spool travel vector, *s*** parameter.

#### Dependencies

To enable this parameter, set **Area characteristics** to Different for each flow path and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

#### P-T Orifice

**Spool position at maximum P-T orifice area** — Spool offset at maximum area between ports P and T

```
4.5e-3 m (default) | scalar
```

Initial orifice opening distance between ports **P** and **T**. The default represents an underlapped system.

- If the magnitude of **Spool position at maximum orifice area** is less than the value of **Spool travel between closed and open orifice**, the orifice is underlapped, or partially open when the spool position equals 0 m.
- If the magnitude of **Spool position at maximum orifice area** is greater than the value of **Spool travel between closed and open orifice**, the orifice is overlapped. This means the valve remains closed over a range of spool positions.
- If the magnitude of **Spool position at maximum orifice area** is equal to the value of **Spool travel between closed and open orifice**, the orifice is zero-lapped. This means the valve is closed when the spool position equals 0 and begins to open as soon as the spool position changes.

**P-T spool travel between closed and open orifice** — Maximum stroke for the spool between ports P and T

```
0.005 m (default) | positive scalar
```

Maximum distance of spool travel for the orifice between ports **P** and **T**. This value provides an upper limit to calculations so that simulations do not return unphysical values.

#### Dependencies

To enable this parameter, set **Area characteristics** type to Different for each flow path.

**P-T maximum orifice area** — Maximum area between ports P and T  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the orifice between ports **P** and **T** in its fully open position.

#### Dependencies

To enable this parameter, set **Area characteristics** to Different for each flow path and **Orifice parameterization** to Linear - area vs. spool travel.

**P-T orifice spool travel vector** — Vector of valve opening distances  
 $[0, .00125, .0025, .00375, .005] \text{ m}$  (default) | 1-by- $n$  vector

Vector of control member travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **P-T orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Area characteristics** to Different for each flow path and **Orifice parameterization** to Tabulated data - Area vs. spool travel.

**P-T orifice area vector** — Vector of valve opening areas  
 $[1e-10, 1e-05, 4e-05, 8e-05, .0001] \text{ m}^2$  (default) | 1-by- $n$  vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **P-T orifice spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

#### Dependencies

To enable this parameter, set **Area characteristics** to Different for each flow path and **Opening parameterization** to Tabulated data - Area vs. spool travel.

**P-T orifice spool travel vector, ds** — Vector of valve opening distances  
 $[0, .00125, .0025, .00375, .005] \text{ m}$  (default) | 1-by- $n$  vector

Vector of control member travel distances for tabular parametrization of volumetric flow rate. The spool travel vector forms an independent axis with the **P-T orifice pressure drop vector, dp** parameter for the 3-D dependent **P-T orifice volumetric flow rate table, q(ds,dp)** parameter. A positive displacement corresponds to valve opening. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Area characteristics** to Different for each flow path and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**P-T orifice pressure drop vector,  $dp$**  — Vector of pressure drop values over the valve  
[-.1, .3, .5, .7] MPa (default) | 1-by- $n$  vector

Vector of pressure drop values for tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **P-T orifice spool travel vector,  $ds$**  parameter for the 3-D dependent **P-T orifice volumetric flow rate table,  $q(ds,dp)$**  parameter. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Area characteristics** to Different for each flow path and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**P-T orifice volumetric flow rate table,  $q(ds,dp)$**  — Vector of volumetric flow rate for tabular parameterization - different flow paths  
[-9.05e-10, 1.57e-09, 2.02e-09, 2.39e-09;  
-9.05e-05, .000157, .000202, .000239; -.000362, .000627, .00081, .000958;  
-.000724, .00125, .00162, .00192; -.000905, .00156, .002, .00239] m<sup>3</sup>/s  
(default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of elements in the **P-T orifice pressure drop vector,  $dp$**  parameter.
- $N$  is the number of elements in the **P-T orifice spool travel vector,  $ds$**  parameter.

#### Dependencies

To enable this parameter, set **Area characteristics** to Different for each flow path and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

#### Faults

**Enable faults** — Fault option  
Off (default) | On

Enable externally or temporally triggered faults. When faulting occurs, the valve area normally set by the opening parameterization will be set to the value specified in the **Spool position when faulted** parameter.

**Spool position when faulted** — Set faulted characteristics  
Positive (default) | Negative | Maintain last value

Sets the faulted valve spool position. You can choose for the valve to seize when the spool is in the positive position, negative position, or at the position when faulting is triggered.

#### Dependencies

To enable this parameter, set **Enable faults** to On.

**Fault trigger** — External trigger option  
Off (default) | Fault when  $Tr \geq 0.5$

Whether a fault trigger occurs due to an external event or at a specified time.

When set to `External`, port **Tr** is enabled. A physical signal at port **Tr** that is greater than `0.5` triggers faulting.

When set to `Temporal`, when the **Simulation time for fault event** is reached, the valve area will be set to the value specified in the **Spool position when faulted** parameter.

#### Dependencies

To enable this parameter, set **Enable faults** to `On`.

**Simulation time for fault event** — Time at which faulting is triggered  
5 s (default) | positive scalar

When the **Simulation time for fault event** is reached, the valve area is set to the value specified in the **Spool position when faulted** parameter.

#### Dependencies

To enable this parameter, set **Enable faults** to `On` and **Fault trigger** to `Temporal`.

## 3-Way Directional Valve (G)

Controlled valve with three ports in a gas network

### Libraries:

Simscape / Fluids / Gas / Valves & Orifices / Directional Control Valves

### Description

The 3-Way Directional Valve (G) block represents a valve with three gas ports (**P**, **A**, and **T**) and two flow paths between **P-A** and **A-T**. The paths each run through an orifice of variable width. The input signal specified at port **S** controls the position of the spool. The valve closes when the spool covers the orifice opening.

In a representative system, the **P** port connects to the pump, the **T** port connects to the tank, and the **A** port connects to a single-acting actuator. Opening the **P-A** flow path, while closing **A-T**, allows the pump to pressurize the actuator. Opening the **A-T** flow path, while closing **P-A**, allows the tank to absorb the excess pressure from the actuator, freeing the shaft to translate in reverse.

This image shows a common use for a three-way directional valve in a physical system:

The flow can be laminar or turbulent, and it can reach up to sonic speeds. The maximum velocity happens at the throat of the valve where the flow is narrowest and fastest. The flow chokes and the velocity saturates when a drop in downstream pressure can no longer increase the velocity. Choking occurs when the back-pressure ratio reaches the critical value characteristic of the valve. The block does not capture supersonic flow.

### Valve Positions

The valve is continuously variable and it shifts smoothly between one normal and two working positions.

When the instantaneous displacement of the spool at port **S** is zero, the valve reverts to the normal position where it is no longer operating. Unless the lands of the spool are at an offset to their orifices, the valve is fully closed.

The working positions are the positions the valve moves to when the spool is maximally displaced, in either positive or negative direction, from the normal position. One orifice will then generally be closed and the other open to full capacity. Image **I** shows a valve where the displacement is in the negative direction, the **P-A** orifice is closed, and the **A-T** orifice is open. Image **II** shows a valve where the displacement is in the positive direction, the **P-A** orifice is open, and the **A-T** orifice is closed.

I.

II.

The spool displacement that puts the valve in its working position depends on the offsets of the lands on the spool. The parameters in the **Valve Opening Fraction Offsets** section specify the block constants for the spool displacements of the ports.

### Orifice Opening Fractions

Between valve positions, the opening of an orifice depends on where the land of the spool is, relative to the rim. This distance is the orifice opening, and the block normalizes this distance so that its value is a fraction of the maximum distance at which the orifice is fully open. The normalized variable is the orifice opening fraction.

The orifice opening fractions range from -1 when the valve is in the position shown in image **I** to +1 when the valve is in the position shown in image **II**.

The block calculates the opening fractions from the spool displacement and opening fraction offset. The displacement and offset are unitless fractions of the maximum land-orifice distance.

The opening fraction of the **P-A** orifice is:

$$h_{PA} = H_{PA} + x.$$

The opening fraction of the **A-T** orifice is:

$$h_{AT} = H_{AT} - x.$$

In both equations:

- $h$  is the opening fraction of the orifice specified by the subscript **P-A** or **A-T**. If the calculation returns a value outside of the range  $0 - 1$ , the block uses the nearest limit.
- $H$  is the opening fraction offset for the orifice. The parameters in the **Valve Opening Fraction Offsets** section specify the opening fraction offsets. To allow for unusual valve configurations, the block imposes no limit on their values, although generally these will fall between  $-1$  and  $+1$ .
- $x$  is the normalized instantaneous displacement of the spool, specified by a physical signal at port **S**. To compensate for extreme opening fraction offsets, there is no limit on the signal value. The value is typically between  $-1$  and  $+1$ .

### Opening Fraction Offsets

By default, the valve is fully closed when its control displacement is zero. In this state, the valve is zero-lapped.

You can offset the lands of the spool to model an underlapped or overlapped valve. Underlapped valves are partially open in the normal position. Overlapped valves are fully closed slightly beyond the normal position. The figure shows how the orifice opening fractions vary with the instantaneous spool displacement:

- **Image I:** A zero-lapped valve. The opening fraction offsets are both zero. When the valve is in the normal position, the lands of the spool completely cover both orifices.
- **Image II:** An underlapped valve. The opening fraction offsets are both positive. When the valve is in the normal position, the lands of the spool partially cover both orifices.
- **Image III:** An overlapped valve. The opening fraction offsets are both negative. The lands of the spool completely cover both orifices not only in the normal position but over a small region of spool displacements around it.

## Valve Parameterizations

The block behavior depends on the **Valve parametrization** parameter:

- **Cv flow coefficient** — The flow coefficient  $C_v$  determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential. [2][3]
- **Kv flow coefficient** — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential. [2][3]
- **Sonic conductance** — The sonic conductance of the resistive element at steady state determines the block parameterization. The sonic conductance measures the ease with which a gas can flow when *choked*, which is a condition in which the flow velocity is at the local speed of sound. Choking occurs when the ratio between downstream and upstream pressures reaches a critical value known as the *critical pressure ratio*. [1]
- **Orifice area** — The size of the flow restriction determines the block parametrization. [4]

## Opening Characteristics

The flow characteristic relates the opening of the valve to the input that produces it, which is often the spool travel. The block expresses the opening as a sonic conductance, flow coefficient, or restriction area, depending on the setting of the **Valve parametrization** parameter. The control input is the orifice opening fraction, a function of the spool displacement specified at port **S**.

The flow characteristic is normally given at steady state, with the inlet at a constant, carefully controlled pressure. The flow characteristic depends only on the valve and can be linear or nonlinear. To capture the flow characteristics, use the **Opening characteristic** parameter:

- **Linear** — The measure of flow capacity is a linear function of the orifice opening fraction. As the opening fraction rises from 0 to 1, the measure of flow capacity scales from the specified minimum to the specified maximum.

- **Tabulated** — The measure of flow capacity is a general function, which can be linear or nonlinear, of the orifice opening fraction. The function is specified in tabulated form, with the independent variable specified by the **Opening fraction vector**

## Numerical Smoothing

When the **Opening characteristic** parameter is Linear, and the **Smoothing factor** parameter is nonzero, the block applies numerical smoothing to the orifice opening fraction. Enabling smoothing helps maintain numerical robustness in your simulation.

For more information, see “Numerical Smoothing”.

### **Leakage Flow**

The leakage flow ensures that no section of a fluid network becomes isolated. Isolated fluid sections can reduce the numerical robustness of the model, slow the rate of simulation and, in some cases, cause the simulation to fail. The **Leakage flow fraction** parameter represents the leakage flow area in the block as a small number greater than zero.

### **Composite Structure**

This block is a composite component comprising two instances of the Orifice (G) block, one connected between ports **P** and **A** and a second block between **A** and **T**. Refer to the Orifice (G) block for more detail on the valve parameterizations and block calculations.

### **Assumptions and Limitations**

- The **Sonic** conductance setting of the **Valve parameterization** parameter is for pneumatic applications. If you use this setting for gases other than air, you may need to scale the sonic conductance by the square root of the specific gravity.
- The equation for the **Orifice area** parameterization is less accurate for gases that are far from ideal.
- This block does not model supersonic flow.

### **Ports**

#### **Input**

**S** — Valve control signal, unitless  
physical signal

Instantaneous displacement of the control member against its normal unactuated position, specified as a physical signal. The block normalizes the displacement against the maximum position of the control member that required to open the orifice fully. The signal is unitless and its instantaneous value is typically in the range between -1 and +1.

#### **Conserving**

**A** — Valve opening  
gas

Gas conserving port associated with the opening through which the flow enters or exits the valve.

**P** — Valve opening  
gas

Gas conserving port associated with the opening through which the flow enters or exits the valve.

**T** — Valve opening  
gas

Gas conserving port associated with the opening through which the flow enters or exits the valve.

## Parameters

**Valve parameterization** — Parameterization used to specify flow characteristics of orifice  
 Cv flow coefficient (default) | Kv flow coefficient | Sonic conductance | Orifice area

Method to calculate the mass flow rate.

- **Cv flow coefficient** — The flow coefficient  $C_v$  determines the block parameterization.
- **Kv flow coefficient** — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization.
- **Sonic conductance** — The sonic conductance of the resistive element at steady state determines the block parameterization.
- **Orifice area** — The size of the flow restriction determines the block parametrization.

**Opening characteristic** — Method to calculate the opening characteristics of the valve  
 Linear (default) | Tabulated

Method the block uses to calculate the opening area of the valve. The linear setting treats the opening area as a linear function of the orifice opening fraction. The tabulated setting allows for a general, nonlinear relationship you can specify in tabulated form.

**Opening fraction vector** — Control signal values at which to specify tabulated parameter data  
 0 : 0.2 : 1 (default) | vector of positive numbers

Vector of control signal values at which to specify the chosen measure of flow capacity: **Sonic conductance vector**, **Cv coefficient vector**, **Kv coefficient vector**, or **Orifice area vector**. The control signal is between 0 and 1, with each value corresponding to an opening fraction of the resistive element. The greater the value, the greater the opening and easier the flow.

The opening fractions must increase monotonically across the vector from left to right. The size of this vector must be the same as the **Sonic conductance vector**, **Cv coefficient vector**, **Kv coefficient vector**, or **Orifice area vector** parameter.

### Dependencies

To enable this parameter, set **Opening characteristic** to Tabulated.

**Maximum Cv flow coefficient** — Cv coefficient that corresponds to maximally open component  
 4 (default) | positive scalar

Value of the  $C_v$  flow coefficient when the restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

### Dependencies

To enable this parameter, set **Valve parameterization** to Cv flow coefficient, and **Opening characteristic** to Linear.

**xT pressure differential ratio factor at choked flow** — Ratio of pressure differentials  
 0.7 (default) | positive scalar

Ratio between the inlet pressure,  $p_{in}$ , and the outlet pressure,  $p_{out}$ , defined as  $(p_{in} - p_{out})/p_{in}$  where choking first occurs. If you do not have this value, look it up in table 2 in ISA-75.01.01 [3]. Otherwise, the default value of 0.7 is reasonable for many valves.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Cv flow coefficient or Kv flow coefficient.

**Leakage flow fraction** — Ratio of flow rates

1e-6 (default) | positive scalar

Ratio of the flow rate of the orifice when it is closed to when it is open.

**Dependencies**

To enable this parameter, set **Opening characteristic** to Linear.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the orifice is in near-open or near-closed positions. Set this parameter to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Dependencies**

To enable this parameter, set **Opening characteristic** to Linear.

**Cv flow coefficient vector** — Cv coefficients corresponding to values in opening fraction vector

[1e-06, .8, 1.6, 2.4, 3.2, 4] (default) | vector of positive numbers

Vector of  $C_v$  flow coefficients. Each coefficient corresponds to a value in the **Opening fraction vector** parameter. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential. The flow coefficients must increase monotonically from left to right, with greater opening fractions representing greater flow coefficients. The size of the vector must be the same as the **Opening fraction vector**.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Cv flow coefficient, and **Opening characteristic** to Tabulated.

**Maximum Kv flow coefficient** — Kv coefficient that corresponds to maximally open component

3.6 (default) | positive scalar

Value of the  $K_v$  flow coefficient when the restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Kv flow coefficient, and **Opening characteristic** to Linear.

**Kv flow coefficient vector** — Kv coefficients corresponding to values in opening fraction vector

[1e-06, .72, 1.44, 2.16, 2.88, 3.6] (default) | vector of positive numbers

Vector of  $K_v$  flow coefficients. Each coefficient corresponds to a value in the **Opening fraction vector** parameter. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential. The flow coefficients must increase monotonically from left to right, with greater opening fractions representing greater flow coefficients. The size of the vector must be the same as the **Opening fraction vector** parameter.

#### Dependencies

To enable this parameter, set **Valve parameterization** to *Kv flow coefficient*, and **Opening characteristic** to *Tabulated*.

**Maximum sonic conductance** — Sonic conductance corresponding to maximally open component  
12 l/(bar\*s) (default) | positive scalar

Value of the sonic conductance when the cross-sectional area available for flow is at a maximum.

#### Dependencies

To enable this parameter, set **Valve parameterization** to *Sonic conductance*, and **Opening characteristic** to *Linear*.

**Critical pressure ratio** — Ratio of downstream and upstream pressures at which the flow first chokes  
0.3 (default) | positive scalar

Pressure ratio at which flow first begins to choke and the flow velocity reaches its maximum, given by the local speed of sound. The pressure ratio is the outlet pressure divided by inlet pressure.

#### Dependencies

To enable this parameter, set **Valve parameterization** to *Sonic conductance*, and **Opening characteristic** to *Linear*.

**Subsonic index** — Exponent used to characterize mass flow in subsonic flow regime  
0.5 (default) | positive scalar

Empirical value used to more accurately calculate the mass flow rate in the subsonic flow regime.

#### Dependencies

To enable this parameter, set **Valve parameterization** to *Sonic conductance*.

**ISO reference temperature** — ISO 8778 reference temperature  
293.15 K (default) | scalar

Temperature at standard reference atmosphere, defined as 293.15 K in ISO 8778.

#### Dependencies

To enable this parameter, set **Valve parameterization** to *Sonic conductance*.

**ISO reference density** — ISO 8778 reference density  
1.185 kg/m<sup>3</sup> (default) | positive scalar

Density at standard reference atmosphere, defined as 1.185 kg/m<sup>3</sup> in ISO 8778.

#### Dependencies

To enable this parameter, set **Valve parameterization** to *Sonic conductance*.

**Sonic conductance vector** — Sonic conductances corresponding to values in opening fraction vector  
 $[1e-05, 2.4, 4.8, 7.2, 9.6, 12] \text{ l}/(\text{bar}\cdot\text{s})$  (default) | vector of positive values

Vector of sonic conductances inside the resistive element. Each conductance corresponds to a value in the **Opening fraction vector** parameter. The sonic conductances must increase monotonically from left to right, with greater opening fractions representing greater sonic conductances. The size of the vector must be the same as the **Opening fraction vector** parameter.

#### Dependencies

To enable this parameter, set **Valve parameterization** to **Sonic conductance**, and **Opening characteristic** to **Tabulated**.

**Critical pressure ratio vector** — Critical pressure ratios corresponding to values in opening fraction vector

$0.3 * \text{ones}(1,6)$  (default) | vector of positive numbers

Vector of critical pressure ratios at which the flow first chokes, with each critical pressure ratio corresponding to a value in the **Opening fraction vector** parameter. The critical pressure ratio is the fraction of downstream-to-upstream pressures at which the flow velocity reaches the local speed of sound. The size of the vector must be the same as the **Opening fraction vector** parameter.

#### Dependencies

To enable this parameter, set **Valve parameterization** to **Sonic conductance**, and **Opening characteristic** to **Tabulated**.

**Maximum orifice area** — Flow area corresponding to maximally open component

$1e-4 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the orifice opening when the cross-sectional area available for flow is at a maximum.

#### Dependencies

To enable this parameter, set **Valve parameterization** to **Orifice area**, and **Opening characteristic** to **Linear**.

**Discharge coefficient** — Discharge coefficient

$0.64$  (default) | positive scalar in the range of  $[0,1]$

Correction factor that accounts for discharge losses in theoretical flows.

#### Dependencies

To enable this parameter, set **Valve parameterization** to **Orifice area**.

**Orifice area vector** — Vector of orifice opening area values

$[1e-10, 2e-05, 4e-05, 6e-05, 8e-05, .0001] \text{ m}^2$  (default) | vector

Vector of cross-sectional areas of the orifice opening. The values in this vector correspond one-to-one with the elements in the **Opening fraction vector** parameter. The first element of this vector is the orifice leakage area and the last element is the maximum orifice area.

#### Dependencies

To enable this parameter, set **Valve parameterization** to **Orifice area**, and **Opening characteristic** to **Tabulated**.

**Laminar flow pressure ratio** — Pressure ratio at which flow transitions between laminar and turbulent regimes

0.999 (default) | positive scalar

Pressure ratio at which flow transitions between laminar and turbulent flow regimes. The pressure ratio is the outlet pressure divided by inlet pressure. Typical values range from 0.995 to 0.999.

**Cross-sectional area at ports A, P, and T** — Area normal to the flow path at the valve ports

0.01 m<sup>2</sup> (default) | positive scalar in units of area

Area normal to the flow path at the valve ports. The ports are assumed to be of the same size. The flow area specified here should ideally match those of the inlets of adjoining components.

#### Valve Opening Fraction Offsets

**Between Ports P and A** — Opening fraction offset for the P-A orifice

0 (default) | unitless scalar

Opening fraction of the **P-A** orifice when the value of the input signal **S** is zero. The valve is then in the normal position. The opening fraction measures the distance of a land of the spool to its appointed orifice, here **P-A**, normalized by the maximum such distance. It is unitless and generally between 0 and 1.

**Between Ports A and T** — Opening fraction offset for the A-T orifice

0 (default) | unitless scalar

Opening fraction of the **A-T** orifice when the value of the input signal **S** is zero. The valve is then in the normal position. The opening fraction measures the distance of a land of the spool to its appointed orifice, here **A-T**, normalized by the maximum such distance. It is unitless and generally between 0 and 1.

## Version History

### Introduced in R2018b

#### R2022b: Model gas systems using improved flow computations

In previous versions, the blocks in the gas library used a conversion factor to implement different orifice parameterizations in terms of sonic conductance. You can use the **Valve parameterization** parameter to specify the parameterization.

The new parameterizations also include new parameters:

- **xT pressure differential ratio factor at choked flow**
- **Discharge coefficient**
- **Leakage flow fraction.** This parameter replaces the **Cv coefficient (USCS) at leakage flow**, **Kv coefficient (SI) at leakage flow**, **Sonic conductance at leakage flow**, and **Restriction area at leakage flow** parameters.

To improve clarity:

- The **Opening parameterization** parameter has been renamed to **Opening characteristic**.

- The **Reference temperature** and **Reference density** parameters have been renamed to **ISO reference temperature** and **ISO reference density**, respectively.
- The **Cv coefficient (USCS) at maximum flow** and **Kv coefficient (USCS) at maximum flow** parameters have been renamed to **Maximum Cv coefficient** and **Maximum Kv coefficient**, respectively.
- The **Sonic conductance at maximum flow** parameter has been renamed to **Maximum sonic conductance**.

## 3-Way Directional Valve (TL)

3-position directional valve in a thermal liquid network

### Libraries:

Simscape / Fluids / Thermal Liquid / Valves & Orifices / Directional Control Valves

### Description

The 3-Way Directional Valve (TL) block represents a valve with three openings in a thermal liquid network, typically between an actuator, pump, and tank. The valve operation is controlled by a single spool displaced according to the signal at port **S**. You can set the baseline configuration of your valve by specifying the orifices that are open when the spool moves in the positive direction and negative directions in the **Positive spool position open connections** and **Negative spool position open connections** parameters, respectively.

You can set the model for valve opening in the **Orifice parameterization** parameter as a linear relationship or function of user-provided data, which can be applied to one or all flow paths in the valve.

In this configuration, **Positive spool position open connections** is set to A-T only. When the signal at port **S** moves the spool to a positive position, the path between ports **A** and **T** is open to flow. The paths between ports **P** and **A** and between ports **P** and **T** are closed:

In this configuration, **Negative spool position open connections** is set to P-A only. When the signal at port **S** moves the spool to a negative position, the path between ports **P** and **A** is open to flow and the paths between ports **T** and **A** and between ports **P** and **T** are closed:

You can open the path between ports **P** and **T** by setting either **Positive spool position open connections** or **Negative spool position open connections** to P-T only or P-A, A-T, and P-T.

A flow path can be open in either the positive or negative spool positions, but not both.

### Valve Orifice Parameterizations

The **Orifice parameterization** sets the method for calculating the valve open area. The calculations are based either on the orifice parameters or tabulated data sets specified in the **Model Parameterization** tab. The block uses the same data for all flow paths if **Area characteristics** is set to **Identical for all flow paths**; otherwise, individual values are applied in the **Different for all flow paths** setting. The orifice parameterizations are:

- Linear - area vs. spool travel

The opening area is a linear function of the spool travel distance and the signal received at port **S**:

$$A_{orifice} = \frac{(A_{max} - A_{leak})}{\Delta S_{max}} \Delta S + A_{leak},$$

where:

- $A_{max}$  is the **Maximum orifice area**.
- $A_{leak}$  is the **Leakage area**.
- $\Delta S_{max}$  is the **Spool travel between closed and open orifice**.
- $\Delta S$  is the spool travel distance. For flow paths that are open in the positive position:

$$\Delta S = S_{orifice\_max} - \Delta S_{max} + S,$$

and for flow paths that are open in the negative position:

$$\Delta S = S_{orifice\_max} + \Delta S_{max} - S,$$

where  $S_{orifice\_max}$  is the **Spool position at maximum orifice area**.

When the valve is in a near-open or near-closed position in the linear parameterization, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the opening area between  $A_{leak}$  and  $A_{max}$ . For more information, see “Numerical Smoothing”.

- Tabulated data - Area vs. spool travel

Provide spool travel vectors for your system or for individual flow paths between ports **P** and **A**, **A** and **T**, and **P** and **T**. This data will be used to calculate the relationship between the orifice opening area and spool travel distance. Interpolation is used to determine the opening area between given data points.  $A_{leak}$  and  $A_{max}$  are the first and last parameters of the **Opening area vector**, respectively.

- Tabulated data - Volumetric flow rate vs. spool travel and pressure drop

Provide spool travel and pressure drop vectors. The volumetric flow rate is calculated based on the relationship between pressure change and the spool travel distance. Interpolation is used to determine flow rate between given data points. The mass flow rate is the product of the volumetric flow rate and the local density.

When you set **Orifice parameterization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop the block calculates the mass flow rate directly from the control member position and the pressure drop across the valve. The relationship between the three variables can be nonlinear and it is given by the tabulated data in the **Spool travel vector**, **ds**, **Pressure drop vector**, **dp**, and **Mass flow rate table**, **mdot(ds,dp)** parameters.

### Visualize Orifice Openings

To visualize spool offsets and displacement, right-click the block and select **Fluids > Plot Valve Characteristics**. The plot shows the orifices selected in the **Valve Configuration** settings. The parameterization selection sets the axes, which are either:

- Orifice area versus spool position
- Volumetric flow rate versus spool position, queried at a specific pressure differential
- Mass flow rate versus spool position for the reference inflow temperature and reference inflow pressure, queried at a specific pressure differential

To update the data after changing the block parameters, click **Reload Data** on the figure window.

This image shows an example valve configuration. In the **Valve Configuration** settings:

- **Positive spool position open connections** is P-A only.
- **Negative spool position open connections** is A-T only.

All other spool positions are at the default values.

### Assumptions

- Fluid inertia is ignored.
- Spool loading due to inertial, spring, and other forces is ignored.
- All valve orifices are assumed to be identical in size unless otherwise specified.

### Ports

#### Input

**S** — Control member displacement  
physical signal

Displacement of the valve control member, in m. This is equivalent to the spool position.

#### Conserving

**P** — Flow passage  
thermal liquid

Opening through which the flow can enter or exit the valve. This port is typically connected to a fluid supply line.

**T** — Flow passage  
thermal liquid

Opening through which the flow can enter or exit the valve. This port is typically connected to a fluid return line.

**A** — Flow passage  
thermal liquid

Opening through which the flow can enter or exit the valve. This port is typically connected to an actuation line.

## Parameters

### Model Parameterization

**Positive spool position open connections** — Flow paths open when the spool is in a positive position

P-A only (default) | All closed | P-A, A-T, and P-T | P-T only | A-T only

Flow paths open when the spool is in a positive position. This parameter sets the valve configuration and defines the direction of spool movement according to the signal received at port **S**.

**Negative spool position open connections** — Flow paths open when the spool moves in the negative direction

A-T only (default) | All closed | P-A, A-T, and P-T | P-A only | P-T only

Flow paths open when the spool moves in the negative direction. This parameter sets the valve configuration and defines the direction of spool movement according to the signal received at port **S**.

**Area characteristics** — Flow equations for orifices

Identical for all flow paths (default) | Different for each flow path

Applies uniform or individual flow equations for the valve orifice area. **Identical for all flow paths** uses the same orifice and spool geometries, flow rates, pressure, and area vectors for all valve orifices. When using **Different for each flow path**, the spool offsets and tabulated data are assigned to the orifices between ports **P** and **A**, ports **A** and **T**, and ports **P** and **T**. In both cases, ports **A**, **P**, and **T** have the same cross-sectional areas, discharge coefficients, and Reynolds numbers. The same **Orifice parameterization** is also applied to all flow paths.

**Orifice parameterization** — Method of calculating opening area

Linear area vs. spool travel (default) | Tabulated data - Area vs. spool travel |  
Tabulated data - Volumetric flow rate vs. spool travel and pressure drop  
Tabulated data - Mass flow rate vs. spool travel and pressure drop

Method of calculating the valve opening area. In the tabulated data parameterizations, you can provide your own valve area and spool travel data for nonlinear valve opening profiles, or you can provide data in terms of volumetric flow rate, spool travel, and pressure drop over the flow path. The thermal liquid domain allows you to parameterize the orifice using tabulated mass flow rate data.

**Spool travel between closed and open orifice** — Maximum spool stroke

5e-3 m (default) | positive scalar

Maximum distance of spool travel. This value provides an upper limit to calculations so that simulations do not return unphysical values.

#### Dependencies

To enable this parameter, set **Area characteristics** to `Identical` for all flow paths.

**Maximum orifice area** — Maximum orifice opening area  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Largest open area during operation of valve.

#### Dependencies

To enable this parameter, set **Area characteristics** to `Identical` for all flow paths.

**Spool travel vector** — Vector of valve opening distance  
 $[0, .00125, .0025, .00375, .005] \text{ m}$  (default) | 1-by-n vector

Vector of control member travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **Orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Area characteristics** to `Identical` for all flow paths and **Orifice parameterization** to `Tabulated data - Area vs. spool travel`.

**Orifice area vector** — Vector of valve opening areas  
 $[1e-10, 1e-05, 4e-05, 8e-05, .0001] \text{ m}^2$  (default) | 1-by-n vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **Spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

#### Dependencies

To enable this parameter, set **Area characteristics** to `Identical` for all flow paths and **Opening parameterization** to `Tabulated data - Area vs. spool travel`.

**Leakage area** — Gap area when in fully closed position  
 $1e-10 \text{ m}^2$  (default) | positive scalar

Sum of all gaps when the valve is in its fully closed position. Any area smaller than this value is maintained at the specified leakage area. This contributes to numerical stability by maintaining continuity in the flow.

#### Dependencies

To enable this parameter, set **Area characteristics** to `Identical` for all flow paths and **Orifice parameterization** to `Linear - area vs. spool travel`.

**Smoothing factor** — Numerical smoothing factor  
 $0.01$  (default) | positive scalar in the range  $[0,1]$

Continuous smoothing factor that introduces a layer of gradual change based to the flow response when the valve is in near-open and near-closed positions. To increase the stability of your simulation in these regimes, set this parameter to a nonzero value less than one.

**Spool travel vector,  $\mathbf{ds}$**  — Vector of valve opening distances  
 $[0, .00125, .0025, .00375, .005]$  m (default) | 1-by- $n$  vector

Vector of control member travel distances for tabular parametrization of volumetric flow rate. The spool travel vector forms an independent axis with the **Pressure drop vector,  $\mathbf{dp}$**  parameter for the 3-D dependent **Volumetric flow rate table,  $\mathbf{q}(\mathbf{ds},\mathbf{dp})$**  or **Mass flow rate table,  $\mathbf{mdot}(\mathbf{ds},\mathbf{dp})$**  parameters. A positive displacement corresponds to valve opening. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Volumetric flow rate vs. spool travel and pressure drop or Tabulated data - Mass flow rate vs. spool travel and pressure drop.

**Pressure drop vector,  $\mathbf{dp}$**  — Vector of valve pressure drop values  
 $[-.1, .3, .5, .7]$  MPa (default) | 1-by- $n$  vector

Vector of pressure drop values for tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **Spool travel vector,  $\mathbf{s}$**  parameter for the 3-D dependent **Volumetric flow rate table,  $\mathbf{q}(\mathbf{ds},\mathbf{dp})$**  or **Mass flow rate table,  $\mathbf{mdot}(\mathbf{ds},\mathbf{dp})$**  parameters. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Volumetric flow rate vs. spool travel and pressure drop or Tabulated data - Mass flow rate vs. spool travel and pressure drop.

**Volumetric flow rate table,  $\mathbf{q}(\mathbf{ds},\mathbf{dp})$**  — Array of volumetric flow rates  
 $[-9.05e-10, 1.57e-09, 2.02e-09, 2.39e-09;$   
 $-9.05e-05, .000157, .000202, .000239; -.000362, .000627, .00081, .000958;$   
 $-.000724, .00125, .00162, .00192; -.000905, .00156, .002, .00239]$  m<sup>3</sup>/s  
 (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of elements in the **Spool travel vector,  $\mathbf{ds}$**  parameter.
- $N$  is the number of elements in the **Pressure drop vector,  $\mathbf{dp}$**  parameter.

#### Dependencies

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**Reference inflow temperature** — Temperature at which pressure-drop data is specified  
 293.15 K (default) | positive scalar

Temperature at which the tabulated pressure-drop data is specified.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop.

**Reference inflow pressure** — Pressure at which pressure-drop tabulated data is specified  
0.101325 MPa (default) | positive scalar

Pressure at which the tabulated pressure-drop data is specified. The block uses this parameter to calculate a third reference parameter, the reference density. The reference that it uses to scale the tabulated pressure drop data for pressures and temperatures deviating from the reference conditions.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop.

**Mass flow rate table, mdot(ds,dp)** — Mass flow rate  
1e3 \* [-9.05e-10, 1.57e-09, 2.02e-09, 2.39e-09;  
-9.05e-05, .000157, .000202, .000239; -.000362, .000627, .00081, .000958;  
-.000724, .00125, .00162, .00192; -.000905, .00156, .002, .00239] kg/s (default)  
| M-by-N matrix

Mass flow rate for  $M$  given control member positions and  $N$  given pressure drops over the orifice. The control member position represents a spool or other mechanism that controls the opening area.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop.

**Discharge coefficient** — Discharge coefficient  
0.64 (default) | positive scalar

Correction factor that accounts for discharge losses in theoretical flows.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

**Pressure recovery** — Whether to account for pressure increase in area expansions  
on (default) | off

Select to account for pressure increase when fluid flows from a region of a smaller cross-sectional area to a region of larger cross-sectional area.

**Cross-sectional area at ports A, P and T** — Area at valve entry or exit  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area at the entry and exit ports **A**, **P**, and **T**. These areas are used in the pressure-flow rate equation that determines volumetric flow rate through the valve.

## P-A Orifice

**Spool position at maximum P-A orifice area** — Spool offset at maximum area between ports P and A

4.5e-3 m (default) | scalar

Initial orifice opening distance between ports **P** and **A**. The default represents a underlapped system.

- If the magnitude of **Spool position at maximum orifice area** is less than the value of **Spool travel between closed and open orifice**, the orifice is underlapped, or partially open when the spool position equals 0 m.
- If the magnitude of **Spool position at maximum orifice area** is greater than the value of **Spool travel between closed and open orifice**, the orifice is overlapped. This means the valve remains closed over a range of spool positions.
- If the magnitude of **Spool position at maximum orifice area** is equal to the value of **Spool travel between closed and open orifice**, the orifice is zero-lapped. This means the valve is closed when the spool position equals 0 and begins to open as soon as the spool position changes.

**P-A spool travel between closed and open orifice** — Maximum stroke for the spool between ports P and A

0.005 m (default) | positive scalar

Maximum distance of spool travel for the orifice between ports **P** and **A**. This value provides an upper limit to calculations so that simulations do not return unphysical values.

### Dependencies

To enable this parameter, set **Area characteristics** to **Different** for each flow path.

**P-A maximum orifice area** — Maximum area between ports P and A

1e-4 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the orifice between ports **P** and **A** in its fully open position.

### Dependencies

To enable this parameter, set **Area characteristics** to **Different** for each flow path and **Orifice parameterization** to **Linear - area vs. spool travel**.

**P-A orifice spool travel vector** — Vector of valve opening distance

[0, .00125, .0025, .00375, .005] m (default) | 1-by-n vector

Vector of control member travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **P-A orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

### Dependencies

To enable this parameter, set **Area characteristics** to **Different** for each flow path and **Orifice parameterization** to **Tabulated data - Area vs. spool travel**.

**P-A orifice area vector** — Vector of valve opening areas

[1e-10, 1e-05, 4e-05, 8e-05, .0001] m<sup>2</sup> (default) | 1-by-n vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **P-A orifice spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

#### Dependencies

To enable this parameter, set **Area characteristics** to Different for each flow path and **Opening parameterization** to Tabulated data - Area vs. spool travel.

**P-A orifice spool travel vector, ds** — Vector of valve opening distances

[0, .00125, .0025, .00375, .005] m (default) | 1-by-*n* vector

Vector of control member travel distances for tabular parametrization of volumetric flow rate. The spool travel vector forms an independent axis with the **P-A orifice pressure drop vector, dp** parameter for the 3-D dependent **P-A orifice volumetric flow rate table, q(s,dp)** or **Mass flow rate table, mdot(ds,dp)** parameters. A positive displacement corresponds to valve opening. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Volumetric flow rate vs. spool travel and pressure drop or Tabulated data - Mass flow rate vs. spool travel and pressure drop.

**P-A orifice pressure drop vector, dp** — Vector of pressure drop values over the valve

[-.1, .3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of pressure drop values for tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **P-A orifice spool travel vector, s** parameter for the 3-D dependent **P-A orifice volumetric flow rate table, q(s,dp)** or **Mass flow rate table, mdot(ds,dp)** parameters. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Volumetric flow rate vs. spool travel and pressure drop or Tabulated data - Mass flow rate vs. spool travel and pressure drop.

**P-A orifice volumetric flow rate table, q(ds,dp)** — Vector of valve volumetric flow rates

[-9.05e-10, 1.57e-09, 2.02e-09, 2.39e-09;  
-9.05e-05, .000157, .000202, .000239; -.000362, .000627, .00081, .000958;  
-.000724, .00125, .00162, .00192; -.000905, .00156, .002, .00239] m<sup>3</sup>/s  
(default) | *M*-by-*N* matrix

*M*-by-*N* matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the corresponding vectors:

- *M* is the number of elements in the **P-A orifice pressure drop vector, dp** parameter.
- *N* is the number of elements in the **P-A orifice spool travel vector, s** parameter.

### Dependencies

To enable this parameter, set **Area characteristics** to Different for each flow path and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**P-A orifice mass flow rate table,  $\dot{m}(ds,dp)$**  — Vector of valve mass flow rates  
 $1e3 * [-9.05e-10, 1.57e-09, 2.02e-09, 2.39e-09;$   
 $-9.05e-05, .000157, .000202, .000239; -.000362, .000627, .00081, .000958;$   
 $-.000724, .00125, .00162, .00192; -.000905, .00156, .002, .00239]$  kg/s (default)  
 | *M*-by-*N* matrix

*M*-by-*N* matrix of mass flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the corresponding vectors:

- *M* is the number of elements in the **P-A orifice pressure drop vector,  $dp$**  parameter.
- *N* is the number of elements in the **P-A orifice spool travel vector,  $s$**  parameter.

### Dependencies

To enable this parameter, set **Area characteristics** to Different for each flow path and **Orifice parameterization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop.

### A-T Orifice

**Spool position at maximum A-T orifice area** — Spool offset at maximum area between ports A and T  
 $-4.5e-3$  m (default) | scalar

Initial orifice opening distance between ports **A** and **T**. The default represents a underlapped system.

- If the magnitude of **Spool position at maximum orifice area** is less than the value of **Spool travel between closed and open orifice**, the orifice is underlapped, or partially open when the spool position equals 0 m.
- If the magnitude of **Spool position at maximum orifice area** is greater than the value of **Spool travel between closed and open orifice**, the orifice is overlapped. This means the valve remains closed over a range of spool positions.
- If the magnitude of **Spool position at maximum orifice area** is equal to the value of **Spool travel between closed and open orifice**, the orifice is zero-lapped. This means the valve is closed when the spool position equals 0 and begins to open as soon as the spool position changes.

**A-T spool travel between closed and open orifice** — Maximum stroke for the spool between ports A and T  
 $0.005$  m (default) | positive scalar

Maximum distance of spool travel for the orifice between ports **A** and **T**. This value provides an upper limit to calculations so that simulations do not return unphysical values.

### Dependencies

To enable this parameter, set **Area characteristics** type to Different for each flow path.

**A-T maximum orifice area** — Maximum area between ports A and T  
 $1e-4$  m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the orifice between ports **A** and **T** in its fully open position.

#### Dependencies

To enable this parameter, set **Area characteristics** to `Different` for each flow path and **Orifice parameterization** to `Linear - area vs. spool travel`.

**A-T orifice spool travel vector** — Vector of valve opening distances  
`[0, .00125, .0025, .00375, .005] m (default) | 1-by-n vector`

Vector of control member travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **A-T orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Area characteristics** to `Different` for each flow path and **Orifice parameterization** to `Tabulated data - Area vs. spool travel`.

**A-T orifice area vector** — Vector of valve opening areas  
`[1e-10, 1e-05, 4e-05, 8e-05, .0001] m^2 (default) | 1-by-n vector`

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **A-T orifice spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

#### Dependencies

To enable this parameter, set **Area characteristics** to `Different` for each flow path and **Opening parameterization** to `Tabulated data - Area vs. spool travel`.

**A-T orifice spool travel vector, ds** — Vector of valve opening distances  
`[0, .00125, .0025, .00375, .005] m (default) | 1-by-n vector`

Vector of control member travel distances for tabular parametrization of volumetric flow rate. The spool travel vector forms an independent axis with the **A-T orifice pressure drop vector, dp** parameter for the 3-D dependent **A-T orifice volumetric flow rate table, q(ds,dp)** or **Mass flow rate table, mdot(ds,dp)** parameters. A positive displacement corresponds to valve opening. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Area characteristics** to `Identical` for all flow paths and **Orifice parameterization** to `Volumetric flow rate vs. spool travel and pressure drop` or `Tabulated data - Mass flow rate vs. spool travel and pressure drop`.

**A-T orifice pressure drop vector, dp** — Vector of pressure drop values over the valve  
`[-.1, .3, .5, .7] MPa (default) | 1-by-n vector`

Vector of pressure drop values for tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **A-T orifice spool travel vector, s** parameter for the 3-D dependent **A-T orifice volumetric flow rate table, q(ds,dp)** or **Mass flow rate table, mdot(ds,dp)** parameters. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

### Dependencies

To enable this parameter, set **Area characteristics** to `Identical` for all flow paths and **Orifice parameterization** to `Volumetric flow rate vs. spool travel` and pressure drop or `Tabulated data - Mass flow rate vs. spool travel` and pressure drop.

**A-T orifice volumetric flow rate table,  $q(ds,dp)$**  — Vector of volumetric flow rate for tabular parameterization - different flow paths  
 $[-9.05e-10, 1.57e-09, 2.02e-09, 2.39e-09;$   
 $-9.05e-05, .000157, .000202, .000239; -.000362, .000627, .00081, .000958;$   
 $-.000724, .00125, .00162, .00192; -.000905, .00156, .002, .00239]$  m<sup>3</sup>/s  
 (default) | *M*-by-*N* matrix

*M*-by-*N* matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the corresponding vectors:

- *M* is the number of elements in the **A-T orifice pressure drop vector,  $dp$**  parameter.
- *N* is the number of elements in the **A-T orifice spool travel vector,  $s$**  parameter.

### Dependencies

To enable this parameter, set **Area characteristics** to `Different` for each flow path and **Orifice parameterization** to `Tabulated data - Volumetric flow rate vs. spool travel` and pressure drop.

**A-T orifice mass flow rate table,  $\dot{m}(ds,dp)$**  — Vector of mass flow rate for tabular parameterization - different flow paths  
 $1e3 * [-9.05e-10, 1.57e-09, 2.02e-09, 2.39e-09;$   
 $-9.05e-05, .000157, .000202, .000239; -.000362, .000627, .00081, .000958;$   
 $-.000724, .00125, .00162, .00192; -.000905, .00156, .002, .00239]$  kg/s (default)  
 | *M*-by-*N* matrix

*M*-by-*N* matrix of mass flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the corresponding vectors:

- *M* is the number of elements in the **A-T orifice pressure drop vector,  $dp$**  parameter.
- *N* is the number of elements in the **A-T orifice spool travel vector,  $s$**  parameter.

### Dependencies

To enable this parameter, set **Area characteristics** to `Different` for each flow path and **Orifice parameterization** to `Tabulated data - Mass flow rate vs. spool travel` and pressure drop.

### P-T Orifice

**Spool position at maximum P-T orifice area** — Spool offset at maximum area between ports P and T  
 $4.5e-3$  m (default) | scalar

Initial orifice opening distance between ports **P** and **T**. The default represents a underlapped system.

- If the magnitude of **Spool position at maximum orifice area** is less than the value of **Spool travel between closed and open orifice**, the orifice is underlapped, or partially open when the spool position equals 0 m.

- If the magnitude of **Spool position at maximum orifice area** is greater than the value of **Spool travel between closed and open orifice**, the orifice is overlapped. This means the valve remains closed over a range of spool positions.
- If the magnitude of **Spool position at maximum orifice area** is equal to the value of **Spool travel between closed and open orifice**, the orifice is zero-lapped. This means the valve is closed when the spool position equals 0 and begins to open as soon as the spool position changes.

**P-T spool travel between closed and open orifice** — Maximum stroke for the spool between ports P and T

0.005 m (default) | positive scalar

Maximum distance of spool travel for the orifice between ports **P** and **T**. This value provides an upper limit to calculations so that simulations do not return unphysical values.

#### Dependencies

To enable this parameter, set **Area characteristics** type to **Different** for each flow path.

**P-T maximum orifice area** — Maximum area between ports P and T

1e-4 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the orifice between ports **P** and **T** in its fully open position.

#### Dependencies

To enable this parameter, set **Area characteristics** to **Different** for each flow path and **Orifice parameterization** to **Linear - area vs. spool travel**.

**P-T orifice spool travel vector** — Vector of valve opening distances

[0, .00125, .0025, .00375, .005] m (default) | 1-by-n vector

Vector of control member travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **P-T orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Area characteristics** to **Different** for each flow path and **Orifice parameterization** to **Tabulated data - Area vs. spool travel**.

**P-T orifice area vector** — Vector of valve opening areas

[1e-10, 1e-05, 4e-05, 8e-05, .0001] m<sup>2</sup> (default) | 1-by-n vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **P-T orifice spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

#### Dependencies

To enable this parameter, set **Area characteristics** to **Different** for each flow path and **Opening parameterization** to **Tabulated data - Area vs. spool travel**.

**P-T orifice spool travel vector, ds** — Vector of valve opening distances

[0, .00125, .0025, .00375, .005] m (default) | 1-by-n vector

Vector of control member travel distances for tabular parametrization of volumetric flow rate. The spool travel vector forms an independent axis with the **P-T orifice pressure drop vector,  $dp$**  parameter for the 3-D dependent **P-T orifice volumetric flow rate table,  $q(ds,dp)$**  or **Mass flow rate table,  $\dot{m}(ds,dp)$**  parameters. A positive displacement corresponds to valve opening. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Volumetric flow rate vs. spool travel and pressure drop or Tabulated data - Mass flow rate vs. spool travel and pressure drop.

**P-T orifice pressure drop vector,  $dp$**  — Vector of pressure drop values over the valve  
[-.1, .3, .5, .7] MPa (default) | 1-by- $n$  vector

Vector of pressure drop values for tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **P-T orifice spool travel vector,  $ds$**  parameter for the 3-D dependent **P-T orifice volumetric flow rate table,  $q(ds,dp)$**  or **Mass flow rate table,  $\dot{m}(ds,dp)$**  parameters. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Volumetric flow rate vs. spool travel and pressure drop or Tabulated data - Mass flow rate vs. spool travel and pressure drop.

**P-T orifice volumetric flow rate table,  $q(ds,dp)$**  — Vector of volumetric flow rate for tabular parameterization - different flow paths  
[-9.05e-10, 1.57e-09, 2.02e-09, 2.39e-09;  
-9.05e-05, .000157, .000202, .000239; -.000362, .000627, .00081, .000958;  
-.000724, .00125, .00162, .00192; -.000905, .00156, .002, .00239] m<sup>3</sup>/s  
(default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of elements in the **P-T orifice pressure drop vector,  $dp$**  parameter.
- $N$  is the number of elements in the **P-T orifice spool travel vector,  $ds$**  parameter.

#### Dependencies

To enable this parameter, set **Area characteristics** to Different for each flow path and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**P-T orifice mass flow rate table,  $\dot{m}(ds,dp)$**  — Vector of mass flow rate for tabular parameterization - different flow paths  
1e3 \* [-9.05e-10, 1.57e-09, 2.02e-09, 2.39e-09;  
-9.05e-05, .000157, .000202, .000239; -.000362, .000627, .00081, .000958;  
-.000724, .00125, .00162, .00192; -.000905, .00156, .002, .00239] kg/s (default)

$M$ -by- $N$  matrix of mass flow rates based on independent values of pressure drop and spool travel distance.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of elements in the **P-T orifice pressure drop vector,  $dp$**  parameter.
- $N$  is the number of elements in the **P-T orifice spool travel vector,  $ds$**  parameter.

### **Dependencies**

To enable this parameter, set **Area characteristics** to Different for each flow path and **Orifice parameterization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop.

## **Version History**

### **Introduced in R2016a**

### **R2022b: Right-click blocks to view opening characteristic plots**

You can view the plot of the area or volumetric flow rate with respect to spool position for each orifice by right-clicking the block and selecting **Fluids > Plot Valve Characteristics**.

## **Extended Capabilities**

### **C/C++ Code Generation**

Generate C and C++ code using Simulink® Coder™.

## 3-Zone Pipe (2P)

Conduit for the transport of a phase-changing fluid with heat transfer

### Libraries:

Simscape / Fluids / Two-Phase Fluid / Pipes & Fittings

### Description

The 3-Zone Pipe (2P) block models a pipe with a phase-changing fluid. Each fluid phase is called a *zone*, which is a fractional value between 0 and 1. Zones do not mix. The block uses a boundary-following model to track the sub-cooled liquid (L), vapor-liquid mixture (M), and super-heated vapor (V) in three zones. The relative amount of space a zone occupies in the system is called a *zone length fraction* within the system.

Port **H** is a thermal port that represents the environmental temperature. The rate of heat transfer between the fluid and the environment depends on the fluid phase of each zone. The pipe wall is modeled within the block and the pipe wall temperature in each zone may be different. The pressure and temperature are influenced by fluid dynamic compressibility and the fluid zone thermal capacity.

### Heat Transfer Between the Fluid and the Wall

The convective heat transfer coefficient between the fluid and the wall,  $\alpha_F$ , varies per zone according to the Nusselt number:

$$\alpha_F = \frac{Nu k}{D_H}$$

where:

- Nu is the zone Nusselt number.
- k the average fluid thermal conductivity.
- $D_H$  is the pipe **Hydraulic diameter**, the equivalent diameter of a non-circular pipe.

The Nusselt number used in the heat transfer coefficient is the greater of the turbulent- and laminar-flow Nusselt numbers.

For turbulent flows in the subcooled liquid or superheated vapor zones, the Nusselt number is calculated with the Gnielinski correlation:

$$Nu = \frac{\frac{f}{8}(\text{Re} - 1000)\text{Pr}}{1 + 12.7\left(\frac{f}{8}\right)^{1/2}(\text{Pr}^{2/3} - 1)}$$

where:

- Re is the zone average Reynolds number.
- Pr is the zone average Prandtl number.

- $f$  is the Darcy friction factor, calculated from the Haaland correlation:

$$\frac{1}{\sqrt{f}} = -1.8 \log \left[ \left( \frac{\varepsilon}{3.7 D_H} \right)^{1.11} + \frac{6.9}{Re} \right],$$

where  $\varepsilon$  is the wall **Internal surface absolute roughness**.

For turbulent flows in the liquid-vapor mixture zone, the Nusselt number is calculated with the Cavallini-Zecchin correlation:

$$Nu = \frac{a Re_{SL}^b Pr_{SL}^c \left\{ \left[ \left( \sqrt{\frac{\rho_{SL}}{\rho_{SV}}} - 1 \right) x_{Out} + 1 \right]^{1+b} - \left[ \left( \sqrt{\frac{\rho_{SL}}{\rho_{SV}}} - 1 \right) x_{In} + 1 \right]^{1+b} \right\}}{(1+b) \left( \sqrt{\frac{\rho_{SL}}{\rho_{SV}}} - 1 \right) (x_{Out} - x_{In})}.$$

Where:

- $Re_{SL}$  is the Reynolds number of the saturated liquid.
- $Pr_{SL}$  is the Prandtl number of the saturated liquid.
- $\rho_{SL}$  is the density of the saturated liquid.
- $\rho_{SV}$  is the density of the saturated vapor.
- $a = 0.05$ ,  $b = 0.8$ , and  $c = 0.33$ .

When fins are modeled on the pipe internal surface, the heat transfer coefficient is:

$$\alpha_F = \frac{Nu k}{D_H} (1 + \eta_{Int} s_{Int}),$$

where:

- $\eta_{Int}$  is the **Internal fin efficiency**.
- $s_{Int}$  is the **Ratio of internal fins surface area to no-fin surface area**.

For laminar flows, the Nusselt number is set by the **Laminar flow Nusselt number** parameter.

#### Empirical Nusselt Number Formulation

When the **Heat transfer coefficient model** parameter is Colburn equation, the block calculates the Nusselt number for the subcooled liquid and superheated vapor zones by using the empirical Colburn equation

$$Nu = a Re^b Pr^c,$$

where  $a$ ,  $b$ , and  $c$  are values in the **Coefficients [a, b, c] for  $a \cdot Re^b \cdot Pr^c$  in liquid zone** and **Coefficients [a, b, c] for  $a \cdot Re^b \cdot Pr^c$  in vapor zone** parameters.

The block calculates the Nusselt number for liquid-vapor mixture zones by using the Cavallini-Zecchin equation with the variables in the **Coefficients [a, b, c] for  $a \cdot Re^b \cdot Pr^c$  in mixture zone** parameter.

#### Specific Enthalpy

The heat transfer rate from the fluid is based on the change in specific enthalpy in each zone:

$$Q = \dot{m}_Q(\Delta h_L + \Delta h_M + \Delta h_V),$$

where  $\dot{m}_Q$  is the mass flow rate for heat transfer. It is the pipe inlet mass flow rate, either  $\dot{m}_A$  or  $\dot{m}_B$ , depending on the direction of fluid flow.

In the liquid and vapor zones, the change in specific enthalpy is defined as:

$$\Delta h = c_p(T_H - T_I) \left[ 1 - \exp\left(-\frac{zS_W}{\dot{m}_Q c_p (\alpha_F^{-1} + \alpha_E^{-1})}\right) \right],$$

where:

- $c_p$  is the specific heat of the liquid or vapor.
- $T_H$  is the environmental temperature.
- $T_I$  is the liquid inlet temperature.
- $z$  is the fluid zone length fraction.
- $\alpha_E$  is the heat transfer coefficient between the wall and the environment.
- $S_W$  is wall surface area:

$$S_W = \frac{4A}{D_H}L,$$

where:

- $A$  is the pipe **Cross-sectional area**.
- $L$  is the **Pipe length**.

Note that this wall surface area does not include fin area, which is defined in the **Ratio of external fins surface area to no-fin surface area** and **Ratio of internal fins surface area to no-fin surface area** parameters. Fins are set in proportion to the wall surface area. A value of 0 means there are no fins on the pipe wall.

In the liquid-vapor mixture zone, the change in specific enthalpy is calculated as:

$$\Delta h = (T_H - T_S) \frac{zS_W}{\dot{m}_Q (\alpha_F^{-1} + \alpha_E^{-1})},$$

where  $T_S$  is the fluid saturation temperature. It is assumed that the liquid-vapor mixture is always at this temperature.

### Heat Transfer Rate

The total heat transfer between the fluid and the pipe wall is the sum of the heat transfer in each fluid phase:

$$Q_F = Q_{F,L} + Q_{F,V} + Q_{F,M}.$$

The heat transfer rate between the fluid and the pipe in the liquid zone is:

$$Q_{F,L} = \dot{m}_Q c_{p,L} [T_{W,L} - \min(T_I, T_S)] \left[ 1 - \exp\left(-\frac{z_L S_W \alpha_L}{\dot{m}_Q c_{p,L}}\right) \right].$$

where  $T_{WL}$  is the temperature of the wall surrounding the liquid zone.

The heat transfer rate between the fluid and the pipe in the mixture zone is:

$$Q_{F,M} = (T_H - T_{\text{Sat}})z_M S_W \alpha_M.$$

The heat transfer rate between the fluid and the pipe in the vapor zone is:

$$Q_{F,V} = \dot{m}_Q c_{p,V} [T_{W,V} - \min(T_L, T_{\text{Sat}})] \left[ 1 - \exp\left(-\frac{z_V S_W \alpha_V}{\dot{m}_Q c_{p,V}}\right) \right],$$

where  $T_{W,V}$  is the temperature of the wall surrounding the vapor zone.

### Heat Transfer Between the Wall and the Environment

If the pipe wall has a finite thickness, the heat transfer coefficient between the wall and the environment,  $\alpha_E$ , is defined by:

$$\frac{1}{\alpha_E} = \frac{1}{\alpha_W} + \frac{1}{\alpha_{\text{Ext}}(1 + \eta_{\text{Ext}} s_{\text{Ext}})},$$

where  $\alpha_W$  is the heat transfer coefficient due to conduction through the wall:

$$\alpha_W = \frac{k_W}{D_H \ln\left(1 + \frac{t_W}{D_H}\right)},$$

and where:

- $k_W$  is the **Wall thermal conductivity**.
- $t_W$  is the **Wall thickness**.
- $\alpha_{\text{Ext}}$  is the **External environment heat transfer coefficient**.
- $\eta_{\text{Ext}}$  is the **External fin efficiency**.
- $s_{\text{Ext}}$  is the **Ratio of external fins surface area to no-fin surface area**.

If the wall does not have thermal mass, the heat transfer coefficient between the wall and environment equals the heat transfer coefficient of the environment,  $\alpha_{\text{Ext}}$ .

### Heat Transfer Rate

The heat transfer rate between each wall zone and the environment is:

$$Q_{H,\text{zone}} = (T_H - T_W)z S_W \alpha_E.$$

The total heat transfer between the wall and the environment is:

$$Q_H = Q_{H,L} + Q_{H,V} + Q_{H,M}.$$

### Governing Differential Equations

The heat transfer rate depends on the thermal mass of the wall,  $C_W$ :

$$C_W = c_{p,W} \rho_W S_W \left( t_W + \frac{t_W^2}{D_H} \right),$$

where:

- $c_{p,W}$  is the **Wall specific heat**.
- $\rho_W$  is the **Wall density**.

The governing equations for heat transfer between the fluid and the external environment are, for the liquid zone:

$$Q_{H,L} - Q_{F,L} = C_W \left[ z_L \frac{dT_{W,L}}{dt} + \max\left(\frac{dz_L}{dt}, 0\right) (T_{W,L} - T_{W,M}) \right],$$

for the mixture zone:

$$Q_{H,M} - Q_{F,M} = C_W \left[ z_M \frac{dT_{W,M}}{dt} + \min\left(\frac{dz_L}{dt}, 0\right) (T_{W,L} - T_{W,M}) + \min\left(\frac{dz_V}{dt}, 0\right) (T_{W,V} - T_{W,M}) \right],$$

and for the vapor zone:

$$Q_{H,V} - Q_{F,V} = C_W \left[ z_V \frac{dT_{W,V}}{dt} + \max\left(\frac{dz_V}{dt}, 0\right) (T_{W,V} - T_{W,M}) \right].$$

### Momentum Balance

The pressure differential over the pipe consists of two factors: changes in pressure due to changes in density, and changes in pressure due to friction at the pipe walls.

For turbulent flows, when the Reynolds number is above the **Turbulent flow lower Reynolds number limit**, pressure loss is calculated in terms of the Darcy friction factor. The pressure differential between port **A** and the internal node I is:

$$p_A - p_I = \left( \frac{1}{\rho_I} - \frac{1}{\rho_A^*} \right) \left( \frac{\dot{m}_A}{S} \right)^2 + \frac{f_A \dot{m}_A |\dot{m}_A| (L + L_{Add})}{2 \rho_I D_H S^2},$$

where:

- $\rho_I$  is the fluid density at internal node I.
- $\rho_A^*$  is the fluid density at port **A**. This is the same as  $\rho_A$  when the flow is steady-state; when the flow is transient, it is calculated from the fluid internal state with the adiabatic expression:

$$u_A^* + \frac{p_A}{\rho_A^*} + \frac{1}{2} \left( \frac{\dot{m}_A}{\rho_A^* S} \right)^2 = h + \frac{1}{2} \left( \frac{\dot{m}_A}{\rho S} \right)^2,$$

where:

- $h$  is the average specific enthalpy,  $h = h_L z_L + h_V z_V + h_M z_M$ .
- $\rho$  is the average density,  $\rho = \rho_L z_L + \rho_M z_M + \rho_V z_V$ .

This is due to the fact that heat transfer calculation takes place at the internal node I.

- $\dot{m}_A$  is the mass flow rate through port **A**.
- $L$  is the **Pipe length**.
- $L_{Add}$  is the **Aggregate equivalent length of local resistances**, which is the equivalent length of a tube that introduces the same amount of loss as the sum of the losses due to other local resistances.

Note that the Darcy friction factor is dependent on the Reynolds number, and is calculated at both ports.

The pressure differential between port **B** and internal node I is:

$$p_B - p_I = \left( \frac{1}{\rho_I} - \frac{1}{\rho_B^*} \right) \left( \frac{\dot{m}_B}{S} \right)^2 + \frac{f_B \dot{m}_B |\dot{m}_B| (L + L_{Add})}{2\rho_I D_H S^2}.$$

where:

- $\rho_B^*$  is the fluid density at port **B**. This is the same as  $\rho_B$  when the flow is steady-state; when the flow is transient, it is calculated from the fluid internal state with the adiabatic expression:

$$u_B^* + \frac{p_B}{\rho_B^*} + \frac{1}{2} \left( \frac{\dot{m}_B}{\rho_B^* S} \right)^2 = h + \frac{1}{2} \left( \frac{\dot{m}_B}{\rho S} \right)^2.$$

- $\dot{m}_B$  is the mass flow rate through port **B**.

For laminar flows, when the Reynolds number is below the **Laminar flow upper Reynolds number limit**, the pressure loss due to friction is calculated in terms of the **Laminar friction constant for Darcy friction factor**,  $\lambda$ . The pressure differential between port **A** and internal node I is:

$$p_A - p_I = \left( \frac{1}{\rho_I} - \frac{1}{\rho_A^*} \right) \left( \frac{\dot{m}_A}{S} \right)^2 + \frac{\lambda \mu \dot{m}_A (L + L_{Add})}{2\rho_I D_H^2 S},$$

where  $\mu$  is the average fluid dynamic viscosity:

$$\mu = \mu_L z_L + \mu_M z_M + \mu_V z_V.$$

The pressure differential between port **B** and internal node I is:

$$p_B - p_I = \left( \frac{1}{\rho_I} - \frac{1}{\rho_B^*} \right) \left( \frac{\dot{m}_B}{S} \right)^2 + \frac{\lambda \mu \dot{m}_B (L + L_{Add})}{2\rho_I D_H^2 S}.$$

For transitional flows, the pressure differential due to viscous friction is a smoothed blend between the values for laminar and turbulent pressure losses.

### Mass Balance

The total mass accumulation rate is defined as:

$$\frac{dM}{dt} = \dot{m}_A + \dot{m}_B,$$

where  $M$  is the total fluid mass in the pipe. In terms of fluid zones, the mass accumulation rate is a function of the change in density,  $\rho$ , with respect to pressure,  $p$ , and the fluid specific internal energy,  $u$ :

$$\frac{dM}{dt} = \left[ \left( \frac{\partial \rho}{\partial p} \right)_u \frac{dp}{dt} + \left( \frac{\partial \rho}{\partial u} \right)_p \frac{du_{out}}{dt} + \rho_L \frac{dz_L}{dt} + \rho_M \frac{dz_M}{dt} + \rho_V \frac{dz_V}{dt} \right] V,$$

where:

- $u_{out}$  is the specific internal energy after all heat transfer has occurred.
- $V$  is the total fluid volume, or the volume of the pipe.

### Energy Balance

The energy conservation equation is:

$$M \frac{du_{out}}{dt} + (\dot{m}_A + \dot{m}_B)u_{out} = \phi_A + \phi_B + Q_F,$$

where:

- $\phi_A$  is the energy flow rate at port **A**.
- $\phi_B$  is the energy flow rate at port **B**.
- $Q_F$  is the heat transfer rate between the fluid and the wall.

### Assumptions and Limitations

- The pipe wall is perfectly rigid.
- The flow is fully developed. Friction losses and heat transfer do not include entrance effects.
- Fluid inertia is negligible.
- The effect of gravity is negligible.
- When the pressure is above the fluid critical pressure, large values of thermal fluid properties (such as Prandtl number, thermal conductivity, and specific heat) may not accurately reflect the heat exchange in the pipe.

## Ports

### Output

**Z** — Zone length fractions  
physical signal

Vector with the length fractions of the liquid, mixed-phase, and vapor zones in the pipe.

### Conserving

**A** — Pipe opening  
two-phase fluid

Opening through which the two-phase fluid flows into or out of the pipe. Ports **A** and **B** can each function as either inlet or outlet. Thermal conduction is allowed between the two-phase fluid ports and the fluid internal to the pipe (though its impact is typically relevant only at near zero flow rates).

**B** — Pipe opening  
two-phase fluid

Opening through which the two-phase fluid flows into or out of the pipe. Ports **A** and **B** can each function as either inlet or outlet. Thermal conduction is allowed between the two-phase fluid ports and the fluid internal to the pipe (though its impact is typically relevant only at near zero flow rates).

**H** — Pipe wall  
thermal

Thermal boundary condition at the outer surface of the pipe wall. Use this port to capture heat exchange of various kinds—for example, conductive, convective, or radiative—between the pipe wall and the environment. Heat exchange between the inner surface of the wall and the fluid is captured directly in the block.

## Parameters

### Geometry

**Pipe length** — Distance between the ports of the pipe  
5 m (default) | positive scalar with units of length

Distance between the ports of the pipe. The liquid, two-phase, and vapor zones each comprise a fraction of this distance. The zone fractions can vary but their aggregate length, being the same as the distance of the pipe, is fixed.

**Cross-sectional area** — Internal area normal to the direction of the flow  
0.01 m<sup>2</sup> (default) | positive scalar with units of area

Internal area of the pipe normal to the direction of flow. The cross section of the pipe is assumed to be constant throughout its length.

**Hydraulic diameter** — Diameter of a cylindrical pipe with the given cross-sectional area  
0.1 m (default) | positive scalar in units of length

Ratio of the opening area of a cross section of the pipe to the perimeter of that area. The pipe is not required to be cylindrical, and its cross-section have any shape. This parameter gives the diameter that a general cross section would have if it were circular.

### Viscous Friction

**Aggregate equivalent length of local resistances** — Minor pressure loss in the pipe expressed as a length  
1 m (default) | positive scalar in units of length

Combined length of all local resistances present in the pipe. Local resistances include bends, fittings, armatures, and pipe inlets and outlets. The effect of the local resistances is to increase the effective length of the pipe. This length is added to the geometrical pipe length for friction calculations.

**Internal surface absolute roughness** — Average depth of surface defects on the internal surface of the pipe  
15e-6 m (default) | positive scalar in units of length

Average depth of all surface defects on the internal surface of the pipe. The surface defects affect the pressure loss across the pipe in the turbulent flow regime.

**Laminar flow upper Reynolds number limit** — Reynolds number below which the flow is laminar  
2e+3 (default) | positive unitless scalar

Reynolds number above which the pipe flow begins to transition from laminar to turbulent. This value is the maximum Reynolds number corresponding to fully developed laminar flow.

**Turbulent flow lower Reynolds number limit** — Reynolds number above which the flow is turbulent  
4e+3 (default) | positive unitless scalar

Reynolds number below which the pipe flow begins to transition from turbulent to laminar. This value is the minimum Reynolds number corresponding to fully developed turbulent flow.

**Shape factor for laminar flow viscous friction** — Dimensionless factor used to capture the effect of geometry on viscous friction losses

64 (default) | positive unitless scalar

Dimensionless factor used to capture the effects of cross-sectional geometry on the viscous friction losses incurred in the laminar flow regime. Typical values are 64 for a circular cross section, 57 for a square cross section, and 62 for a rectangular cross section with an aspect ratio of 2.

### Heat Transfer

**External environment heat transfer coefficient** — Heat transfer coefficient between the environment and the pipe wall

100 W/(m<sup>2</sup>\*K) (default) | positive scalar with units of power/(area\*temperature)

Heat transfer coefficient for heat exchange between the environment (at port **H**) and the outer surface of the pipe wall. If this parameter is set to `inf`, then the thermal resistance between the environment and the wall is assumed to be zero. The pipe wall then has a uniform temperature equal to that associated with port **H**.

**Wall thickness** — Average thickness of the pipe wall material

0 m (default) | positive scalar with units of length

Average thickness of the pipe wall material. If this value is set to 0, then both thermal resistance due to conduction through the pipe wall and thermal storage due to the thermal mass of the pipe wall are assumed to be negligible.

**Wall thermal conductivity** — Thermal conductivity of the pipe wall material

390 W/(m\*K) (default) | positive scalar with units of power/(length\*temperature)

Thermal conductivity of the pipe wall material. If this parameter is set to `inf`, then thermal resistance due to conduction through the pipe wall is assumed to be negligible.

**Wall specific heat** — Heat capacity per unit mass of pipe wall material

390 J/kg/K (default) | positive scalar with units of energy/(mass\*temperature)

Heat capacity per unit mass of the pipe wall material. If this parameter is set to 0, then thermal storage due to the thermal mass of the pipe is assumed to be negligible.

**Wall density** — Mass density of the pipe wall material

9e3 kg/m<sup>3</sup> (default) | positive scalar with units of mass/volume

Mass density of the pipe wall material. If this parameter is set to 0, then thermal storage due to the thermal mass of the pipe wall is assumed to be negligible.

**Ratio of external fins surface area to no-fin surface area** — Ratio of heat transfer surface area with external fins to that without

0 (default) | positive unitless scalar

Ratio of the total heat transfer surface area of the fins on the external side of the pipe wall to that of the pipe wall without any fins. The presence of fins serves to enhance the convective heat transfer between the pipe wall and the environment.

**External fin efficiency** — Ratio of actual to ideal heat exchange rates with external fins

0.5 (default) | positive unitless scalar

Ratio of the actual heat exchange rate between the external fins and the environment to its ideal value (if the fins were entirely held at the temperature of the pipe wall). This parameter is a function of fin geometry.

**Ratio of internal fins surface area to no-fin surface area** — Ratio of heat transfer surface area with internal fins to that without

0 (default) | positive unitless scalar

Ratio of the total heat transfer surface area of the fins on the internal side of the pipe wall to that of the pipe wall without any fins. The presence of fins serves to enhance the convective heat transfer between the pipe wall and the fluid.

**Internal fin efficiency** — Ratio of actual to ideal heat exchange rates with internal fins

0.5 (default) | positive unitless scalar

Ratio of the actual heat exchange rate between the internal fins and the environment to its ideal value (if the fins were entirely held at the temperature of the pipe wall). This parameter is a function of fin geometry.

**Heat transfer coefficient model** — Method of calculating heat transfer coefficient between fluid and wall

Correlation for flow inside tubes (default) | Colburn equation

Method of calculating the heat transfer coefficient between the fluid and the wall. The available settings are:

- **Colburn equation.** Use this setting to calculate the heat transfer coefficient with user-defined variables  $a$ ,  $b$ , and  $c$ . In the liquid and vapor zones, the heat transfer coefficient is based on the Colburn equation. In the liquid-vapor mixture zone, the heat transfer coefficient is based on the Cavallini-Zecchin equation.
- **Correlation for flow inside tubes.** Use this setting to calculate the heat transfer coefficient for pipe flows. In the liquid and vapor zones, the heat transfer coefficient is calculated with the Gnielinski correlation. In the liquid-vapor mixture zone, the heat transfer coefficient is calculated with the Cavallini-Zecchin equation.

**Coefficients [a, b, c] for  $a \cdot Re^b \cdot Pr^c$  in liquid zone** — Colburn equation coefficients in liquid zone

[.023, .8, .33] (default) | three-element vector of positive scalars

Three-element vector that contains the empirical coefficients of the Colburn equation. Each fluid zone has a distinct Nusselt number, which the block calculates by using the Colburn equation for each zone. The general form of the Colburn equation is:

$$Nu = aRe^bPr^c.$$

#### Dependencies

To enable this parameter, set **Heat transfer coefficient model** to Colburn equation.

**Coefficients [a, b, c] for  $a \cdot Re^b \cdot Pr^c$  in mixture zone** — Cavallini-Zecchin equation coefficients in mixture zone

[.05, .8, .33] (default) | three-element vector of positive scalars

Three-element vector that contains the empirical coefficients for the Cavallini-Zecchin equation. Each fluid zone has a distinct Nusselt number, which the block calculates in the mixture zone by using the Cavallini-Zecchin equation:

$$\text{Nu} = \frac{a \text{Re}_{\text{SL}}^b \text{Pr}_{\text{SL}}^c \left\{ \left[ \left( \sqrt{\frac{\rho_{\text{SL}}}{\rho_{\text{SV}}}} - 1 \right) x_{\text{Out}} + 1 \right]^{1+b} - \left[ \left( \sqrt{\frac{\rho_{\text{SL}}}{\rho_{\text{SV}}}} - 1 \right) x_{\text{In}} + 1 \right]^{1+b} \right\}}{(1+b) \left( \sqrt{\frac{\rho_{\text{SL}}}{\rho_{\text{SV}}}} - 1 \right) (x_{\text{Out}} - x_{\text{In}})}$$

#### Dependencies

To enable this parameter, set **Heat transfer coefficient model** to Colburn equation.

**Coefficients [a, b, c] for  $a \cdot \text{Re}^b \cdot \text{Pr}^c$  in vapor zone** — Colburn equation coefficients in vapor zone

[.023, .8, .33] (default) | three-element vector of positive scalars

Three-element vector that contains the empirical coefficients of the Colburn equation. Each fluid zone has a distinct Nusselt number, which the block calculates by using the Colburn equation for each zone. The general form of the Colburn equation is:

$$\text{Nu} = a \text{Re}^b \text{Pr}^c.$$

#### Dependencies

To enable this parameter, set **Heat transfer coefficient model** to Colburn equation.

**Nusselt number for laminar flow heat transfer** — Ratio of convective to conductive heat exchange rates in the laminar flow regime

3.66 (default)

Ratio of convective to conductive heat exchange rates in the laminar flow regime. This parameter is a function of pipe cross section geometry. Typical values are 3.66 for a circular cross section, 2.98 for a square cross section, and 3.39 for a rectangular cross section with an aspect ratio of 2.

#### Effects and Initial Conditions Tab

**Initial fluid energy specification** — Thermodynamic variable whose initial value to set  
Temperature (default) | Vapor quality | Vapor void fraction | Specific enthalpy |  
Specific internal energy

Thermodynamic variable in terms of which to define the initial conditions of the component.

The value for **Initial fluid energy specification** limits the available initial states for the two-phase fluid. When **Initial fluid energy specification** is:

- **Temperature** — Specify an initial state that is a subcooled liquid or superheated vapor. You cannot specify a liquid-vapor mixture because the temperature is constant across the liquid-vapor mixture region.
- **Vapor quality** — Specify an initial state that is a liquid-vapor mixture. You cannot specify a subcooled liquid or a superheated vapor because the liquid mass fraction is 0 and 1, respectively, across the whole region. Additionally, the block limits the pressure to below the critical pressure.
- **Vapor void fraction** — Specify an initial state that is a liquid-vapor mixture. You cannot specify a subcooled liquid or a superheated vapor because the liquid mass fraction is 0 and 1,

respectively, across the whole region. Additionally, the block limits the pressure to below the critical pressure.

- **Specific enthalpy** — Specify the specific enthalpy of the fluid. The block does not limit the initial state.
- **Specific internal energy** — Specify the specific internal energy of the fluid. The block does not limit the initial state.

**Initial pressure** — Absolute pressure at the start of simulation

0.101325 MPa (default) | scalar with units of pressure

Pressure in the pipe at the start of simulation, specified against absolute zero.

**Initial temperature** — Absolute temperature at the start of simulation

293.15 K (default) | scalar or two-element vector with units of temperature

Fluid temperature in the pipe at the start of simulation. This parameter can be a scalar or a 2-element vector. If it is a scalar, the initial temperature is assumed to be uniform throughout the pipe. If it is a vector, the initial temperature is assumed to vary linearly between the ports. The first vector element gives the initial temperature at the inlet and the second vector element that at the outlet.

#### Dependencies

This parameter is active when the **Initial fluid energy specification** option is set to Temperature.

**Initial vapor quality** — Mass fraction of vapor at the start of simulation

0.5 (default) | unitless scalar between 0 and 1

Vapor quality, or mass fraction of vapor, in the pipe at the start of simulation. This parameter can be a scalar or a 2-element vector. If it is a scalar, the initial vapor quality is assumed to be uniform throughout the pipe. If it is a vector, the initial vapor quality is assumed to vary linearly between the ports. The first vector element gives the initial vapor quality at the inlet and the second vector element that at the outlet.

#### Dependencies

This parameter is active when the **Initial fluid energy specification** option is set to Vapor quality.

**Initial vapor void fraction** — Volume fraction of vapor at the start of simulation

0.5 (default) | unitless scalar between 0 and 1

Vapor void fraction, or vapor volume fraction, in the pipe at the start of simulation. This parameter can be a scalar or a 2-element vector. If it is a scalar, the initial vapor void fraction is assumed to be uniform throughout the pipe. If it is a vector, the initial vapor void fraction is assumed to vary linearly between the ports. The first vector element gives the initial vapor void fraction at the inlet and the second vector element that at the outlet..

#### Dependencies

This parameter is active when the **Initial fluid energy specification** option is set to Vapor void fraction.

**Initial specific enthalpy** — Specific enthalpy at the start of simulation

1500 kJ/kg (default) | scalar with units of energy/mass

Specific enthalpy of the fluid in the pipe at the start of simulation. This parameter can be a scalar or a 2-element vector. If it is a scalar, the initial specific enthalpy is assumed to be uniform throughout the pipe. If it is a vector, the initial specific enthalpy is assumed to vary linearly between the ports. The first vector element gives the initial specific enthalpy at the inlet and the second vector element that at the outlet.

### Dependencies

This parameter is active when the **Initial fluid energy specification** option is set to **Specific enthalpy**.

**Initial specific internal energy** — Specific internal energy at the start of simulation  
1500 kJ/kg (default) | scalar with units of energy/mass

Specific internal energy of the fluid in the pipe at the start of simulation. This parameter can be a scalar or a 2-element vector. If it is a scalar, the initial specific internal energy is assumed to be uniform throughout the pipe. If it is a vector, the initial specific internal energy is assumed to vary linearly between the ports. The first vector element gives the initial specific internal energy at the inlet and the second vector element that at the outlet.

### Dependencies

This parameter is active when the **Initial fluid energy specification** option is set to **Specific internal energy**.

## Version History

Introduced in R2018b

### R2022b: Parameterize using a new heat transfer coefficient model

The 3-Zone Pipe (2P) block now allows you to more explicitly control the heat transfer process. You can set the new **Heat transfer coefficient model** parameter to:

- **Correlation for flow inside tubes** — The Gnielinski correlation predicts heat transfer of turbulent flows in subcooled liquid or superheated vapor zones, and the Cavallini-Zecchin correlation predicts the heat transfer of turbulent flows in the liquid-vapor mixture zone. The block predefines the coefficients  $a$ ,  $b$ , and  $c$ . This is how the block operates in previous releases.
- **Colburn equation** — The block allows you to define the coefficients  $a$ ,  $b$ , and  $c$  for each flow zone by using the **Coefficients [a, b, c] for  $a \cdot \text{Re}^b \cdot \text{Pr}^c$  in liquid zone**, **Coefficients [a, b, c] for  $a \cdot \text{Re}^b \cdot \text{Pr}^c$  in mixture zone**, and **Coefficients [a, b, c] for  $a \cdot \text{Re}^b \cdot \text{Pr}^c$  in vapor zone** parameters. You specify these parameters as three-element vectors where the first element is  $a$ , the second is  $b$ , and the third is  $c$ .

(To be removed) Four-port three-position directional control valve

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

### Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Valves / Directional Valves

### Description

The 4-Way Directional Valve block represents a directional control valve with four ports and three positions, or flow paths. The ports connect to what in a typical model are a hydraulic pump (port **P**), a storage tank (port **T**), and a double-acting actuator (ports **A** and **B**). Fluid can flow from the pump to the actuator via path **P-A** or **P-B** and from the actuator to the tank via path **A-T** or **B-T**—depending on the working side of the actuator.

### Typical Valve Setup

In the default configuration, one valve position corresponds to the **P-A** and **B-T** flow paths maximally open and the **P-B** and **A-T** flow paths maximally closed (position **I** in the figure). Another valve position corresponds to the inverse configuration, with **P-B** and **A-T** maximally open and **P-A** and **B-T** maximally closed (position **II**). The third valve position corresponds to all flow paths maximally closed (position **III**). A translating spool serves as the valve control member and determines the position that the valve is in—**I**, **II**, **III**, or in between.

I.

II.

III.

### Valve Positions

Physical signal port **S** controls the spool displacement. In the default configuration, a zero displacement signal corresponds to valve position **III**. A positive displacement signal shifts the spool toward valve position **I**. A negative displacement shifts the spool toward valve position **II**. The spool displacement acts indirectly by setting the spool position relative to each flow path—a length known here as the *orifice opening*. The orifice opening in turn determines the opening area of the respective flow path.

### Orifice Openings

The orifice opening of a flow path depends partly on its *opening offset*—the orifice opening of a flow path at zero spool displacement. The block models only the effects of the opening offsets. An offset can be due to a change in distance between ports or spool lands—the thick disks built into the spool

to obstruct flow. It can also be due to a change in the thicknesses of the spool lands. The orifice openings are computed separately for each flow path in terms of the respective opening offset:

$$h_{PA} = h_{PA0} + x$$

$$h_{PB} = h_{PB0} - x$$

$$h_{AT} = h_{AT0} - x$$

$$h_{BT} = h_{BT0} + x$$

where:

- $h_{PA}$ ,  $h_{PB}$ ,  $h_{AT}$ , and  $h_{BT}$  are the orifice openings of the **P-A**, **P-B**, **A-T**, and **P-B** flow paths. The orifice openings are computed during simulation.
- $h_{PA0}$ ,  $h_{PB0}$ ,  $h_{AT0}$ , and  $h_{BT0}$  are the orifice opening offsets of the **P-A**, **P-B**, **A-T**, and **P-B** flow paths. The opening offsets are specified in the **Valve opening offsets** tab.
- $x$  is the spool displacement relative to what in the zero-offset case is a fully closed valve. The spool displacement is specified through physical signal port **S**.

The figure shows the effects of the opening offsets on the orifice openings. Plot **I** corresponds to the default configuration with both opening offsets equal to zero. Plot **II** corresponds to a valve with both opening offsets greater than zero and plot **III** to a valve with both opening offsets smaller than zero. These cases are similar in behavior to zero-lapped (**I**), underlapped (**II**) and overlapped (**III**) valves. The valve schematics to the right show what the offset might look like. The circle highlights the offset in path **P-B**.

### Zero (I), Positive (II), and Negative (III) Opening Offsets

An underlapped valve is always partially open and allows some flow at all spool displacements. An overlapped valve is fully closed over an extended range of spool displacements and requires longer spool travel to open. The table summarizes the opening offsets for zero-lapped, underlapped, and overlapped valves. Other configurations are possible—e.g., with one opening offset positive and the other negative.

Valve Lapping	Opening Offsets
Zero-lapped (default)	All zero
Underlapped	All positive
Overlapped	All negative

### Opening Areas

The **Model parameterization** setting determines the calculations used for the opening areas of the flow paths—or, in the Pressure-flow characteristic case, the volumetric flow rates. The calculations are based on orifice parameters or tabulated data sets specified in the **Model Parameterization** tab. The block uses the same data for all flow paths if the **Area characteristics** parameter in the **Basic Parameters** tab is set to **Identical** for all flow paths and different data otherwise. Model parameterizations that you can select include:

- **Maximum area and opening** — Specify the maximum opening area and the corresponding orifice opening. The opening area is a linear function of the orifice opening,

$$A_{AT} = \frac{A_{AT,Max}}{h_{AT,Max}} h_{AT} + A_{Leak}$$

where  $A$  is the opening area and  $h$  the orifice opening of a given flow path. The subscript **Max** refers to a fully open orifice and the subscript **Leak** to a fully closed orifice—one with internal leakage flow area only. The figure shows a plot of the linear function  $A(h)$ .

- **Area vs. opening table** — Specify the opening area at discrete orifice openings as a 1-D lookup table. The opening area is computed for a given orifice opening by interpolation or extrapolation of the tabulated data. The figure shows a conceptual plot of the tabulated function  $A(h)$ .

- **Pressure-flow characteristic** — Specify the volumetric flow rate at discrete orifice openings and pressure differentials as a 2-D lookup table. The opening area is computed for a given orifice opening and pressure differential by interpolation or extrapolation of the tabulated data. The figure shows a conceptual plot of the tabulated function  $q(h, p)$ .

### Flow Regime and Internal Leakage

Volumetric flow rates are computed analytically in the **Maximum area and opening** and **Area vs. opening table** parameterizations. The calculations are based on additional block parameters such as the flow discharge coefficient and account for the effects of flow regime—laminar or turbulent. Regime transition occurs at the specified critical laminar flow ratio or critical Reynolds number.

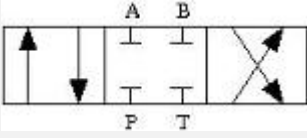

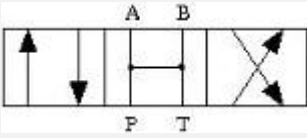

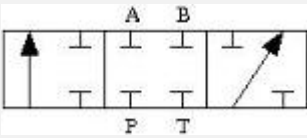

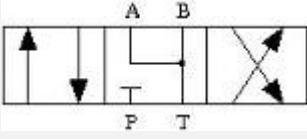

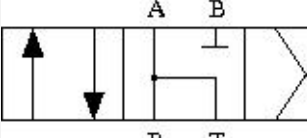

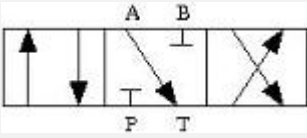

The **Maximum area and opening** and **Area vs. opening table** parameterizations also account for a small internal leakage area even in the fully closed state. The leakage area ensures that portions of the hydraulic network do not become isolated when a flow path is closed. Isolated, or “hanging”, network portions affect the computational efficiency of the model and can cause simulation to fail.

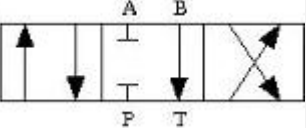

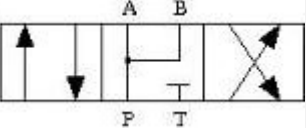

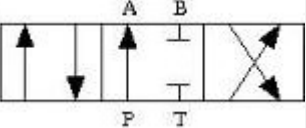

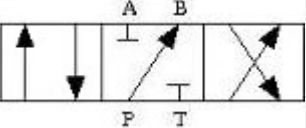

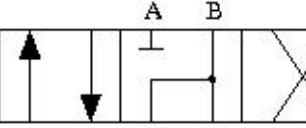

The effects of flow regime and internal leakage are assumed to be reflected in the tabulated flow rate data specified directly in the Pressure-flow characteristic parameterization.

### **Valve Configurations**

The opening offsets are by default zero. This configuration corresponds to a valve with all flow paths closed in the neutral position (**III** in the “Valve Positions” on page 1-117 schematic). Many other configurations exist. You can model a specific configuration by setting the opening offsets as shown in the table. All opening offset parameters are in the **Valve opening offsets** tab of the block property inspector

The 4-Way Directional Valve Configurations

No	Configuration	Initial Openings
1		<p>All four orifices are overlapped in neutral position:</p> <ul style="list-style-type: none"> <li>• <b>Orifice P-A initial opening</b> &lt; 0</li> <li>• <b>Orifice P-B initial opening</b> &lt; 0</li> <li>• <b>Orifice A-T initial opening</b> &lt; 0</li> <li>• <b>Orifice B-T initial opening</b> &lt; 0</li> </ul>

### Structural Component Diagram

The block is a composite component with four Variable Orifice blocks driven by a single physical signal. Blocks Variable Orifice P-A and Variable Orifice P-B represent the **P-A** and **P-B** flow paths. Blocks Variable orifice A-T and Variable orifice B-T represent the **A-T** and **B-T** flow paths. The physical signal is specified through Connection Port block **S**.

The **Orifice orientation** block parameters are set so that a positive signal acts to open Variable Orifice P-A and Variable Orifice B-T while closing Variable Orifice A-T and Variable Orifice P-B. A negative signal has the opposite effect—acting to open Variable Orifice A-T

and Variable Orifice P-B while closing Variable Orifice P-A and Variable Orifice B-T.

### Valve Structural Diagram

#### Assumptions

- Fluid inertia is ignored.
- Control member loading due to inertial, spring, and other forces is ignored.
- All valve orifices are assumed identical in size unless otherwise specified.

### Ports

#### Input

**S** — Control member displacement, m  
physical signal

Physical signal input port for the control member displacement.

#### Conserving

**P** — Pressure supply connection port  
hydraulic (isothermal liquid)

Hydraulic (isothermal liquid) conserving port associated with the pressure supply line inlet.

**T** — Return line connection port  
hydraulic (isothermal liquid)

Hydraulic (isothermal liquid) conserving port associated with the return line connection.

**A** — Actuator connection port  
hydraulic (isothermal liquid)

Hydraulic (isothermal liquid) conserving port associated with the actuator connection port.

**B** — Actuator connection port  
hydraulic (isothermal liquid)

Hydraulic (isothermal liquid) conserving port associated with the actuator connection port.

## Parameters

### Basic Parameters

**Area characteristics** — Symmetry of the flow path opening characteristics

Identical for all flow paths (default) | Different for each flow path

Choice of different or identical flow path opening characteristics. Select **Different for each flow path** to specify flow path parameters or tabulated data separately for each flow path.

**Model parameterization** — Types of valve parameters to use as input

Maximum area and opening (default) | Area vs. opening table | Pressure-flow characteristic

Parameterization of the valve model. Options include:

- **By maximum area and opening** — Specify the maximum orifice opening and opening area. The opening area varies linearly with the spool displacement specified at physical signal port **S**.
- **By area vs. opening table** — Specify the flow path opening area at discrete orifice openings as a 1-D lookup table. The opening area is computed by interpolation or extrapolation of the tabulated data.
- **By pressure-flow characteristic** — Specify the flow path volumetric flow rates at discrete orifice openings and pressure differentials. The flow rate is computed by interpolation or extrapolation of the tabulated data.

**Interpolation method** — Method of computing values inside the lookup table range

Linear (default) | Smooth

Method of computing values inside the tabulated data range. The **Linear** method joins adjacent data points with straight line or surface segments with generally discontinuous slope at the segment boundaries. Surface segments are used in the 2-D lookup table specified in the **Pressure-flow characteristic** model parameterization.

The **Smooth** method replaces the straight segments with curved versions that have continuous slope everywhere inside the tabulated data range. The segments form a smooth line or surface passing through all of the tabulated data points without the discontinuities in first-order derivatives characteristic of the **Linear** interpolation method.

### Dependencies

This parameter is active when the **Model Parameterization** parameter is set to By area vs. opening table or Pressure-flow characteristic.

**Extrapolation method** — Method of computing values outside of the lookup table range  
Linear (default) | Nearest

Method of computing values outside of the tabulated data range. The Linear method extends the line segment drawn between the last two data points at each end of the data range outward with a constant slope.

The Nearest method extends the last data point at each end of the data range outward as a horizontal line with constant value.

### Dependencies

This parameter is active when the **Model Parameterization** parameter is set to By area vs. opening table or Pressure-flow characteristic.

**Flow discharge coefficient** — Semi-empirical parameter for valve capacity characterization  
0.7 (default) | unitless scalar between 0 and 1

Ratio of the actual and theoretical flow rates through the valve. This parameter depends on the geometrical properties of the valve. Values are usually provided in textbooks and manufacturer data sheets.

**Dependencies**

This parameter is active when the **Model Parameterization** parameter is set to `By maximum area and opening` or `By area vs. opening` table.

**Leakage area** — Internal leakage area between valve inlets  
`1e-12 m^2 (default) | positive scalar in units of area`

Total area of internal leaks in the completely closed state. The purpose of this parameter is to maintain the numerical integrity of the fluid network by preventing a portion of that network from becoming isolated when the valve is completely closed.

**Dependencies**

This parameter is active when the **Model Parameterization** parameter is set to `By maximum area and opening` or `By area vs. opening` table.

**Laminar transition specification** — Choice of parameter used to define the laminar-turbulent transition  
`Pressure ratio (default) | Reynolds number`

Select the parameter to base the laminar-turbulent transition on. Options include:

- `Pressure ratio` — Flow transitions between laminar and turbulent at the pressure ratio specified in the **Laminar flow pressure ratio** parameter. Use this option for the smoothest and most numerically robust flow transitions.
- `Reynolds number` — The transition occurs at the Reynolds number specified in the **Critical Reynolds number** parameter. Flow transitions are more abrupt and can cause simulation issues at near-zero flow rates.

**Dependencies**

This parameter is active when the **Model Parameterization** parameter is set to `By maximum area and opening` or `By area vs. opening` table.

**Laminar flow pressure ratio** — Pressure ratio at the laminar-turbulent flow transition  
`0.999 (default) | unitless scalar between 0 and 1`

Pressure ratio at which the flow transitions between the laminar and turbulent regimes. The pressure ratio is the fraction of the outlet pressure over the inlet pressure.

**Dependencies**

This parameter is active when the **Model Parameterization** parameter is set to `By maximum area and opening` or `By area vs. opening` table and the **Laminar transition specification** parameter is set to `Pressure ratio`.

**Critical Reynolds number** — Reynolds number at the laminar-turbulent flow transition  
`12 (default) | unitless positive scalar`

Maximum Reynolds number for laminar flow. This parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value, 12, corresponds to a round orifice in thin material with sharp edges.

**Dependencies**

This parameter is active when the **Model Parameterization** parameter is set to By maximum area and opening or By area vs. opening table and the **Laminar transition specification** parameter is set to Reynolds number.

**Model Parameterization: Maximum area and opening**

**Maximum opening** — Orifice opening at which the opening area is a maximum  
0.005 m (default) | positive scalar with units of length

Orifice opening at which the opening area of a flow path is a maximum. The maximum opening is the same for all flow paths when this parameter is exposed. For the orifice opening definitions, see “Orifice Openings” on page 1-117.

**Dependencies**

This parameter is active when the **Area characteristics** parameter is set to Identical for all flow paths and the **Model parameterization** parameter is set to Maximum area and opening.

**Maximum opening area** — Maximum cross-sectional area of a flow path  
0.5e-4 m<sup>2</sup> (default) | positive scalar with units of area

Maximum cross-sectional area of a flow path. The maximum opening areas are the same for all paths when this parameter is exposed. For the opening area calculations, see “Opening Areas” on page 1-119.

**Dependencies**

This parameter is active when the **Area characteristics** parameter is set to Identical for all flow paths and the **Model parameterization** parameter is set to Maximum area and opening.

**P-A, maximum opening** — P-A orifice opening at which the opening area is a maximum  
0.005 m (default) | positive scalar with units of length

Control member position at which the P-A opening area is equal to the **P-A, maximum opening area** parameter value.

**Dependencies**

This parameter is active when the **Area characteristics** parameter is set to Different for each flow path and the **Model parameterization** parameter is set to Maximum area and opening.

**P-A, maximum opening area** — Maximum flow area of the P-A flow path  
0.5e-4 m<sup>2</sup> (default) | positive scalar with units of area

Maximum cross-sectional area of the **P-A** flow path. The maximum opening areas are different for each flow path when this parameter is exposed. For the opening area calculations, see “Opening Areas” on page 1-119.

**Dependencies**

This parameter is active when the **Area characteristics** parameter is set to Different for each flow path and the **Model parameterization** parameter is set to Maximum area and opening.

**P-B, maximum opening** — P-B Orifice opening at which the opening area is a maximum  
0.005 m (default) | positive scalar with units of length

Control member position at which the P-B opening area is equal to the **P-B, maximum opening area** parameter value.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to Different for each flow path and the **Model parameterization** parameter is set to Maximum area and opening.

**P-B, maximum opening area** — Maximum flow area of the P-B flow path

0.5e-4 m<sup>2</sup> (default) | positive scalar with units of area

Maximum cross-sectional area of the **P-B** flow path. The maximum opening areas are different for each flow path when this parameter is exposed. For the opening area calculations, see “Opening Areas” on page 1-119.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to Different for each flow path and the **Model parameterization** parameter is set to Maximum area and opening.

**A-T, maximum opening** — A-T Orifice opening at which the opening area is a maximum

0.005 m (default) | positive scalar with units of length

Control member position at which the A-T opening area is equal to the **A-T, maximum opening area** parameter value.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to Different for each flow path and the **Model parameterization** parameter is set to Maximum area and opening.

**A-T, maximum opening area** — Maximum flow area of the A-T flow path

0.5e-4 m<sup>2</sup> (default) | positive scalar with units of area

Maximum cross-sectional area of the **A-T** flow path. The maximum opening areas are different for each flow path when this parameter is exposed. For the opening area calculations, see “Opening Areas” on page 1-119.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to Different for each flow path and the **Model parameterization** parameter is set to Maximum area and opening.

**B-T, maximum opening** — B-T Orifice opening at which the opening area is a maximum

0.005 m (default) | positive scalar with units of length

Control member position at which the B-T opening area is equal to the **B-T, maximum opening area** parameter value.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to Different for each flow path and the **Model parameterization** parameter is set to Maximum area and opening.

**B-T, maximum opening area** — Maximum flow area of the B-T flow path

0.5e-4 m<sup>2</sup> (default) | positive scalar with units of area

Maximum cross-sectional area of the **B-T** flow path. The maximum opening areas are different for each flow path when this parameter is exposed. For the opening area calculations, see “Opening Areas” on page 1-119.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to **Different** for each flow path and the **Model parameterization** parameter is set to **Maximum area and opening**.

#### Model Parameterization: Area vs. opening table

**Opening vector** — Orifice openings at which to specify the flow path opening areas  
 $[-0.002, 0.0, 0.002, 0.005, 0.015]$  m (default) | numerical array with units of length

Array of orifice openings used to construct the opening area 1-D lookup table for all flow paths. The opening characteristics are identical for all flow paths when this parameter is exposed. The number of elements in the array determines the number of elements in the table.

The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for **Linear** interpolation and three elements for **Smooth** interpolation.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to **Identical** for all flow paths and the **Model parameterization** parameter is set to **Area vs. opening table**.

**Opening area vector** — Opening areas corresponding to the orifice openings specified in the **Opening vector** parameter  
 $[1.0e-9, 2.0352e-7, 4.0736e-5, 0.00011438, 0.00034356]$  m<sup>2</sup> (default) | numerical array with units of area

Array of flow path opening areas corresponding to the specified orifice openings. The opening characteristics are identical for all flow paths when this parameter is exposed. The number of elements in the array must match the number of elements in the **Opening vector** parameter.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to **Identical** for all flow paths and the **Model parameterization** parameter is set to **Area vs. opening table**.

**P-A, opening vector** — P-A orifice openings at which to specify the P-A opening area  
 $[-0.002, 0.0, 0.002, 0.005, 0.015]$  m (default) | numerical array with units of length

Array of **P-A** orifice openings used to construct the opening area 1-D lookup table for the **P-A** flow path. The number of elements in the array determines the number of elements in the table.

The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for **Linear** interpolation and three elements for **Smooth** interpolation.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to **Different** for each flow path and the **Model parameterization** parameter is set to **Area vs. opening table**.

**P-A, opening area vector** — P-A opening areas corresponding to the orifice openings specified in the P-A, opening vector parameter

[1.0e-9, 2.0352e-7, 4.0736e-5, 0.00011438, 0.00034356] m<sup>2</sup> (default) | numerical array with units of area

Array of **P-A** opening areas corresponding to the specified **P-A** orifice openings. The number of elements in the array must match the number of elements in the **P-A, opening vector** parameter.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to Different for each flow path and the **Model parameterization** parameter is set to Area vs. opening table.

**P-B, opening vector** — P-B orifice openings at which to specify the P-B opening area

[-0.002, 0.0, 0.002, 0.005, 0.015] m (default) | numerical array with units of length

Array of **P-B** orifice openings used to construct the opening area 1-D lookup table for the **P-B** flow path. The number of elements in the array determines the number of elements in the table.

The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for Linear interpolation and three elements for Smooth interpolation.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to Different for each flow path and the **Model parameterization** parameter is set to Area vs. opening table.

**P-B, opening area vector** — P-B opening areas corresponding to the orifice openings specified in the P-B, opening vector parameter

[1.0e-9, 2.0352e-7, 4.0736e-5, 0.00011438, 0.00034356] m<sup>2</sup> (default) | numerical array with units of area

Array of **P-B** opening areas corresponding to the specified **P-B** orifice openings. The number of elements in the array must match the number of elements in the **P-B, opening vector** parameter.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to Different for each flow path and the **Model parameterization** parameter is set to Area vs. opening table.

**A-T, opening vector** — A-T orifice openings at which to specify the A-T opening area

[-0.002, 0.0, 0.002, 0.005, 0.015] m (default) | numerical array with units of length

Array of **A-T** orifice openings used to construct the opening area 1-D lookup table for the **A-T** flow path. The number of elements in the array determines the number of elements in the table.

The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for Linear interpolation and three elements for Smooth interpolation.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to Different for each flow path and the **Model parameterization** parameter is set to Area vs. opening table.

**A-T, opening area vector** — A-T opening areas corresponding to the orifice openings specified in the A-T, opening vector parameter

[1.0e-9, 2.0352e-7, 4.0736e-5, 0.00011438, 0.00034356] m<sup>2</sup> (default) | numerical array with units of area

Array of **A-T** opening areas corresponding to the specified **A-T** orifice openings. The number of elements in the array must match the number of elements in the **A-T, opening vector** parameter.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to **Different** for each flow path and the **Model parameterization** parameter is set to **Area vs. opening table**.

**B-T, opening vector** — B-T orifice openings at which to specify the B-T opening area

[-0.002, 0.0, 0.002, 0.005, 0.015] m (default) | numerical array with units of length

Array of **B-T** orifice openings used to construct the opening area 1-D lookup table for the **B-T** flow path. The number of elements in the array determines the number of elements in the table.

The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for **Linear** interpolation and three elements for **Smooth** interpolation.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to **Different** for each flow path and the **Model parameterization** parameter is set to **Area vs. opening table**.

**B-T, opening area vector** — B-T opening areas corresponding to the orifice openings specified in the B-T, opening vector parameter

[1.0e-9, 2.0352e-7, 4.0736e-5, 0.00011438, 0.00034356] m<sup>2</sup> (default) | numerical array with units of area

Array of **B-T** opening areas corresponding to the specified **B-T** orifice openings. The number of elements in the array must match the number of elements in the **B-T, opening vector** parameter.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to **Different** for each flow path and the **Model parameterization** parameter is set to **Area vs. opening table**.

#### Model Parameterization: Pressure-flow characteristic

**Opening vector, s** — Orifice openings at which to specify the flow rate tabulated data

[-0.002, 0.0, 0.002, 0.005, 0.015] m (default) | numerical array with units of length

Array of orifice openings used to construct the volumetric flow rate 2-D lookup table. The number of elements in the array determines the number of rows in the table. The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for **Linear** interpolation and three elements for **Smooth** interpolation.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to **Identical** for all flow paths and the **Model parameterization** parameter is set to **Pressure-flow characteristic**.

**Pressure differential vector, dp** — Pressure differentials at which to specify the flow rate data  
 [-10000000.0, -5000000.0, -2000000.0, 2000000.0, 5000000.0, 10000000.0] Pa  
 (default) | numerical array with units of pressure

Array of pressure differentials used to construct the volumetric flow rate 2-D lookup table. The number of elements in the array determines the number of columns in the table. The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for Linear interpolation and three elements for Smooth interpolation.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to Identical for all flow paths and the **Model parameterization** parameter is set to Pressure-flow characteristic.

**Volumetric flow rate table, q(s,dp)** — Volumetric flow rates at the specified control member displacements and pressure differentials  
 5-by-6 matrix with elements between -0.0344 and 0.0344 m<sup>3</sup>/s (default) | numerical array with units of length

Matrix with the volumetric flow rates corresponding to the specified orifice openings and pressure differentials. The number of rows must match the number of elements in the **Opening vector, s** parameter. The number of columns must match the number of elements in the **Pressure differential vector, dp** parameter.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to Identical for all flow paths and the **Model parameterization** parameter is set to Pressure-flow characteristic.

**P-A, opening vector, s** — Orifice openings at which to specify the P-A flow rate data  
 [-0.002, 0.0, 0.002, 0.005, 0.015] m (default) | numerical array with units of length

Array of **P-A** orifice openings used to construct the **P-A** volumetric flow rate 2-D lookup table. The number of elements in the array determines the number of rows in the table. The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for Linear interpolation and three elements for Smooth interpolation.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to Different for each flow path and the **Model parameterization** parameter is set to Pressure-flow characteristic.

**P-A, pressure differential vector, dp** — Pressure differentials at which to specify the flow rate data for the P-A flow path  
 [-10000000.0, -5000000.0, -2000000.0, 2000000.0, 5000000.0, 10000000.0] Pa  
 (default) | numerical array with units of pressure

Array of pressure differentials used to construct the volumetric flow rate 2-D lookup table for the P-A flow path. The number of elements in the array determines the number of columns in the table.

The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for Linear interpolation and three elements for Smooth interpolation.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to Different for each flow path and the **Model parameterization** parameter is set to Pressure-flow characteristic.

**P-A, volumetric flow rate table,  $q(s,dp)$**  — Volumetric flow rates at the specified control member displacements and pressure differentials for the P-A flow path  
5-by-6 matrix with elements between  $-0.0344$  and  $0.0344$  m<sup>3</sup>/s (default) | numerical array with units of length

Matrix with the volumetric flow rates through the P-A flow path at the specified control member displacements and pressure differentials. The number of rows must match the number of elements in the **P-A, opening vector,  $s$**  parameter. The number of columns must match the number of elements in the **P-A, pressure differential vector,  $dp$**  parameter.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to Different for each flow path and the **Model parameterization** parameter is set to Pressure-flow characteristic.

**P-B, opening vector,  $s$**  — Control member displacements at which to specify the flow rate data for the P-B flow path  
[-0.002, 0.0, 0.002, 0.005, 0.015] m (default) | numerical array with units of length

Array of control member displacements used to construct the volumetric flow rate 2-D lookup table for the P-B flow path. The number of elements in the array determines the number of rows in the table.

The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for Linear interpolation and three elements for Smooth interpolation.

#### Dependencies

This parameter is active when the **Area characteristics** parameter is set to Different for each flow path and the **Model parameterization** parameter is set to Pressure-flow characteristic.

**P-B, pressure differential vector,  $dp$**  — Pressure differentials at which to specify the flow rate data for the P-B flow path  
[-10000000.0, -5000000.0, -2000000.0, 2000000.0, 5000000.0, 10000000.0] Pa (default) | numerical array with units of pressure

Array of pressure differentials used to construct the volumetric flow rate 2-D lookup table for the P-B flow path. The number of elements in the array determines the number of columns in the table.

The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for Linear interpolation and three elements for Smooth interpolation.

**Dependencies**

This parameter is active when the **Area characteristics** parameter is set to **Different** for each flow path and the **Model parameterization** parameter is set to **Pressure-flow** characteristic.

**P-B, volumetric flow rate table,  $q(s,dp)$**  — Volumetric flow rates at the specified control member displacements and pressure differentials for the P-B flow path

5-by-6 matrix with elements between  $-0.0344$  and  $0.0344$  m<sup>3</sup>/s (default) | numerical array with units of length

Matrix with the volumetric flow rates through the P-B flow path at the specified control member displacements and pressure differentials. The number of rows must match the number of elements in the **P-B, opening vector,  $s$**  parameter. The number of columns must match the number of elements in the **P-A, pressure differential vector,  $dp$**  parameter.

**Dependencies**

This parameter is active when the **Area characteristics** parameter is set to **Different** for each flow path and the **Model parameterization** parameter is set to **Pressure-flow** characteristic.

**A-T, opening vector,  $s$**  — Control member displacements at which to specify the flow rate data for the A-T flow path

$[-0.002, 0.0, 0.002, 0.005, 0.015]$  m (default) | numerical array with units of length

Array of control member displacements used to construct the volumetric flow rate 2-D lookup table for the A-T flow path. The number of elements in the array determines the number of rows in the table.

The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for **Linear** interpolation and three elements for **Smooth** interpolation.

**Dependencies**

This parameter is active when the **Area characteristics** parameter is set to **Different** for each flow path and the **Model parameterization** parameter is set to **Pressure-flow** characteristic.

**A-T, pressure differential vector,  $dp$**  — Pressure differentials at which to specify the flow rate data for the A-T flow path

$[-10000000.0, -5000000.0, -2000000.0, 2000000.0, 5000000.0, 10000000.0]$  Pa (default) | numerical array with units of pressure

Array of pressure differentials used to construct the volumetric flow rate 2-D lookup table for the A-T flow path. The number of elements in the array determines the number of columns in the table.

The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for **Linear** interpolation and three elements for **Smooth** interpolation.

**Dependencies**

This parameter is active when the **Area characteristics** parameter is set to `Different` for each flow path and the **Model parameterization** parameter is set to `Pressure-flow characteristic`.

**A-T, volumetric flow rate table,  $q(s,dp)$**  — Volumetric flow rates at the specified control member displacements and pressure differentials for the A-T flow path

5-by-6 matrix with elements between  $-0.0344$  and  $0.0344$  m<sup>3</sup>/s (default) | numerical array with units of length

Matrix with the volumetric flow rates through the A-T flow path at the specified control member displacements and pressure differentials. The number of rows must match the number of elements in the **A-T, opening vector,  $s$**  parameter. The number of columns must match the number of elements in the **A-T, pressure differential vector,  $dp$**  parameter.

**Dependencies**

This parameter is active when the **Area characteristics** parameter is set to `Different` for each flow path and the **Model parameterization** parameter is set to `Pressure-flow characteristic`.

**B-T, opening vector,  $s$**  — Control member displacements at which to specify the flow rate data for the B-T flow path

`[-0.002, 0.0, 0.002, 0.005, 0.015]` m (default) | numerical array with units of length

Array of control member displacements used to construct the volumetric flow rate 2-D lookup table for the B-T flow path. The number of elements in the array determines the number of rows in the table.

The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for `Linear` interpolation and three elements for `Smooth` interpolation.

**Dependencies**

This parameter is active when the **Area characteristics** parameter is set to `Different` for each flow path and the **Model parameterization** parameter is set to `Pressure-flow characteristic`.

**B-T, pressure differential vector,  $dp$**  — Pressure differentials at which to specify the flow rate data for the B-T flow path

`[-10000000.0, -5000000.0, -2000000.0, 2000000.0, 5000000.0, 10000000.0]` Pa (default) | numerical array with units of pressure

Array of pressure differentials used to construct the volumetric flow rate 2-D lookup table for the B-T flow path. The number of elements in the array determines the number of columns in the table.

The array must increase from left to right but the intervals between the array element values need not be uniform. There must be at least two elements for `Linear` interpolation and three elements for `Smooth` interpolation.

### Dependencies

This parameter is active when the **Area characteristics** parameter is set to **Different** for each flow path and the **Model parameterization** parameter is set to **Pressure-flow characteristic**.

**B-T, volumetric flow rate table,  $q(s,dp)$**  — Volumetric flow rates at the specified control member displacements and pressure differentials for the B-T flow path

5-by-6 matrix with elements between  $-0.0344$  and  $0.0344$  m<sup>3</sup>/s (default) | numerical array with units of length

Matrix with the volumetric flow rates through the B-T flow path at the specified control member displacements and pressure differentials. The number of rows must match the number of elements in the **B-T, opening vector,  $s$**  parameter. The number of columns must match the number of elements in the **B-T, pressure differential vector,  $dp$**  parameter.

### Dependencies

This parameter is active when the **Area characteristics** parameter is set to **Different** for each flow path and the **Model parameterization** parameter is set to **Pressure-flow characteristic**.

### Valve Opening Offsets

**Between P-A** — P-A orifice opening at zero spool displacement

0 m (default) | scalar number with units of lengths

Orifice opening of the **P-A** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve.

**Between P-B** — P-B orifice opening at zero spool displacement

0 m (default) | scalar number with units of lengths

Orifice opening of the **P-B** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve.

**Between A-T** — A-T orifice opening at zero spool displacement

0 m (default) | scalar number with units of length

Orifice opening of the **A-T** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve.

**Between B-T** — BT orifice opening at zero spool displacement

0 m (default) | scalar number with units of length

Orifice opening of the **P-B** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve.

## Version History

### **R2023a: To be removed**

### Library

Directional Valves

### Description

The 4-Way Directional Valve A block simulates a configuration of hydraulic continuous 4-way directional valve where the valve unloads the pump in neutral position. The fluid is pumped in the valve through the inlet line P and is distributed between two outside hydraulic lines A and B (usually connected to a double-acting actuator) and the return line T. The block has four hydraulic connections, corresponding to inlet port (P), actuator ports (A and B), and return port (T), and one physical signal port connection (S), which controls the spool position. The block is built of six Variable Orifice blocks, connected as shown in the following diagram.

All blocks are controlled by the same position signal, provided through the physical signal port S, but the **Orifice orientation** parameter in the block instances is set in such a way that positive signal at port S opens the orifices colored blue in the block diagram (orifices P-A, B-T, and T1-T) and closes the orifices colored yellow (orifices A-T, P-B, and P-T1). As a result, the openings of the orifices are computed as follows:

$$h_{PA} = h_{PA0} + x$$

$$h_{PB} = h_{PB0} - x$$

$$h_{AT} = h_{AT0} - x$$

$$h_{BT} = h_{BT0} + x$$

$$h_{PT1} = h_{PT10} - x$$

$$h_{T1T} = h_{T1T0} + x$$

where

$h_{PA}$	Orifice opening for the Variable Orifice P-A block
$h_{PB}$	Orifice opening for the Variable Orifice P-B block
$h_{AT}$	Orifice opening for the Variable Orifice A-T block
$h_{BT}$	Orifice opening for the Variable Orifice B-T block
$h_{PT1}$	Orifice opening for the Variable Orifice P-T1 block
$h_{T1T}$	Orifice opening for the Variable Orifice T1-T block
$h_{PA0}$	Initial opening for the Variable Orifice P-A block

$h_{PB0}$	Initial opening for the Variable Orifice P-B block
$h_{AT0}$	Initial opening for the Variable Orifice A-T block
$h_{BT0}$	Initial opening for the Variable Orifice B-T block
$h_{PT10}$	Initial opening for the Variable Orifice P-T1 block
$h_{T1T0}$	Initial opening for the Variable Orifice T1-T block
$x$	Control member displacement from initial position

For information on the block parameterization options, basic parameter descriptions, assumptions and limitations, global and restricted parameters, see the 4-Way Directional Valve block reference page.

## Parameters

- “Basic Parameters Tab” on page 1-141
- “Valve Opening Offsets Tab” on page 1-143

### Basic Parameters Tab

#### Model parameterization

Select one of the following methods for specifying the valve:

- **By maximum area and opening** — Provide values for the maximum valve passage area and the maximum valve opening. The passage area is linearly dependent on the control member displacement, that is, the valve is closed at the initial position of the control member (zero displacement), and the maximum opening takes place at the maximum displacement. This is the default method.
- **By area vs. opening table** — Provide tabulated data of valve openings and corresponding valve passage areas. The passage area is determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.
- **By pressure-flow characteristic** — Provide tabulated data of valve openings, pressure differentials, and corresponding flow rates. The flow rate is determined by two-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.

#### Valve passage maximum area

Specify the area of a fully opened valve. The parameter value must be greater than zero. The default value is  $5e-5 \text{ m}^2$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

#### Valve maximum opening

Specify the maximum displacement of the control member. The parameter value must be greater than zero. The default value is  $5e-3 \text{ m}$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

#### Valve opening vector, $s$

Specify the vector of input values for valve openings as a one-dimensional array. The input values vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in meters, are  $[-0.002 \ 0 \ 0.002 \ 0.005 \ 0.015]$ . If **Model parameterization** is set to **By area vs. opening table**, the **Tabulated valve openings** values will be used together with **Tabulated**

**valve passage area** values for one-dimensional table lookup. If **Model parameterization** is set to By pressure-flow characteristic, the **Tabulated valve openings** values will be used together with **Tabulated pressure differentials** and **Tabulated flow rates** for two-dimensional table lookup.

### Valve passage area vector

Specify the vector of output values for valve passage area as a one-dimensional array. The valve passage area vector must be of the same size as the valve openings vector. All the values must be positive. The default values, in  $m^2$ , are [1e-09 2.0352e-07 4.0736e-05 0.00011438 0.00034356]. This parameter is used if **Model parameterization** is set to By area vs. opening table.

### Pressure differential vector, dp

Specify the vector of input values for pressure differentials as a one-dimensional array. The vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in Pa, are [-1e+07 -5e+06 -2e+06 2e+06 5e+06 1e+07]. This parameter is used if **Model parameterization** is set to By pressure-flow characteristic.

### Volumetric flow rate table, q(s,dp)

Specify the flow rates as an m-by-n matrix, where m is the number of valve openings and n is the number of pressure differentials. Each value in the matrix specifies flow rate taking place at a specific combination of valve opening and pressure differential. The matrix size must match the dimensions defined by the input vectors. The default values, in  $m^3/s$ , are:

```
[-1e-07 -7.0711e-08 -4.4721e-08 4.4721e-08 7.0711e-08 1e-07;
-2.0352e-05 -1.4391e-05 -9.1017e-06 9.1017e-06 1.4391e-05 2.0352e-05;
-0.0040736 -0.0028805 -0.0018218 0.0018218 0.0028805 0.0040736;
-0.011438 -0.0080879 -0.0051152 0.0051152 0.0080879 0.011438;
-0.034356 -0.024293 -0.015364 0.015364 0.024293 0.034356;]
```

This parameter is used if **Model parameterization** is set to By pressure-flow characteristic.

### Interpolation method

Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- Linear — Select this option to get the best performance.
- Smooth — Select this option to produce a continuous curve (By area vs. opening table) or surface (By pressure-flow characteristic) with continuous first-order derivatives.

For more information on interpolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

### Extrapolation method

Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- Linear — Select this option to produce a curve or surface with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.
- Nearest — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

**Flow discharge coefficient**

Semi-empirical parameter for valve capacity characterization. Its value depends on the geometrical properties of the valve, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.7.

**Laminar transition specification**

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

**Laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

**Critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12, which corresponds to a round orifice in thin material with sharp edges. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

**Leakage area**

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is  $1e-12 \text{ m}^2$ .

**Valve Opening Offsets Tab****Between ports P and A**

Orifice opening of the **P-A** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

**Between ports P and B**

Orifice opening of the **P-B** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

**Between ports A and T**

Orifice opening of the **A-T** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

**Between ports B and T**

Orifice opening of the **B-T** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

**Between ports P and T1**

Orifice opening of the **P-T1** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $\theta$  corresponds to a zero-lapped valve. The default value is  $2.5e-3$  m.

**Between ports T1 and T**

Orifice opening of the **T1-T** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $\theta$  corresponds to a zero-lapped valve. The default value is  $2.5e-3$  m.

**Ports**

The block has the following ports:

**P**

Hydraulic conserving port associated with the pressure supply line inlet.

**T**

Hydraulic conserving port associated with the return line connection.

**A**

Hydraulic conserving port associated with the actuator connection port.

**B**

Hydraulic conserving port associated with the actuator connection port.

**S**

Physical signal port to control spool displacement.

**Version History****Introduced in R2009b****R2023a: To be removed**

### Library

Directional Valves

### Description

The 4-Way Directional Valve B block simulates a configuration of hydraulic continuous 4-way directional valve where port A is permanently connected to port P, and all four ports are interconnected in neutral position. The fluid is pumped in the valve through the inlet line P and is distributed between two outside hydraulic lines A and B (usually connected to a double-acting actuator) and the return line T. The block has four hydraulic connections, corresponding to inlet port (P), actuator ports (A and B), and return port (T), and one physical signal port connection (S), which controls the spool position. The block is built of a Fixed Orifice block in the P-A path and four Variable Orifice blocks, connected as shown in the following diagram.

All Variable Orifice blocks are controlled by the same position signal, provided through the physical signal port S, but the **Orifice orientation** parameter in the block instances is set in such a way that positive signal at port S opens the orifices colored blue in the block diagram (orifices A-T1 and P-B ) and closes the orifices colored yellow (orifices T1-T and B-T). As a result, the openings of the orifices are computed as follows:

$$h_{AT1} = h_{AT10} - x$$

$$h_{PB} = h_{PB0} - x$$

$$h_{T1T} = h_{T1T0} + x$$

$$h_{BT} = h_{BT0} + x$$

where

$h_{AT1}$	Orifice opening for the Variable Orifice A-T1 block
$h_{PB}$	Orifice opening for the Variable Orifice P-B block
$h_{T1T}$	Orifice opening for the Variable Orifice T1-T block
$h_{BT}$	Orifice opening for the Variable Orifice B-T block
$h_{AT10}$	Initial opening for the Variable Orifice A-T1 block
$h_{PB0}$	Initial opening for the Variable Orifice P-B block
$h_{T1T0}$	Initial opening for the Variable Orifice T1-T block
$h_{BT0}$	Initial opening for the Variable Orifice B-T block

x	Control member displacement from initial position

For information on the block parameterization options, basic parameter descriptions, assumptions and limitations, global and restricted parameters, see the 4-Way Directional Valve block reference page.

## Parameters

- “Basic Parameters Tab” on page 1-147
- “Valve Opening Offsets Tab” on page 1-149

### Basic Parameters Tab

Compared to the Basic Parameters tab of the 4-Way Directional Valve block, there is one additional parameter:

#### Path P-A passage area

Specify the area of the P-A passage. The parameter value must be greater than zero. The default value is  $5e-5 \text{ m}^2$ . This parameter is used if **Model parameterization** is set to By maximum area and opening.

The rest of the parameters on this tab are identical to those of the 4-Way Directional Valve block:

### Model parameterization

Select one of the following methods for specifying the valve:

- **By maximum area and opening** — Provide values for the maximum valve passage area and the maximum valve opening. The passage area is linearly dependent on the control member displacement, that is, the valve is closed at the initial position of the control member (zero displacement), and the maximum opening takes place at the maximum displacement. This is the default method.
- **By area vs. opening table** — Provide tabulated data of valve openings and corresponding valve passage areas. The passage area is determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.
- **By pressure-flow characteristic** — Provide tabulated data of valve openings, pressure differentials, and corresponding flow rates. The flow rate is determined by two-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.

### Valve passage maximum area

Specify the area of a fully opened valve. The parameter value must be greater than zero. The default value is  $5e-5 \text{ m}^2$ . This parameter is used if **Model parameterization** is set to By maximum area and opening.

### Valve maximum opening

Specify the maximum displacement of the control member. The parameter value must be greater than zero. The default value is  $5e-3 \text{ m}$ . This parameter is used if **Model parameterization** is set to By maximum area and opening.

### Valve opening vector, s

Specify the vector of input values for valve openings as a one-dimensional array. The input values vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear

interpolation, at least three values for smooth interpolation. The default values, in meters, are [-0.002 0 0.002 0.005 0.015]. If **Model parameterization** is set to **By area vs. opening table**, the **Tabulated valve openings** values will be used together with **Tabulated valve passage area** values for one-dimensional table lookup. If **Model parameterization** is set to **By pressure-flow characteristic**, the **Tabulated valve openings** values will be used together with **Tabulated pressure differentials** and **Tabulated flow rates** for two-dimensional table lookup.

### Valve passage area vector

Specify the vector of output values for valve passage area as a one-dimensional array. The valve passage area vector must be of the same size as the valve openings vector. All the values must be positive. The default values, in  $m^2$ , are [1e-09 2.0352e-07 4.0736e-05 0.00011438 0.00034356]. This parameter is used if **Model parameterization** is set to **By area vs. opening table**.

### Pressure differential vector, dp

Specify the vector of input values for pressure differentials as a one-dimensional array. The vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in Pa, are [-1e+07 -5e+06 -2e+06 2e+06 5e+06 1e+07]. This parameter is used if **Model parameterization** is set to **By pressure-flow characteristic**.

### Volumetric flow rate table, q(s,dp)

Specify the flow rates as an  $m$ -by- $n$  matrix, where  $m$  is the number of valve openings and  $n$  is the number of pressure differentials. Each value in the matrix specifies flow rate taking place at a specific combination of valve opening and pressure differential. The matrix size must match the dimensions defined by the input vectors. The default values, in  $m^3/s$ , are:

```
[-1e-07 -7.0711e-08 -4.4721e-08 4.4721e-08 7.0711e-08 1e-07;
-2.0352e-05 -1.4391e-05 -9.1017e-06 9.1017e-06 1.4391e-05 2.0352e-05;
-0.0040736 -0.0028805 -0.0018218 0.0018218 0.0028805 0.0040736;
-0.011438 -0.0080879 -0.0051152 0.0051152 0.0080879 0.011438;
-0.034356 -0.024293 -0.015364 0.015364 0.024293 0.034356;]
```

This parameter is used if **Model parameterization** is set to **By pressure-flow characteristic**.

### Interpolation method

Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- **Linear** — Select this option to get the best performance.
- **Smooth** — Select this option to produce a continuous curve (**By area vs. opening table**) or surface (**By pressure-flow characteristic**) with continuous first-order derivatives.

For more information on interpolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

### Extrapolation method

Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- **Linear** — Select this option to produce a curve or surface with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.

- **Nearest** — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

### **Flow discharge coefficient**

Semi-empirical parameter for valve capacity characterization. Its value depends on the geometrical properties of the valve, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.7.

### **Laminar transition specification**

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

### **Laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

### **Critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12, which corresponds to a round orifice in thin material with sharp edges. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

### **Leakage area**

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is  $1e-12 \text{ m}^2$ .

## **Valve Opening Offsets Tab**

### **Between ports P and B**

Orifice opening of the **P-B** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $2.5e-3 \text{ m}$ .

### **Between ports B and T**

Orifice opening of the **B-T** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $2.5e-3 \text{ m}$ .

### **Between ports A and T1**

Orifice opening of the **A-T1** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $2.5e-3 \text{ m}$ .

**Between ports T1 and T**

Orifice opening of the **T1-T** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $\theta$  corresponds to a zero-lapped valve. The default value is  $2.5e-3$  m.

**Ports**

The block has the following ports:

P

Hydraulic conserving port associated with the pressure supply line inlet.

T

Hydraulic conserving port associated with the return line connection.

A

Hydraulic conserving port associated with the actuator connection port.

B

Hydraulic conserving port associated with the actuator connection port.

S

Physical signal port to control spool displacement.

### Library

Directional Valves

### Description

The 4-Way Directional Valve C block simulates a configuration of hydraulic continuous 4-way directional valve where port P is connected to port A and port B is connected to port T in the left position; in the right position, both port A and port B are connected to P; and all ports are interconnected in neutral position. The fluid is pumped in the valve through the inlet line P and is distributed between two outside hydraulic lines A and B (usually connected to a double-acting actuator) and the return line T. The block has four hydraulic connections, corresponding to inlet port (P), actuator ports (A and B), and return port (T), and one physical signal port connection (S), which controls the spool position. The block is built of a Fixed Orifice block in the P-B path and four Variable Orifice blocks, connected as shown in the following diagram.

All Variable Orifice blocks are controlled by the same position signal, provided through the physical signal port S, but the **Orifice orientation** parameter in the block instances is set in such a way that positive signal at port S opens the orifices colored blue in the block diagram (orifices B-T1 and A-T) and closes the orifices colored yellow (orifices P-A and T1-T). As a result, the openings of the orifices are computed as follows:

$$h_{PA} = h_{PA0} - x$$

$$h_{AT} = h_{AT0} + x$$

$$h_{BT1} = h_{BT10} + x$$

$$h_{T1T} = h_{T1T0} - x$$

where

$h_{PA}$	Orifice opening for the Variable Orifice P-A block
$h_{AT}$	Orifice opening for the Variable Orifice A-T block
$h_{BT1}$	Orifice opening for the Variable Orifice B-T1 block
$h_{T1T}$	Orifice opening for the Variable Orifice T1-T block
$h_{PA0}$	Initial opening for the Variable Orifice P-A block
$h_{PB0}$	Initial opening for the Variable Orifice P-B block
$h_{BT10}$	Initial opening for the Variable Orifice B-T1 block
$h_{T1T0}$	Initial opening for the Variable Orifice T1-T block

x	Control member displacement from initial position
---	---

For information on the block parameterization options, basic parameter descriptions, assumptions and limitations, global and restricted parameters, see the 4-Way Directional Valve block reference page.

## Parameters

- “Basic Parameters Tab” on page 1-153
- “Valve Opening Offsets Tab” on page 1-155

### Basic Parameters Tab

Compared to the Basic Parameters tab of the 4-Way Directional Valve block, there is one additional parameter:

#### Path P-B passage area

Specify the area of the P-B passage. The parameter value must be greater than zero. The default value is  $5e-5 \text{ m}^2$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

The rest of the parameters on this tab are identical to those of the 4-Way Directional Valve block:

### Model parameterization

Select one of the following methods for specifying the valve:

- **By maximum area and opening** — Provide values for the maximum valve passage area and the maximum valve opening. The passage area is linearly dependent on the control member displacement, that is, the valve is closed at the initial position of the control member (zero displacement), and the maximum opening takes place at the maximum displacement. This is the default method.
- **By area vs. opening table** — Provide tabulated data of valve openings and corresponding valve passage areas. The passage area is determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.
- **By pressure-flow characteristic** — Provide tabulated data of valve openings, pressure differentials, and corresponding flow rates. The flow rate is determined by two-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.

### Valve passage maximum area

Specify the area of a fully opened valve. The parameter value must be greater than zero. The default value is  $5e-5 \text{ m}^2$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

### Valve maximum opening

Specify the maximum displacement of the control member. The parameter value must be greater than zero. The default value is  $5e-3 \text{ m}$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

### Valve opening vector, s

Specify the vector of input values for valve openings as a one-dimensional array. The input values vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear

interpolation, at least three values for smooth interpolation. The default values, in meters, are [-0.002 0 0.002 0.005 0.015]. If **Model parameterization** is set to **By area vs. opening table**, the **Tabulated valve openings** values will be used together with **Tabulated valve passage area** values for one-dimensional table lookup. If **Model parameterization** is set to **By pressure-flow characteristic**, the **Tabulated valve openings** values will be used together with **Tabulated pressure differentials** and **Tabulated flow rates** for two-dimensional table lookup.

### Valve passage area vector

Specify the vector of output values for valve passage area as a one-dimensional array. The valve passage area vector must be of the same size as the valve openings vector. All the values must be positive. The default values, in  $m^2$ , are [1e-09 2.0352e-07 4.0736e-05 0.00011438 0.00034356]. This parameter is used if **Model parameterization** is set to **By area vs. opening table**.

### Pressure differential vector, dp

Specify the vector of input values for pressure differentials as a one-dimensional array. The vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in Pa, are [-1e+07 -5e+06 -2e+06 2e+06 5e+06 1e+07]. This parameter is used if **Model parameterization** is set to **By pressure-flow characteristic**.

### Volumetric flow rate table, q(s,dp)

Specify the flow rates as an  $m$ -by- $n$  matrix, where  $m$  is the number of valve openings and  $n$  is the number of pressure differentials. Each value in the matrix specifies flow rate taking place at a specific combination of valve opening and pressure differential. The matrix size must match the dimensions defined by the input vectors. The default values, in  $m^3/s$ , are:

```
[-1e-07 -7.0711e-08 -4.4721e-08 4.4721e-08 7.0711e-08 1e-07;
-2.0352e-05 -1.4391e-05 -9.1017e-06 9.1017e-06 1.4391e-05 2.0352e-05;
-0.0040736 -0.0028805 -0.0018218 0.0018218 0.0028805 0.0040736;
-0.011438 -0.0080879 -0.0051152 0.0051152 0.0080879 0.011438;
-0.034356 -0.024293 -0.015364 0.015364 0.024293 0.034356;]
```

This parameter is used if **Model parameterization** is set to **By pressure-flow characteristic**.

### Interpolation method

Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- **Linear** — Select this option to get the best performance.
- **Smooth** — Select this option to produce a continuous curve (**By area vs. opening table**) or surface (**By pressure-flow characteristic**) with continuous first-order derivatives.

For more information on interpolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

### Extrapolation method

Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- **Linear** — Select this option to produce a curve or surface with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.

- **Nearest** — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

### **Flow discharge coefficient**

Semi-empirical parameter for valve capacity characterization. Its value depends on the geometrical properties of the valve, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.7.

### **Laminar transition specification**

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

### **Laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

### **Critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12, which corresponds to a round orifice in thin material with sharp edges. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

### **Leakage area**

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is  $1e-12 \text{ m}^2$ .

## **Valve Opening Offsets Tab**

### **Between ports P and A**

Orifice opening of the **P-A** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $2.5e-3 \text{ m}$ .

### **Between ports A and T**

Orifice opening of the **A-T** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $2.5e-3 \text{ m}$ .

### **Between ports B and T1**

Orifice opening of the **B-T1** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $2.5e-3 \text{ m}$ .

**Between ports T1 and T**

Orifice opening of the **T1-T** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $\theta$  corresponds to a zero-lapped valve. The default value is  $2.5e-3$  m.

**Ports**

The block has the following ports:

P

Hydraulic conserving port associated with the pressure supply line inlet.

T

Hydraulic conserving port associated with the return line connection.

A

Hydraulic conserving port associated with the actuator connection port.

B

Hydraulic conserving port associated with the actuator connection port.

S

Physical signal port to control spool displacement.

Directional Valves

### Description

The 4-Way Directional Valve D block simulates a configuration of hydraulic continuous 4-way directional valve. Ports A and B are connected to port P in the left valve position. In the right position, port P is connected to port A, while port B is connected to port T. All connections are blocked in neutral position. The fluid is pumped in the valve through the inlet line P and is distributed between two outside hydraulic lines A and B (usually connected to a double-acting actuator) and the return line T. The block has four hydraulic connections, corresponding to inlet port (P), actuator ports (A and B), and return port (T), and one physical signal port connection (S), which controls the spool position. The block is built of four Variable Orifice blocks, connected as shown in the following diagram.

All Variable Orifice blocks are controlled by the same position signal, provided through the physical signal port S, but the **Orifice orientation** parameter in the block instances is set in such a way that positive signal at port S opens the orifices colored blue in the block diagram (orifices P-A2 and P-B ) and closes the orifices colored yellow (orifices P-A1 and B-T). As a result, the openings of the orifices are computed as follows:

$$h_{PA1} = h_{PA10} - x$$

$$h_{PA2} = h_{PA20} + x$$

$$h_{PB} = h_{PB0} + x$$

$$h_{BT} = h_{BT0} - x$$

where

$h_{PA1}$	Orifice opening for the Variable Orifice P-A1 block
$h_{PA2}$	Orifice opening for the Variable Orifice P-A2 block
$h_{PB}$	Orifice opening for the Variable Orifice P-B block
$h_{BT}$	Orifice opening for the Variable Orifice B-T block
$h_{PA10}$	Initial opening for the Variable Orifice P-A1 block
$h_{PA20}$	Initial opening for the Variable Orifice P-A2 block
$h_{PB0}$	Initial opening for the Variable Orifice P-B block
$h_{BT0}$	Initial opening for the Variable Orifice B-T block
$x$	Control member displacement from initial position

For information on the block parameterization options, basic parameter descriptions, assumptions and limitations, global and restricted parameters, see the 4-Way Directional Valve block reference page.

## Parameters

- “Basic Parameters Tab” on page 1-159
- “Valve Opening Offsets Tab” on page 1-161

### Basic Parameters Tab

#### Model parameterization

Select one of the following methods for specifying the valve:

- **By maximum area and opening** — Provide values for the maximum valve passage area and the maximum valve opening. The passage area is linearly dependent on the control member displacement, that is, the valve is closed at the initial position of the control member (zero displacement), and the maximum opening takes place at the maximum displacement. This is the default method.
- **By area vs. opening table** — Provide tabulated data of valve openings and corresponding valve passage areas. The passage area is determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.
- **By pressure-flow characteristic** — Provide tabulated data of valve openings, pressure differentials, and corresponding flow rates. The flow rate is determined by two-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.

#### Valve passage maximum area

Specify the area of a fully opened valve. The parameter value must be greater than zero. The default value is  $5e-5 \text{ m}^2$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

#### Valve maximum opening

Specify the maximum displacement of the control member. The parameter value must be greater than zero. The default value is  $5e-3 \text{ m}$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

#### Valve opening vector, **s**

Specify the vector of input values for valve openings as a one-dimensional array. The input values vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in meters, are  $[-0.002 \ 0 \ 0.002 \ 0.005 \ 0.015]$ . If **Model parameterization** is set to **By area vs. opening table**, the **Tabulated valve openings** values will be used together with **Tabulated valve passage area** values for one-dimensional table lookup. If **Model parameterization** is set to **By pressure-flow characteristic**, the **Tabulated valve openings** values will be used together with **Tabulated pressure differentials** and **Tabulated flow rates** for two-dimensional table lookup.

#### Valve passage area vector

Specify the vector of output values for valve passage area as a one-dimensional array. The valve passage area vector must be of the same size as the valve openings vector. All the values must be positive. The default values, in  $\text{m}^2$ , are  $[1e-09 \ 2.0352e-07 \ 4.0736e-05 \ 0.00011438]$

0.00034356]. This parameter is used if **Model parameterization** is set to **By area vs. opening table**.

### Pressure differential vector, dp

Specify the vector of input values for pressure differentials as a one-dimensional array. The vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in Pa, are [-1e+07 -5e+06 -2e+06 2e+06 5e+06 1e+07]. This parameter is used if **Model parameterization** is set to **By pressure-flow characteristic**.

### Volumetric flow rate table, q(s,dp)

Specify the flow rates as an m-by-n matrix, where m is the number of valve openings and n is the number of pressure differentials. Each value in the matrix specifies flow rate taking place at a specific combination of valve opening and pressure differential. The matrix size must match the dimensions defined by the input vectors. The default values, in m<sup>3</sup>/s, are:

```
[-1e-07 -7.0711e-08 -4.4721e-08 4.4721e-08 7.0711e-08 1e-07;
-2.0352e-05 -1.4391e-05 -9.1017e-06 9.1017e-06 1.4391e-05 2.0352e-05;
-0.0040736 -0.0028805 -0.0018218 0.0018218 0.0028805 0.0040736;
-0.011438 -0.0080879 -0.0051152 0.0051152 0.0080879 0.011438;
-0.034356 -0.024293 -0.015364 0.015364 0.024293 0.034356;]
```

This parameter is used if **Model parameterization** is set to **By pressure-flow characteristic**.

### Interpolation method

Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- **Linear** — Select this option to get the best performance.
- **Smooth** — Select this option to produce a continuous curve (**By area vs. opening table**) or surface (**By pressure-flow characteristic**) with continuous first-order derivatives.

For more information on interpolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

### Extrapolation method

Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- **Linear** — Select this option to produce a curve or surface with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.
- **Nearest** — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

### Flow discharge coefficient

Semi-empirical parameter for valve capacity characterization. Its value depends on the geometrical properties of the valve, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.7.

### Laminar transition specification

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

### Laminar flow pressure ratio

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

### Critical Reynolds number

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12, which corresponds to a round orifice in thin material with sharp edges. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

### Leakage area

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is  $1e-12 \text{ m}^2$ .

## Valve Opening Offsets Tab

### Between ports P and A1

Orifice opening of the **P-A1** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $\theta$  corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

### Between ports P and A2

Orifice opening of the **P-A2** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $\theta$  corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

### Between ports P and B

Orifice opening of the **P-B** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $\theta$  corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

### Between ports B and T

Orifice opening of the **B-T** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $\theta$  corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

## Ports

The block has the following ports:

P

Hydraulic conserving port associated with the pressure supply line inlet.

T

Hydraulic conserving port associated with the return line connection.

A

Hydraulic conserving port associated with the actuator connection port.

B

Hydraulic conserving port associated with the actuator connection port.

S

Physical signal port to control spool displacement.

Directional Valves

### Description

The 4-Way Directional Valve E block simulates a configuration of hydraulic continuous 4-way directional valve. Ports A and B are connected to port P in the right valve position. In the left position, port P is connected to port B, while port A is connected to port T. All connections are blocked in neutral position. The fluid is pumped in the valve through the inlet line P and is distributed between two outside hydraulic lines A and B (usually connected to a double-acting actuator) and the return line T. The block has four hydraulic connections, corresponding to inlet port (P), actuator ports (A and B), and return port (T), and one physical signal port connection (S), which controls the spool position. The block is built of four Variable Orifice blocks, connected as shown in the following diagram.

All Variable Orifice blocks are controlled by the same position signal, provided through the physical signal port S, but the **Orifice orientation** parameter in the block instances is set in such a way that positive signal at port S opens the orifices colored blue in the block diagram (orifices P-B1 and A-T) and closes the orifices colored yellow (orifices P-A and P-B2). As a result, the openings of the orifices are computed as follows:

$$h_{PA} = h_{PA0} - x$$

$$h_{PB1} = h_{PB10} + x$$

$$h_{PB2} = h_{PB20} - x$$

$$h_{AT} = h_{AT0} + x$$

where

$h_{PA}$	Orifice opening for the Variable Orifice P-A block
$h_{PB1}$	Orifice opening for the Variable Orifice P-B1 block
$h_{PB2}$	Orifice opening for the Variable Orifice P-B2 block
$h_{AT}$	Orifice opening for the Variable Orifice A-T block
$h_{PA0}$	Initial opening for the Variable Orifice P-A block
$h_{PB10}$	Initial opening for the Variable Orifice P-B1 block
$h_{PB20}$	Initial opening for the Variable Orifice P-B2 block
$h_{AT0}$	Initial opening for the Variable Orifice A-T block
$x$	Control member displacement from initial position

For information on the block parameterization options, basic parameter descriptions, assumptions and limitations, global and restricted parameters, see the 4-Way Directional Valve block reference page.

## Parameters

- “Basic Parameters Tab” on page 1-165
- “Valve Opening Offsets Tab” on page 1-167

### Basic Parameters Tab

#### Model parameterization

Select one of the following methods for specifying the valve:

- **By maximum area and opening** — Provide values for the maximum valve passage area and the maximum valve opening. The passage area is linearly dependent on the control member displacement, that is, the valve is closed at the initial position of the control member (zero displacement), and the maximum opening takes place at the maximum displacement. This is the default method.
- **By area vs. opening table** — Provide tabulated data of valve openings and corresponding valve passage areas. The passage area is determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.
- **By pressure-flow characteristic** — Provide tabulated data of valve openings, pressure differentials, and corresponding flow rates. The flow rate is determined by two-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.

#### Valve passage maximum area

Specify the area of a fully opened valve. The parameter value must be greater than zero. The default value is  $5e-5 \text{ m}^2$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

#### Valve maximum opening

Specify the maximum displacement of the control member. The parameter value must be greater than zero. The default value is  $5e-3 \text{ m}$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

#### Valve opening vector, **s**

Specify the vector of input values for valve openings as a one-dimensional array. The input values vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in meters, are  $[-0.002 \ 0 \ 0.002 \ 0.005 \ 0.015]$ . If **Model parameterization** is set to **By area vs. opening table**, the **Tabulated valve openings** values will be used together with **Tabulated valve passage area** values for one-dimensional table lookup. If **Model parameterization** is set to **By pressure-flow characteristic**, the **Tabulated valve openings** values will be used together with **Tabulated pressure differentials** and **Tabulated flow rates** for two-dimensional table lookup.

#### Valve passage area vector

Specify the vector of output values for valve passage area as a one-dimensional array. The valve passage area vector must be of the same size as the valve openings vector. All the values must be positive. The default values, in  $\text{m}^2$ , are  $[1e-09 \ 2.0352e-07 \ 4.0736e-05 \ 0.00011438 \ 0.00034356]$ . This parameter is used if **Model parameterization** is set to **By area vs. opening table**.

#### Pressure differential vector, **dp**

Specify the vector of input values for pressure differentials as a one-dimensional array. The vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of

values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in Pa, are [-1e+07 -5e+06 -2e+06 2e+06 5e+06 1e+07]. This parameter is used if **Model parameterization** is set to By pressure-flow characteristic.

### Volumetric flow rate table, $q(s,dp)$

Specify the flow rates as an  $m$ -by- $n$  matrix, where  $m$  is the number of valve openings and  $n$  is the number of pressure differentials. Each value in the matrix specifies flow rate taking place at a specific combination of valve opening and pressure differential. The matrix size must match the dimensions defined by the input vectors. The default values, in  $m^3/s$ , are:

```
[-1e-07 -7.0711e-08 -4.4721e-08 4.4721e-08 7.0711e-08 1e-07;
-2.0352e-05 -1.4391e-05 -9.1017e-06 9.1017e-06 1.4391e-05 2.0352e-05;
-0.0040736 -0.0028805 -0.0018218 0.0018218 0.0028805 0.0040736;
-0.011438 -0.0080879 -0.0051152 0.0051152 0.0080879 0.011438;
-0.034356 -0.024293 -0.015364 0.015364 0.024293 0.034356;]
```

This parameter is used if **Model parameterization** is set to By pressure-flow characteristic.

### Interpolation method

Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- **Linear** — Select this option to get the best performance.
- **Smooth** — Select this option to produce a continuous curve (By area vs. opening table) or surface (By pressure-flow characteristic) with continuous first-order derivatives.

For more information on interpolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

### Extrapolation method

Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- **Linear** — Select this option to produce a curve or surface with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.
- **Nearest** — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

### Flow discharge coefficient

Semi-empirical parameter for valve capacity characterization. Its value depends on the geometrical properties of the valve, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.7.

### Laminar transition specification

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.

- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

### Laminar flow pressure ratio

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

### Critical Reynolds number

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12, which corresponds to a round orifice in thin material with sharp edges. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

### Leakage area

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is  $1e-12 \text{ m}^2$ .

## Valve Opening Offsets Tab

### Between ports P and A

Orifice opening of the **P-A** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

### Between ports A and T

Orifice opening of the **A-T** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

### Between ports P and B1

Orifice opening of the **P-B1** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

### Between ports P and B2

Orifice opening of the **P-B2** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

## Ports

The block has the following ports:

P

Hydraulic conserving port associated with the pressure supply line inlet.

T

Hydraulic conserving port associated with the return line connection.

- A  
Hydraulic conserving port associated with the actuator connection port.
- B  
Hydraulic conserving port associated with the actuator connection port.
- S  
Physical signal port to control spool displacement.

Directional Valves

### Description

The 4-Way Directional Valve F block simulates a configuration of hydraulic continuous 4-way directional valve. Ports A and B are connected to port P in the left valve position. In the right position, port P is connected to port A, while port B is connected to port T. In neutral position, ports A and B are connected to port T. The fluid is pumped in the valve through the inlet line P and is distributed between two outside hydraulic lines A and B (usually connected to a double-acting actuator) and the return line T. The block has four hydraulic connections, corresponding to inlet port (P), actuator ports (A and B), and return port (T), and one physical signal port connection (S), which controls the spool position. The block is built of six Variable Orifice blocks, connected as shown in the following diagram.

All Variable Orifice blocks are controlled by the same position signal, provided through the physical signal port S, but the **Orifice orientation** parameter in the block instances is set in such a way that positive signal at port S opens the orifices colored blue in the block diagram (orifices P-A1, A-T1, and P-B) and closes the orifices colored yellow (orifices P-A2, B-T, and T1-T). As a result, the openings of the orifices are computed as follows:

$$h_{PA1} = h_{PA10} + x$$

$$h_{PA2} = h_{PA20} - x$$

$$h_{AT1} = h_{AT10} + x$$

$$h_{T1T} = h_{T1T0} - x$$

$$h_{PB} = h_{PB0} + x$$

$$h_{BT} = h_{BT0} - x$$

where

$h_{PA1}$	Orifice opening for the Variable Orifice P-A1 block
$h_{PA2}$	Orifice opening for the Variable Orifice P-A2 block
$h_{AT1}$	Orifice opening for the Variable Orifice A-T1 block
$h_{T1T}$	Orifice opening for the Variable Orifice T1-T block
$h_{PB}$	Orifice opening for the Variable Orifice P-B block

$h_{BT}$	Orifice opening for the Variable Orifice B-T block
$h_{PA10}$	Initial opening for the Variable Orifice P-A1 block
$h_{PA20}$	Initial opening for the Variable Orifice P-A2 block
$h_{AT10}$	Initial opening for the Variable Orifice A-T1 block
$h_{T1T0}$	Initial opening for the Variable Orifice T1-T block
$h_{PB0}$	Initial opening for the Variable Orifice P-B block
$h_{BT0}$	Initial opening for the Variable Orifice B-T block
$x$	Control member displacement from initial position

For information on the block parameterization options, basic parameter descriptions, assumptions and limitations, global and restricted parameters, see the 4-Way Directional Valve block reference page.

## Parameters

- “Basic Parameters Tab” on page 1-171
- “Valve Opening Offsets Tab” on page 1-173

### Basic Parameters Tab

#### Model parameterization

Select one of the following methods for specifying the valve:

- **By maximum area and opening** — Provide values for the maximum valve passage area and the maximum valve opening. The passage area is linearly dependent on the control member displacement, that is, the valve is closed at the initial position of the control member (zero displacement), and the maximum opening takes place at the maximum displacement. This is the default method.
- **By area vs. opening table** — Provide tabulated data of valve openings and corresponding valve passage areas. The passage area is determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.
- **By pressure-flow characteristic** — Provide tabulated data of valve openings, pressure differentials, and corresponding flow rates. The flow rate is determined by two-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.

#### Valve passage maximum area

Specify the area of a fully opened valve. The parameter value must be greater than zero. The default value is  $5e-5 \text{ m}^2$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

#### Valve maximum opening

Specify the maximum displacement of the control member. The parameter value must be greater than zero. The default value is  $5e-3 \text{ m}$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

#### Valve opening vector, $s$

Specify the vector of input values for valve openings as a one-dimensional array. The input values vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear

interpolation, at least three values for smooth interpolation. The default values, in meters, are [-0.002 0 0.002 0.005 0.015]. If **Model parameterization** is set to **By area vs. opening table**, the **Tabulated valve openings** values will be used together with **Tabulated valve passage area** values for one-dimensional table lookup. If **Model parameterization** is set to **By pressure-flow characteristic**, the **Tabulated valve openings** values will be used together with **Tabulated pressure differentials** and **Tabulated flow rates** for two-dimensional table lookup.

### Valve passage area vector

Specify the vector of output values for valve passage area as a one-dimensional array. The valve passage area vector must be of the same size as the valve openings vector. All the values must be positive. The default values, in  $m^2$ , are [1e-09 2.0352e-07 4.0736e-05 0.00011438 0.00034356]. This parameter is used if **Model parameterization** is set to **By area vs. opening table**.

### Pressure differential vector, dp

Specify the vector of input values for pressure differentials as a one-dimensional array. The vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in Pa, are [-1e+07 -5e+06 -2e+06 2e+06 5e+06 1e+07]. This parameter is used if **Model parameterization** is set to **By pressure-flow characteristic**.

### Volumetric flow rate table, q(s,dp)

Specify the flow rates as an  $m$ -by- $n$  matrix, where  $m$  is the number of valve openings and  $n$  is the number of pressure differentials. Each value in the matrix specifies flow rate taking place at a specific combination of valve opening and pressure differential. The matrix size must match the dimensions defined by the input vectors. The default values, in  $m^3/s$ , are:

```
[-1e-07 -7.0711e-08 -4.4721e-08 4.4721e-08 7.0711e-08 1e-07;
-2.0352e-05 -1.4391e-05 -9.1017e-06 9.1017e-06 1.4391e-05 2.0352e-05;
-0.0040736 -0.0028805 -0.0018218 0.0018218 0.0028805 0.0040736;
-0.011438 -0.0080879 -0.0051152 0.0051152 0.0080879 0.011438;
-0.034356 -0.024293 -0.015364 0.015364 0.024293 0.034356;]
```

This parameter is used if **Model parameterization** is set to **By pressure-flow characteristic**.

### Interpolation method

Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- **Linear** — Select this option to get the best performance.
- **Smooth** — Select this option to produce a continuous curve (**By area vs. opening table**) or surface (**By pressure-flow characteristic**) with continuous first-order derivatives.

For more information on interpolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

### Extrapolation method

Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- **Linear** — Select this option to produce a curve or surface with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.

- **Nearest** — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

### **Flow discharge coefficient**

Semi-empirical parameter for valve capacity characterization. Its value depends on the geometrical properties of the valve, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.7.

### **Laminar transition specification**

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

### **Laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

### **Critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12, which corresponds to a round orifice in thin material with sharp edges. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

### **Leakage area**

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is  $1e-12 \text{ m}^2$ .

## **Valve Opening Offsets Tab**

### **Between ports P and A1**

Orifice opening of the **P-A1** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

### **Between ports P and A2**

Orifice opening of the **P-A2** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

### **Between ports A and T1**

Orifice opening of the **A-T1** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $2.5e-3 \text{ m}$ .

**Between ports T1 and T**

Orifice opening of the **T1-T** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $\theta$  corresponds to a zero-lapped valve. The default value is  $2.5e-3$  m.

**Between ports P and B**

Orifice opening of the **P-B** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $\theta$  corresponds to a zero-lapped valve. The default value is  $-2.5e-3$  m.

**Between ports B and T**

Orifice opening of the **B-T** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $\theta$  corresponds to a zero-lapped valve. The default value is  $2.5e-3$  m.

**Ports**

The block has the following ports:

P

Hydraulic conserving port associated with the pressure supply line inlet.

T

Hydraulic conserving port associated with the return line connection.

A

Hydraulic conserving port associated with the actuator connection port.

B

Hydraulic conserving port associated with the actuator connection port.

S

Physical signal port to control spool displacement.

**Version History****Introduced in R2009b****R2023a: To be removed**

### Library

Directional Valves

### Description

The 4-Way Directional Valve G block simulates a configuration of hydraulic continuous 4-way directional valve. Ports A and B are connected to port P in the right valve position. In the left position, port P is connected to port B, while port A is connected to port T. In neutral position, ports A and B are connected to port T. The fluid is pumped in the valve through the inlet line P and is distributed between two outside hydraulic lines A and B (usually connected to a double-acting actuator) and the return line T. The block has four hydraulic connections, corresponding to inlet port (P), actuator ports (A and B), and return port (T), and one physical signal port connection (S), which controls the spool position. The block is built of six Variable Orifice blocks, connected as shown in the following diagram.

All Variable Orifice blocks are controlled by the same position signal, provided through the physical signal port S, but the **Orifice orientation** parameter in the block instances is set in such a way that positive signal at port S opens the orifices colored blue in the block diagram (orifices P-B1, A-T, and T1-T) and closes the orifices colored yellow (orifices P-A, B-T1, and P-B2). As a result, the openings of the orifices are computed as follows:

$$h_{PB1} = h_{PB10} + x$$

$$h_{PB2} = h_{PB20} - x$$

$$h_{BT1} = h_{BT10} - x$$

$$h_{T1T} = h_{T1T0} + x$$

$$h_{PA} = h_{PA0} - x$$

$$h_{AT} = h_{AT0} + x$$

where

$h_{PB1}$	Orifice opening for the Variable Orifice P-B1 block
$h_{PB2}$	Orifice opening for the Variable Orifice P-B2 block
$h_{BT1}$	Orifice opening for the Variable Orifice B-T1 block
$h_{T1T}$	Orifice opening for the Variable Orifice T1-T block
$h_{PA}$	Orifice opening for the Variable Orifice P-A block
$h_{AT}$	Orifice opening for the Variable Orifice A-T block
$h_{PB10}$	Initial opening for the Variable Orifice P-B1 block
$h_{PB20}$	Initial opening for the Variable Orifice P-B2 block
$h_{BT10}$	Initial opening for the Variable Orifice B-T1 block
$h_{T1T0}$	Initial opening for the Variable Orifice T1-T block

$h_{PA0}$	Initial opening for the Variable Orifice P-A block
$h_{AT0}$	Initial opening for the Variable Orifice A-T block
$x$	Control member displacement from initial position

For information on the block parameterization options, basic parameter descriptions, assumptions and limitations, global and restricted parameters, see the 4-Way Directional Valve block reference page.

## Parameters

- “Basic Parameters Tab” on page 1-178
- “Valve Opening Offsets Tab” on page 1-180

### Basic Parameters Tab

#### Model parameterization

Select one of the following methods for specifying the valve:

- **By maximum area and opening** — Provide values for the maximum valve passage area and the maximum valve opening. The passage area is linearly dependent on the control member displacement, that is, the valve is closed at the initial position of the control member (zero displacement), and the maximum opening takes place at the maximum displacement. This is the default method.
- **By area vs. opening table** — Provide tabulated data of valve openings and corresponding valve passage areas. The passage area is determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.
- **By pressure-flow characteristic** — Provide tabulated data of valve openings, pressure differentials, and corresponding flow rates. The flow rate is determined by two-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.

#### Valve passage maximum area

Specify the area of a fully opened valve. The parameter value must be greater than zero. The default value is  $5e-5 \text{ m}^2$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

#### Valve maximum opening

Specify the maximum displacement of the control member. The parameter value must be greater than zero. The default value is  $5e-3 \text{ m}$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

#### Valve opening vector, $s$

Specify the vector of input values for valve openings as a one-dimensional array. The input values vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in meters, are  $[-0.002 \ 0 \ 0.002 \ 0.005 \ 0.015]$ . If **Model parameterization** is set to **By area vs. opening table**, the **Tabulated valve openings** values will be used together with **Tabulated valve passage area** values for one-dimensional table lookup. If **Model parameterization** is set to **By pressure-flow characteristic**, the **Tabulated valve openings** values will be used together with **Tabulated pressure differentials** and **Tabulated flow rates** for two-dimensional table lookup.

**Valve passage area vector**

Specify the vector of output values for valve passage area as a one-dimensional array. The valve passage area vector must be of the same size as the valve openings vector. All the values must be positive. The default values, in  $m^2$ , are [1e-09 2.0352e-07 4.0736e-05 0.00011438 0.00034356]. This parameter is used if **Model parameterization** is set to By area vs. opening table.

**Pressure differential vector, dp**

Specify the vector of input values for pressure differentials as a one-dimensional array. The vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in Pa, are [-1e+07 -5e+06 -2e+06 2e+06 5e+06 1e+07]. This parameter is used if **Model parameterization** is set to By pressure-flow characteristic.

**Volumetric flow rate table, q(s,dp)**

Specify the flow rates as an m-by-n matrix, where m is the number of valve openings and n is the number of pressure differentials. Each value in the matrix specifies flow rate taking place at a specific combination of valve opening and pressure differential. The matrix size must match the dimensions defined by the input vectors. The default values, in  $m^3/s$ , are:

```
[-1e-07 -7.0711e-08 -4.4721e-08 4.4721e-08 7.0711e-08 1e-07;
-2.0352e-05 -1.4391e-05 -9.1017e-06 9.1017e-06 1.4391e-05 2.0352e-05;
-0.0040736 -0.0028805 -0.0018218 0.0018218 0.0028805 0.0040736;
-0.011438 -0.0080879 -0.0051152 0.0051152 0.0080879 0.011438;
-0.034356 -0.024293 -0.015364 0.015364 0.024293 0.034356;]
```

This parameter is used if **Model parameterization** is set to By pressure-flow characteristic.

**Interpolation method**

Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- **Linear** — Select this option to get the best performance.
- **Smooth** — Select this option to produce a continuous curve (By area vs. opening table) or surface (By pressure-flow characteristic) with continuous first-order derivatives.

For more information on interpolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

**Extrapolation method**

Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- **Linear** — Select this option to produce a curve or surface with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.
- **Nearest** — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

**Flow discharge coefficient**

Semi-empirical parameter for valve capacity characterization. Its value depends on the geometrical properties of the valve, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.7.

**Laminar transition specification**

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

**Laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

**Critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12, which corresponds to a round orifice in thin material with sharp edges. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

**Leakage area**

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is  $1e-12 \text{ m}^2$ .

**Valve Opening Offsets Tab****Between ports P and B1**

Orifice opening of the **P-B1** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

**Between ports P and B2**

Orifice opening of the **P-B2** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

**Between ports B and T1**

Orifice opening of the **B-T1** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $2.5e-3 \text{ m}$ .

**Between ports T1 and T**

Orifice opening of the **T1-T** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $2.5e-3 \text{ m}$ .

**Between ports P and A**

Orifice opening of the **P-A** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $\theta$  corresponds to a zero-lapped valve. The default value is  $-2.5e-3$  m.

**Between ports A and T**

Orifice opening of the **B-T** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $\theta$  corresponds to a zero-lapped valve. The default value is  $2.5e-3$  m.

**Ports**

The block has the following ports:

**P**

Hydraulic conserving port associated with the pressure supply line inlet.

**T**

Hydraulic conserving port associated with the return line connection.

**A**

Hydraulic conserving port associated with the actuator connection port.

**B**

Hydraulic conserving port associated with the actuator connection port.

**S**

Physical signal port to control spool displacement.

### Library

Directional Valves

### Description

The 4-Way Directional Valve H block simulates a configuration of hydraulic continuous 4-way directional valve. Ports A and B are connected to port P in the left valve position. In the right position, port P is connected to port B, while port A is connected to port T. In neutral position, port P is connected to port T to unload the pump. The fluid is pumped in the valve through the inlet line P and is distributed between two outside hydraulic lines A and B (usually connected to a double-acting actuator) and the return line T. The block has four hydraulic connections, corresponding to inlet port (P), actuator ports (A and B), and return port (T), and one physical signal port connection (S), which controls the spool position. The block is built of six Variable Orifice blocks, connected as shown in the following diagram.

All Variable Orifice blocks are controlled by the same position signal, provided through the physical signal port S, but the **Orifice orientation** parameter in the block instances is set in such a way that positive signal at port S opens the orifices colored blue in the block diagram (orifices P-B2, P-A, and T1-T) and closes the orifices colored yellow (orifices P-B1, P-T1, and A-T). As a result, the openings of the orifices are computed as follows:

$$h_{PB1} = h_{PB10} - x$$

$$h_{PB2} = h_{PB20} + x$$

$$h_{PT1} = h_{PT10} - x$$

$$h_{T1T} = h_{T1T0} + x$$

$$h_{PA} = h_{PA0} + x$$

$$h_{AT} = h_{AT0} - x$$

where

$h_{PB1}$	Orifice opening for the Variable Orifice P-B1 block
$h_{PB2}$	Orifice opening for the Variable Orifice P-B2 block
$h_{PT1}$	Orifice opening for the Variable Orifice P-T1 block
$h_{T1T}$	Orifice opening for the Variable Orifice T1-T block
$h_{PA}$	Orifice opening for the Variable Orifice P-A block

$h_{AT}$	Orifice opening for the Variable Orifice A-T block
$h_{PB10}$	Initial opening for the Variable Orifice P-B1 block
$h_{PB20}$	Initial opening for the Variable Orifice P-B2 block
$h_{PT10}$	Initial opening for the Variable Orifice P-T1 block
$h_{T1T0}$	Initial opening for the Variable Orifice T1-T block
$h_{PA0}$	Initial opening for the Variable Orifice P-A block
$h_{AT0}$	Initial opening for the Variable Orifice A-T block
$x$	Control member displacement from initial position

For information on the block parameterization options, basic parameter descriptions, assumptions and limitations, global and restricted parameters, see the 4-Way Directional Valve block reference page.

## Parameters

- “Basic Parameters Tab” on page 1-184
- “Valve Opening Offsets Tab” on page 1-186

### Basic Parameters Tab

#### Model parameterization

Select one of the following methods for specifying the valve:

- **By maximum area and opening** — Provide values for the maximum valve passage area and the maximum valve opening. The passage area is linearly dependent on the control member displacement, that is, the valve is closed at the initial position of the control member (zero displacement), and the maximum opening takes place at the maximum displacement. This is the default method.
- **By area vs. opening table** — Provide tabulated data of valve openings and corresponding valve passage areas. The passage area is determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.
- **By pressure-flow characteristic** — Provide tabulated data of valve openings, pressure differentials, and corresponding flow rates. The flow rate is determined by two-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.

#### Valve passage maximum area

Specify the area of a fully opened valve. The parameter value must be greater than zero. The default value is  $5e-5 \text{ m}^2$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

#### Valve maximum opening

Specify the maximum displacement of the control member. The parameter value must be greater than zero. The default value is  $5e-3 \text{ m}$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

#### Valve opening vector, $s$

Specify the vector of input values for valve openings as a one-dimensional array. The input values vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear

interpolation, at least three values for smooth interpolation. The default values, in meters, are [-0.002 0 0.002 0.005 0.015]. If **Model parameterization** is set to **By area vs. opening table**, the **Tabulated valve openings** values will be used together with **Tabulated valve passage area** values for one-dimensional table lookup. If **Model parameterization** is set to **By pressure-flow characteristic**, the **Tabulated valve openings** values will be used together with **Tabulated pressure differentials** and **Tabulated flow rates** for two-dimensional table lookup.

#### Valve passage area vector

Specify the vector of output values for valve passage area as a one-dimensional array. The valve passage area vector must be of the same size as the valve openings vector. All the values must be positive. The default values, in  $m^2$ , are [1e-09 2.0352e-07 4.0736e-05 0.00011438 0.00034356]. This parameter is used if **Model parameterization** is set to **By area vs. opening table**.

#### Pressure differential vector, dp

Specify the vector of input values for pressure differentials as a one-dimensional array. The vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in Pa, are [-1e+07 -5e+06 -2e+06 2e+06 5e+06 1e+07]. This parameter is used if **Model parameterization** is set to **By pressure-flow characteristic**.

#### Volumetric flow rate table, q(s,dp)

Specify the flow rates as an  $m$ -by- $n$  matrix, where  $m$  is the number of valve openings and  $n$  is the number of pressure differentials. Each value in the matrix specifies flow rate taking place at a specific combination of valve opening and pressure differential. The matrix size must match the dimensions defined by the input vectors. The default values, in  $m^3/s$ , are:

```
[-1e-07 -7.0711e-08 -4.4721e-08 4.4721e-08 7.0711e-08 1e-07;
-2.0352e-05 -1.4391e-05 -9.1017e-06 9.1017e-06 1.4391e-05 2.0352e-05;
-0.0040736 -0.0028805 -0.0018218 0.0018218 0.0028805 0.0040736;
-0.011438 -0.0080879 -0.0051152 0.0051152 0.0080879 0.011438;
-0.034356 -0.024293 -0.015364 0.015364 0.024293 0.034356;]
```

This parameter is used if **Model parameterization** is set to **By pressure-flow characteristic**.

#### Interpolation method

Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- **Linear** — Select this option to get the best performance.
- **Smooth** — Select this option to produce a continuous curve (**By area vs. opening table**) or surface (**By pressure-flow characteristic**) with continuous first-order derivatives.

For more information on interpolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

#### Extrapolation method

Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- **Linear** — Select this option to produce a curve or surface with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.

- **Nearest** — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

### **Flow discharge coefficient**

Semi-empirical parameter for valve capacity characterization. Its value depends on the geometrical properties of the valve, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.7.

### **Laminar transition specification**

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

### **Laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

### **Critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12, which corresponds to a round orifice in thin material with sharp edges. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

### **Leakage area**

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is  $1e-12 \text{ m}^2$ .

## **Valve Opening Offsets Tab**

### **Between ports P and B1**

Orifice opening of the **P-B1** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

### **Between ports P and B2**

Orifice opening of the **P-B2** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

### **Between ports P and T1**

Orifice opening of the **P-T1** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $2.5e-3 \text{ m}$ .

**Between ports T1 and T**

Orifice opening of the **T1-T** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $\theta$  corresponds to a zero-lapped valve. The default value is  $2.5e-3$  m.

**Between ports P and A**

Orifice opening of the **P-A** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $\theta$  corresponds to a zero-lapped valve. The default value is  $-2.5e-3$  m.

**Between ports A and T**

Orifice opening of the **A-T** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $\theta$  corresponds to a zero-lapped valve. The default value is  $2.5e-3$  m.

**Ports**

The block has the following ports:

P

Hydraulic conserving port associated with the pressure supply line inlet.

T

Hydraulic conserving port associated with the return line connection.

A

Hydraulic conserving port associated with the actuator connection port.

B

Hydraulic conserving port associated with the actuator connection port.

S

Physical signal port to control spool displacement.

**Version History****Introduced in R2009b****R2023a: To be removed**

### Library

Directional Valves

### Description

The 4-Way Directional Valve K block simulates a configuration of hydraulic continuous 4-way directional valve. Ports A and B are connected to port P in the right valve position. In the left position, port P is connected to port B, while port A is connected to port T. In neutral position, port P is connected to port T to unload the pump. The fluid is pumped in the valve through the inlet line P and is distributed between two outside hydraulic lines A and B (usually connected to a double-acting actuator) and the return line T. The block has four hydraulic connections, corresponding to inlet port (P), actuator ports (A and B), and return port (T), and one physical signal port connection (S), which controls the spool position. The block is built of six Variable Orifice blocks, connected as shown in the following diagram.

All Variable Orifice blocks are controlled by the same position signal, provided through the physical signal port S, but the **Orifice orientation** parameter in the block instances is set in such a way that positive signal at port S opens the orifices colored blue in the block diagram (orifices P-A1, P-T1, and B-T) and closes the orifices colored yellow (orifices P-A2, P-B, and T1-T). As a result, the openings of the orifices are computed as follows:

$$h_{PA1} = h_{PA10} + x$$

$$h_{PA2} = h_{PA20} - x$$

$$h_{PT1} = h_{PT10} + x$$

$$h_{T1T} = h_{T1T0} - x$$

$$h_{PB} = h_{PB0} - x$$

$$h_{BT} = h_{BT0} + x$$

where

$h_{PA1}$	Orifice opening for the Variable Orifice P-A1 block
$h_{PA2}$	Orifice opening for the Variable Orifice P-A2 block
$h_{PT1}$	Orifice opening for the Variable Orifice P-T1 block
$h_{T1T}$	Orifice opening for the Variable Orifice T1-T block
$h_{PB}$	Orifice opening for the Variable Orifice P-B block
$h_{BT}$	Orifice opening for the Variable Orifice B-T block
$h_{PA10}$	Initial opening for the Variable Orifice P-A1 block
$h_{PA20}$	Initial opening for the Variable Orifice P-A2 block

$h_{PT10}$	Initial opening for the Variable Orifice P-T1 block
$h_{T1T0}$	Initial opening for the Variable Orifice T1-T block
$h_{PB0}$	Initial opening for the Variable Orifice P-B block
$h_{BT0}$	Initial opening for the Variable Orifice B-T block
$x$	Control member displacement from initial position

For information on the block parameterization options, basic parameter descriptions, assumptions and limitations, global and restricted parameters, see the 4-Way Directional Valve block reference page.

## Parameters

- “Basic Parameters Tab” on page 1-191
- “Valve Opening Offsets Tab” on page 1-193

### Basic Parameters Tab

#### Model parameterization

Select one of the following methods for specifying the valve:

- **By maximum area and opening** — Provide values for the maximum valve passage area and the maximum valve opening. The passage area is linearly dependent on the control member displacement, that is, the valve is closed at the initial position of the control member (zero displacement), and the maximum opening takes place at the maximum displacement. This is the default method.
- **By area vs. opening table** — Provide tabulated data of valve openings and corresponding valve passage areas. The passage area is determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.
- **By pressure-flow characteristic** — Provide tabulated data of valve openings, pressure differentials, and corresponding flow rates. The flow rate is determined by two-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.

#### Valve passage maximum area

Specify the area of a fully opened valve. The parameter value must be greater than zero. The default value is  $5e-5 \text{ m}^2$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

#### Valve maximum opening

Specify the maximum displacement of the control member. The parameter value must be greater than zero. The default value is  $5e-3 \text{ m}$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

#### Valve opening vector, $s$

Specify the vector of input values for valve openings as a one-dimensional array. The input values vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in meters, are  $[-0.002 \ 0 \ 0.002 \ 0.005 \ 0.015]$ . If **Model parameterization** is set to **By area vs. opening table**, the **Tabulated valve openings** values will be used together with **Tabulated valve passage area** values for one-dimensional table lookup. If **Model parameterization** is set

to By pressure-flow characteristic, the **Tabulated valve openings** values will be used together with **Tabulated pressure differentials** and **Tabulated flow rates** for two-dimensional table lookup.

### Valve passage area vector

Specify the vector of output values for valve passage area as a one-dimensional array. The valve passage area vector must be of the same size as the valve openings vector. All the values must be positive. The default values, in  $m^2$ , are [1e-09 2.0352e-07 4.0736e-05 0.00011438 0.00034356]. This parameter is used if **Model parameterization** is set to By area vs. opening table.

### Pressure differential vector, dp

Specify the vector of input values for pressure differentials as a one-dimensional array. The vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in Pa, are [-1e+07 -5e+06 -2e+06 2e+06 5e+06 1e+07]. This parameter is used if **Model parameterization** is set to By pressure-flow characteristic.

### Volumetric flow rate table, q(s,dp)

Specify the flow rates as an m-by-n matrix, where m is the number of valve openings and n is the number of pressure differentials. Each value in the matrix specifies flow rate taking place at a specific combination of valve opening and pressure differential. The matrix size must match the dimensions defined by the input vectors. The default values, in  $m^3/s$ , are:

```
[-1e-07 -7.0711e-08 -4.4721e-08 4.4721e-08 7.0711e-08 1e-07;
-2.0352e-05 -1.4391e-05 -9.1017e-06 9.1017e-06 1.4391e-05 2.0352e-05;
-0.0040736 -0.0028805 -0.0018218 0.0018218 0.0028805 0.0040736;
-0.011438 -0.0080879 -0.0051152 0.0051152 0.0080879 0.011438;
-0.034356 -0.024293 -0.015364 0.015364 0.024293 0.034356;]
```

This parameter is used if **Model parameterization** is set to By pressure-flow characteristic.

### Interpolation method

Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- Linear — Select this option to get the best performance.
- Smooth — Select this option to produce a continuous curve (By area vs. opening table) or surface (By pressure-flow characteristic) with continuous first-order derivatives.

For more information on interpolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

### Extrapolation method

Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- Linear — Select this option to produce a curve or surface with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.
- Nearest — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

**Flow discharge coefficient**

Semi-empirical parameter for valve capacity characterization. Its value depends on the geometrical properties of the valve, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.7.

**Laminar transition specification**

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

**Laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

**Critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12, which corresponds to a round orifice in thin material with sharp edges. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

**Leakage area**

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is  $1e-12 \text{ m}^2$ .

**Valve Opening Offsets Tab****Between ports P and A1**

Orifice opening of the **P-A1** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

**Between ports P and A2**

Orifice opening of the **P-A2** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

**Between ports P and T1**

Orifice opening of the **P-T1** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $2.5e-3 \text{ m}$ .

**Between ports T1 and T**

Orifice opening of the **T1-T** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $2.5e-3 \text{ m}$ .

**Between ports P and B**

Orifice opening of the **P-B** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $\theta$  corresponds to a zero-lapped valve. The default value is  $-2.5e-3$  m.

**Between ports B and T**

Orifice opening of the **B-T** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $\theta$  corresponds to a zero-lapped valve. The default value is  $2.5e-3$  m.

**Ports**

The block has the following ports:

P

Hydraulic conserving port associated with the pressure supply line inlet.

T

Hydraulic conserving port associated with the return line connection.

A

Hydraulic conserving port associated with the actuator connection port.

B

Hydraulic conserving port associated with the actuator connection port.

S

Physical signal port to control spool displacement.

**Version History****Introduced in R2009b****R2023a: To be removed**

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

## 4-Way 3-Position Directional Valve (G)

Controlled valve with four ports in a gas network

### Libraries:

Simscape / Fluids / Gas / Valves & Orifices / Directional Control Valves

### Description

The 4-Way 3-Position Directional Valve (G) block represents a valve with four gas ports (**P**, **A**, **B**, and **T**) and flow paths between **P-A** and **A-T** and between **P-B** and **B-T**. The paths each run through an orifice of variable width. The input signal specified at port **S** controls the position of the spool. The valve closes when the spool covers the orifice opening.

In a representative system, the **P** port connects to the pump, the **T** port connects to the tank, and the **A** and **B** ports connect to a double-sided actuator. Opening the **P-A** and **B-T** flow paths allows the pump to pressurize one side of the actuator and the tank to relieve the other. The actuator shaft translates to extend in some systems and retract in others. Opening the **P-B** and **A-T** flow paths flips the pressurized and relieved sides of the actuator so that the shaft can translate in reverse.

This image shows a common use for a four-way, three-position directional valve in a physical system:

The flow can be laminar or turbulent, and it can reach up to sonic speeds. The maximum velocity happens at the throat of the valve where the flow is narrowest and fastest. The flow chokes and the velocity saturates when a drop in downstream pressure can no longer increase the velocity. Choking occurs when the back-pressure ratio reaches the critical value characteristic of the valve. The block does not capture supersonic flow.

## Valve Positions

The valve is continuously variable and it shifts smoothly between one normal and two working positions.

When the instantaneous displacement of the spool at port **S** is zero, the valve reverts to the normal position where it is no longer operating. Unless the lands of the spool are at an offset to their orifices, the valve is fully closed. The working positions are the positions the valve moves to when the spool is maximally displaced from its normal position. That displacement is positive in one case and negative in the other.

Image **I** shows a valve where the displacement is positive, the **P-A** and **B-T** orifices are fully open, and the **P-B** and **A-T** orifices are fully closed. Image **II** shows a valve where the displacement is negative, the **P-A** and **B-T** orifices are fully closed, and the **P-B** and **A-T** orifices are fully open. Image **III** shows a valve where the spool is in the neutral position and all the orifices are closed.

The spool displacement that puts the valve in its working position depends on the offsets of the lands on the spool. The parameters in the **Valve Opening Fraction Offsets** section specify the block constants for the spool displacements of the ports.

### Orifice Opening Fractions

Between valve positions, the opening of an orifice depends on where the land of the spool is, relative to the rim. This distance is the orifice opening, and the block normalizes this distance so that its value is a fraction of the maximum distance at which the orifice is fully open. The normalized variable is the orifice opening fraction.

The orifice opening fractions range from -1 when the valve is in the position shown in image **I** to +1 when the valve is in the position shown in image **II**.

The block calculates the opening fractions from the spool displacement and opening fraction offset. The displacement and offset are unitless fractions of the maximum land-orifice distance.

The opening fraction of the **P-A** orifice is:

$$h_{\mathbf{PA}} = H_{\mathbf{PA}} + x.$$

The opening fraction of the **B-T** orifice is:

$$h_{\mathbf{BT}} = H_{\mathbf{BT}} + x.$$

The opening fraction of the **A-T** orifice is:

$$h_{\mathbf{AT}} = H_{\mathbf{AT}} - x.$$

The opening fraction of the **P-B** orifice is:

$$h_{\mathbf{PB}} = H_{\mathbf{PB}} - x.$$

In the equations:

- $h$  is the opening fraction for the orifice. If the calculation returns a value outside of the range 0 - 1, the block uses the nearest limit.
- $H$  is the opening fraction offset for the orifice. The parameters in the **Valve Opening Fraction Offsets** section specify the opening fraction offsets. To allow for unusual valve configurations, the block imposes no limit on their values, although they are typically between -1 and +1.
- $x$  is the normalized instantaneous displacement of the spool, specified by a physical signal at port **S**. To compensate for extreme opening fraction offsets, there is no limit on the signal value. The value is typically between -1 and +1.

### Opening Fraction Offsets

By default, the valve is fully closed when its control displacement is zero. In this state, the valve is zero-lapped.

You can offset the lands of the spool to model an underlapped or overlapped valve. Underlapped valves are partially open in the normal position. Overlapped valves are fully closed slightly beyond the normal position. The figure shows how the orifice opening fractions vary with the instantaneous spool displacement:

- Image **I**: A zero-lapped valve. The opening fraction offsets are all zero. When the valve is in the normal position, the lands of the spool completely cover all four orifices.
- Image **II**: An underlapped valve. The **P-A** and **B-T** opening fraction offsets are positive and the **P-B** and the **A-T** opening fraction offsets are negative. When the valve is in the normal position, the lands of the spool partially cover the four orifices.
- Image **III**: An overlapped valve. The **P-A** and **B-T** opening fraction offsets are negative and the **P-B** and the **A-T** opening fraction offsets are positive. The control member completely covers all orifices not only in the normal position but over a small region of spool displacements around it.

### Valve Parameterizations

The block behavior depends on the **Valve parametrization** parameter:

- **Cv flow coefficient** — The flow coefficient  $C_v$  determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential. [2][3]
- **Kv flow coefficient** — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential. [2][3]
- **Sonic conductance** — The sonic conductance of the resistive element at steady state determines the block parameterization. The sonic conductance measures the ease with which a gas can flow when *choked*, which is a condition in which the flow velocity is at the local speed of sound. Choking occurs when the ratio between downstream and upstream pressures reaches a critical value known as the *critical pressure ratio*. [1]
- **Orifice area** — The size of the flow restriction determines the block parameterization. [4]

### Opening Characteristics

The flow characteristic relates the opening of the valve to the input that produces it, which is often the spool travel. The block expresses the opening as a sonic conductance, flow coefficient, or restriction area, depending on the setting of the **Valve parametrization** parameter. The control input is the orifice opening fraction, a function of the spool displacement specified at port **S**.

The flow characteristic is normally given at steady state, with the inlet at a constant, carefully controlled pressure. The flow characteristic depends only on the valve and can be linear or nonlinear. To capture the flow characteristics, use the **Opening characteristic** parameter:

- **Linear** — The measure of flow capacity is a linear function of the orifice opening fraction. As the opening fraction rises from 0 to 1, the measure of flow capacity scales from the specified minimum to the specified maximum.

- **Tabulated** — The measure of flow capacity is a general function, which can be linear or nonlinear, of the orifice opening fraction. The function is specified in tabulated form, with the independent variable specified by the **Opening fraction vector**.

### Numerical Smoothing

When the **Opening characteristic** parameter is Linear, and the **Smoothing factor** parameter is nonzero, the block applies numerical smoothing to the orifice opening fraction. Enabling smoothing helps maintain numerical robustness in your simulation.

For more information, see “Numerical Smoothing”.

### Leakage Flow

The leakage flow ensures that no section of a fluid network becomes isolated. Isolated fluid sections can reduce the numerical robustness of the model, slow the rate of simulation and, in some cases, cause the simulation to fail. The **Leakage flow fraction** parameter represents the leakage flow area in the block as a small number greater than zero.

### Composite Structure

This block is a composite component comprising four instances of the Orifice (G) block connected to ports **P**, **A**, **B**, **T**, and **S**. Refer to the Orifice (G) block for more detail on the valve parameterizations and block calculations.

### Assumptions and Limitations

- The Sonic conductance setting of the **Valve parameterization** parameter is for pneumatic applications. If you use this setting for gases other than air, you may need to scale the sonic conductance by the square root of the specific gravity.
- The equation for the Orifice area parameterization is less accurate for gases that are far from ideal.
- This block does not model supersonic flow.

## Ports

### Input

**S** — Valve control signal, unitless  
physical signal

Instantaneous displacement of the control member against its normal unactuated position, specified as a physical signal. The block normalizes the displacement against the maximum position of the control member that required to open the orifice fully. The signal is unitless and its instantaneous value is typically in the range between -1 and +1.

### Conserving

**A** — Valve opening  
gas

Gas conserving port associated with the opening through which the flow enters or exits the valve.

**B** — Valve opening  
gas

Gas conserving port associated with the opening through which the flow enters or exits the valve.

**P** — Valve opening  
gas

Gas conserving port associated with the opening through which the flow enters or exits the valve.

**T** — Valve opening  
gas

Gas conserving port associated with the opening through which the flow enters or exits the valve.

## Parameters

**Valve parameterization** — Parameterization used to specify flow characteristics of orifice  
Cv flow coefficient (default) | Kv flow coefficient | Sonic conductance | Orifice area

Method to calculate the mass flow rate.

- Cv flow coefficient — The flow coefficient  $C_v$  determines the block parameterization.
- Kv flow coefficient — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization.
- Sonic conductance — The sonic conductance of the resistive element at steady state determines the block parameterization.
- Orifice area — The size of the flow restriction determines the block parametrization.

**Opening characteristic** — Method to calculate the opening characteristics of the valve  
Linear (default) | Tabulated

Method the block uses to calculate the opening area of the valve. The linear setting treats the opening area as a linear function of the orifice opening fraction. The tabulated setting allows for a general, nonlinear relationship you can specify in tabulated form.

**Opening fraction vector** — Control signal values at which to specify tabulated parameter data  
 $\theta$  :  $0.2$  :  $1$  (default) | vector of positive numbers

Vector of control signal values at which to specify the chosen measure of flow capacity: **Sonic conductance vector**, **Cv coefficient vector**, **Kv coefficient vector**, or **Orifice area vector**. The control signal is between  $\theta$  and  $1$ , with each value corresponding to an opening fraction of the resistive element. The greater the value, the greater the opening and easier the flow.

The opening fractions must increase monotonically across the vector from left to right. The size of this vector must be the same as the **Sonic conductance vector**, **Cv coefficient vector**, **Kv coefficient vector**, or **Orifice area vector** parameter.

#### Dependencies

To enable this parameter, set **Opening characteristic** to Tabulated.

**Maximum Cv flow coefficient** — Cv coefficient that corresponds to maximally open component  
 $4$  (default) | positive scalar

Value of the  $C_v$  flow coefficient when the restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Cv flow coefficient, and **Opening characteristic** to Linear.

**xT pressure differential ratio factor at choked flow** — Ratio of pressure differentials  
 $0.7$  (default) | positive scalar

Ratio between the inlet pressure,  $p_{in}$ , and the outlet pressure,  $p_{out}$ , defined as  $(p_{in} - p_{out})/p_{in}$  where choking first occurs. If you do not have this value, look it up in table 2 in ISA-75.01.01 [3]. Otherwise, the default value of  $0.7$  is reasonable for many valves.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Cv flow coefficient or Kv flow coefficient.

**Leakage flow fraction** — Ratio of flow rates  
 $1e-6$  (default) | positive scalar

Ratio of the flow rate of the orifice when it is closed to when it is open.

#### Dependencies

To enable this parameter, set **Opening characteristic** to Linear.

**Smoothing factor** — Numerical smoothing factor  
 $0.01$  (default) | positive scalar in the range  $[0,1]$

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the orifice is in near-open or near-closed positions. Set this parameter to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Dependencies**

To enable this parameter, set **Opening characteristic** to Linear.

**Cv flow coefficient vector** — Cv coefficients corresponding to values in opening fraction vector [1e-06, .8, 1.6, 2.4, 3.2, 4] (default) | vector of positive numbers

Vector of  $C_v$  flow coefficients. Each coefficient corresponds to a value in the **Opening fraction vector** parameter. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential. The flow coefficients must increase monotonically from left to right, with greater opening fractions representing greater flow coefficients. The size of the vector must be the same as the **Opening fraction vector**.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Cv flow coefficient, and **Opening characteristic** to Tabulated.

**Maximum Kv flow coefficient** — Kv coefficient that corresponds to maximally open component 3.6 (default) | positive scalar

Value of the  $K_v$  flow coefficient when the restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Kv flow coefficient, and **Opening characteristic** to Linear.

**Kv flow coefficient vector** — Kv coefficients corresponding to values in opening fraction vector [1e-06, .72, 1.44, 2.16, 2.88, 3.6] (default) | vector of positive numbers

Vector of  $K_v$  flow coefficients. Each coefficient corresponds to a value in the **Opening fraction vector** parameter. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential. The flow coefficients must increase monotonically from left to right, with greater opening fractions representing greater flow coefficients. The size of the vector must be the same as the **Opening fraction vector** parameter.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Kv flow coefficient, and **Opening characteristic** to Tabulated.

**Maximum sonic conductance** — Sonic conductance corresponding to maximally open component 12  $\text{l}/(\text{bar}\cdot\text{s})$  (default) | positive scalar

Value of the sonic conductance when the cross-sectional area available for flow is at a maximum.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance, and **Opening characteristic** to Linear.

**Critical pressure ratio** — Ratio of downstream and upstream pressures at which the flow first chokes  
0.3 (default) | positive scalar

Pressure ratio at which flow first begins to choke and the flow velocity reaches its maximum, given by the local speed of sound. The pressure ratio is the outlet pressure divided by inlet pressure.

**Dependencies**

To enable this parameter, set **Valve parameterization** to **Sonic conductance**, and **Opening characteristic** to **Linear**.

**Subsonic index** — Exponent used to characterize mass flow in subsonic flow regime  
0.5 (default) | positive scalar

Empirical value used to more accurately calculate the mass flow rate in the subsonic flow regime.

**Dependencies**

To enable this parameter, set **Valve parameterization** to **Sonic conductance**.

**ISO reference temperature** — ISO 8778 reference temperature  
293.15 K (default) | scalar

Temperature at standard reference atmosphere, defined as 293.15 K in ISO 8778.

**Dependencies**

To enable this parameter, set **Valve parameterization** to **Sonic conductance**.

**ISO reference density** — ISO 8778 reference density  
1.185 kg/m<sup>3</sup> (default) | positive scalar

Density at standard reference atmosphere, defined as 1.185 kg/m<sup>3</sup> in ISO 8778.

**Dependencies**

To enable this parameter, set **Valve parameterization** to **Sonic conductance**.

**Sonic conductance vector** — Sonic conductances corresponding to values in opening fraction vector  
[1e-05, 2.4, 4.8, 7.2, 9.6, 12] 1/(bar\*s) (default) | vector of positive values

Vector of sonic conductances inside the resistive element. Each conductance corresponds to a value in the **Opening fraction vector** parameter. The sonic conductances must increase monotonically from left to right, with greater opening fractions representing greater sonic conductances. The size of the vector must be the same as the **Opening fraction vector** parameter.

**Dependencies**

To enable this parameter, set **Valve parameterization** to **Sonic conductance**, and **Opening characteristic** to **Tabulated**.

**Critical pressure ratio vector** — Critical pressure ratios corresponding to values in opening fraction vector  
0.3 \* ones(1,6) (default) | vector of positive numbers

Vector of critical pressure ratios at which the flow first chokes, with each critical pressure ratio corresponding to a value in the **Opening fraction vector** parameter. The critical pressure ratio is

the fraction of downstream-to-upstream pressures at which the flow velocity reaches the local speed of sound. The size of the vector must be the same as the **Opening fraction vector** parameter.

**Dependencies**

To enable this parameter, set **Valve parameterization** to `Sonic` conductance, and **Opening characteristic** to `Tabulated`.

**Maximum orifice area** — Flow area corresponding to maximally open component  
`1e-4 m2` (default) | positive scalar

Cross-sectional area of the orifice opening when the cross-sectional area available for flow is at a maximum.

**Dependencies**

To enable this parameter, set **Valve parameterization** to `Orifice` area, and **Opening characteristic** to `Linear`.

**Discharge coefficient** — Discharge coefficient  
`0.64` (default) | positive scalar in the range of `[0,1]`

Correction factor that accounts for discharge losses in theoretical flows.

**Dependencies**

To enable this parameter, set **Valve parameterization** to `Orifice` area.

**Orifice area vector** — Vector of orifice opening area values  
`[1e-10, 2e-05, 4e-05, 6e-05, 8e-05, .0001]` m<sup>2</sup> (default) | vector

Vector of cross-sectional areas of the orifice opening. The values in this vector correspond one-to-one with the elements in the **Opening fraction vector** parameter. The first element of this vector is the orifice leakage area and the last element is the maximum orifice area.

**Dependencies**

To enable this parameter, set **Valve parameterization** to `Orifice` area, and **Opening characteristic** to `Tabulated`.

**Laminar flow pressure ratio** — Pressure ratio at which flow transitions between laminar and turbulent regimes  
`0.999` (default) | positive scalar

Pressure ratio at which flow transitions between laminar and turbulent flow regimes. The pressure ratio is the outlet pressure divided by inlet pressure. Typical values range from `0.995` to `0.999`.

**Cross-sectional area at ports A, B, P, and T** — Area normal to the flow path at the valve ports  
`0.01 m2` (default) | positive scalar in units of area

Area normal to the flow path at the valve ports. The ports are assumed to be of the same size. The flow area specified here should ideally match those of the inlets of adjoining components.

**Valve Opening Fraction Offsets**

**Between Ports P and A** — Opening fraction offset for the P-A orifice  
`0` (default) | unitless scalar

Opening fraction of the **P-A** orifice when the value of the input signal **S** is zero. The valve is then in the normal position. The opening fraction measures the distance of a land of the spool to its appointed orifice, here **P-A**, normalized by the maximum such distance. It is unitless and generally between 0 and 1.

**Between Ports B and T** — Opening fraction offset for the B-T orifice  
0 (default) | unitless scalar

Opening fraction of the **B-T** orifice when the value of the input signal **S** is zero. The valve is then in the normal position. The opening fraction measures the distance of a land of the spool to its appointed orifice, here **B-T**, normalized by the maximum such distance. It is unitless and generally between 0 and 1.

**Between Ports P and B** — Opening fraction offset for the P-B orifice  
0 (default) | unitless scalar

Opening fraction of the **P-B** orifice when the value of the input signal **S** is zero. The valve is then in the normal position. The opening fraction measures the distance of a land of the spool to its appointed orifice, here **P-B**, normalized by the maximum such distance. It is unitless and generally between 0 and 1.

**Between Ports A and T** — Opening fraction offset for the A-T orifice  
0 (default) | unitless scalar

Opening fraction of the **A-T** orifice when the value of the input signal **S** is zero. The valve is then in the normal position. The opening fraction measures the distance of a land of the spool to its appointed orifice, here **A-T**, normalized by the maximum such distance. It is unitless and generally between 0 and 1.

## Version History

### Introduced in R2018b

#### R2022b: Model gas systems using improved flow computations

In previous versions, the blocks in the gas library used a conversion factor to implement different orifice parameterizations in terms of sonic conductance. You can use the **Valve parameterization** parameter to specify the parameterization.

The new parameterizations also include new parameters:

- **xT pressure differential ratio factor at choked flow**
- **Discharge coefficient**
- **Leakage flow fraction.** This parameter replaces the **Cv coefficient (USCS) at leakage flow**, **Kv coefficient (SI) at leakage flow**, **Sonic conductance at leakage flow**, and **Restriction area at leakage flow** parameters.

To improve clarity:

- The **Opening parameterization** parameter has been renamed to **Opening characteristic**.
- The **Reference temperature** and **Reference density** parameters have been renamed to **ISO reference temperature** and **ISO reference density**, respectively.

- The **Cv coefficient (USCS) at maximum flow** and **Kv coefficient (USCS) at maximum flow** parameters have been renamed to **Maximum Cv coefficient** and **Maximum Kv coefficient** , respectively.
- The **Sonic conductance at maximum flow** parameter has been renamed to **Maximum sonic conductance**.

**R2022b: Updated block name**

The title of the 4-Way Directional Valve (G) block changed to 4-Way 3-Position Directional Valve (G).

Orifice (G) | 2-Way Directional Valve (G) | 3-Way Directional Valve (G)

## 4-Way 2-Position Directional Valve (IL)

4-way, 2-position directional valve in an isothermal liquid network

### Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Directional Control Valves

### Description

The 4-Way 2-Position Directional Valve (IL) block models a valve with four openings in an isothermal liquid network, typically between an actuator, pump, and tank. The valve operation is controlled by a single spool displaced according to the signal at port **S**. You can set the baseline configuration of your valve by specifying the orifices that are open when the spool moves in the positive direction and negative directions in the **Positive spool position open connections** and **Negative spool position open connections** parameters, respectively.

You can set the model for valve opening in the **Orifice parameterization** parameter as a linear relationship or function of user-provided data, which can be applied to one or all flow paths in the valve.

In some configurations, this valve resembles a 3-way valve. To set additional flow paths when the spool is in the neutral position, see the 4-Way 3-Position Directional Valve (IL) block.

### Example Valve Setup

In this configuration, **Negative spool position open connections** is set to P-A and B-T. When the signal at port **S** moves the spool to a negative position, the paths between ports **P** and **A** and between

ports **B** and **T** are open to flow. The paths between ports **P** and **B** and ports **A** and **T** are closed to flow:

In this configuration, **Positive spool position open connections** is set to P-B and A-T. When the signal at port **S** moves the spool to a positive position, the paths between ports **P** and **B** and between ports **A** and **T** are open to flow and the paths between ports **P** and **A** and between ports **B** and **T** are closed:

Schematically, this configuration is:

The left-hand side corresponds to the positive position and the right-hand side corresponds to the negative position. The valve transitions through positions in the neutral mid-section.

### Spool Displacement and Valve Configuration

The *spool stroke* is the amount of spool travel an orifice takes to fully open from a closed position and is defined for each orifice selected on the **Valve Configuration** tab. The table below shows how the stroke is calculated in accordance with the valve orifice parameterization and flow path characteristics.

**Spool Stroke Based on Parameterization and Flow Path**

<b>Orifice Parameterization</b>	<b>Identical for All Flow Paths</b>	<b>Different for Each Flow Path</b>
Linear - Area vs. spool travel	Defined by the <b>Spool travel between closed and open orifice</b> parameter	Defined by the Spool travel between closed and open orifice parameter, for each orifice
Tabulated data - Area vs. spool travel	The difference between the first and last element of the <b>Spool travel vector</b> parameter	The difference between the first and last element of the spool travel vector parameter for each orifice
Tabulated data - Volumetric flow rate vs. spool travel and pressure drop	The difference between the first and last element of the <b>Spool travel vector, ds</b> parameter	The difference between the first and last element of the spool travel vector, ds parameter for each orifice

To see the orientation of all valve orifices, see the “Visualize Orifice Openings” on page 1-256 section.

The direction of spool movement signaled at port **S** depends on the spool stroke and the orifice orientation:

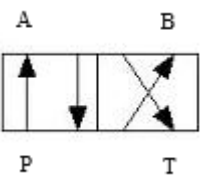

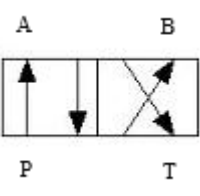

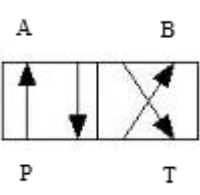

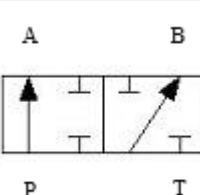

**Orifice Definition and Spool Travel Direction**

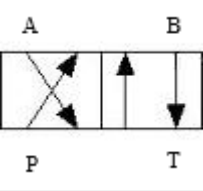

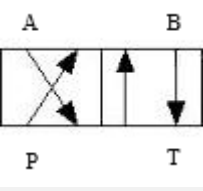

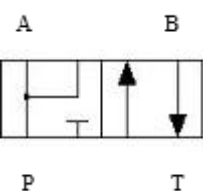

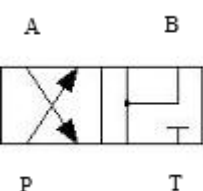

<b>Spool Position when Orifice is Open</b>	<b>Spool Travel, <math>\Delta S</math></b>
Always closed (orifice is not selected in any spool position configuration)	N/A
Always open (orifice is selected in positive, neutral, and negative spool position configurations)	N/A
Negative	$S_{\text{orifice\_max}} + \text{spool stroke} - \mathbf{S}$
Positive	$S_{\text{orifice\_max}} - \text{spool stroke} + \mathbf{S}$

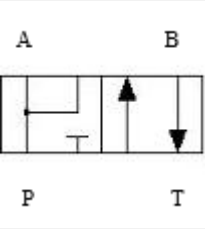

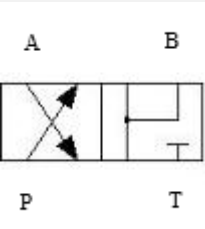

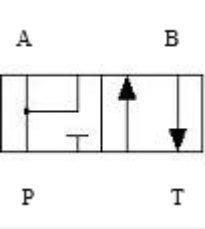

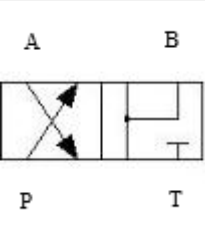

Where  $S_{\text{orifice\_max}}$  is the spool position at the maximum orifice area defined for each orifice. The orifice area saturates at the leakage area when  $\Delta S$  is negative and saturates at the maximum orifice area when the orifice is fully open. When the orifice is fully open,  $\Delta S$  is equal to the spool stroke, so  $\Delta S$  greater than the spool stroke does not further increase the orifice area.

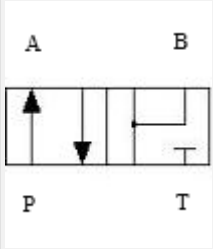

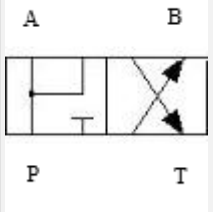

The possible configurations of the 4-Way 2-Position Directional Valve (IL) block are shown below.

4-Way 2-Position Directional Valve Configuration

Configuration	Parameter Values
 <p>All four paths are closed during transition.</p>	<ul style="list-style-type: none"> <li>• <b>Positive spool position open connections:</b> P-A and B-T</li> <li>• <b>Negative spool position open connections:</b> P-B and A-T</li> <li>• <b>Spool position at maximum P-A orifice area</b> &gt; P-A spool stroke</li> <li>• <b>Spool position at maximum P-B orifice area</b> &lt; -P-B spool stroke</li> <li>• <b>Spool position at maximum A-T orifice area</b> &lt; -A-T spool stroke</li> <li>• <b>Spool position at maximum B-T orifice area</b> &gt; B-T spool stroke</li> </ul>

Configuration	Parameter Values
 <p>P-A is closed during transition.</p>	<ul style="list-style-type: none"> <li>• <b>Positive spool position open connections:</b> P-A and B-T</li> <li>• <b>Negative spool position open connections:</b> P-A and P-B</li> <li>• <b>Spool position at maximum P-A orifice area</b> &gt; P-A spool stroke</li> <li>• <b>Spool position at maximum P-B orifice area</b> &lt; -P-B spool stroke</li> <li>• <b>Spool position at maximum B-T orifice area</b> &gt; B-T spool stroke</li> </ul>
 <p>P-B is closed during transition.</p>	<ul style="list-style-type: none"> <li>• <b>Positive spool position open connections:</b> P-A and P-B</li> <li>• <b>Negative spool position open connections:</b> P-B and A-T</li> <li>• <b>Spool position at maximum P-A orifice area</b> &gt; P-A spool stroke</li> <li>• <b>Spool position at maximum P-B orifice area</b> &gt; P-B spool stroke</li> <li>• <b>Spool position at maximum A-T orifice area</b> &gt; -A-T spool stroke</li> </ul>

### Valve Orifice Parameterizations

The **Orifice parameterization** parameter sets the model for the open area or volumetric flow rate through one or all of the valve orifices. If you set **Area characteristics** to `Identical` for all flow paths, the block applies the same data for all flow paths; otherwise, individual parameterizations are applied for the `Different` for all flow paths setting. You can model valve opening in three ways:

- Linear - area vs. spool travel

The opening area is a linear function of the spool position received as a signal at port **S**:

$$A_{orifice} = \frac{(A_{max} - A_{leak})}{\Delta S_{max}} \Delta S + A_{leak},$$

where:

- $\Delta S$  is the spool travel defined in Orifice Definition and Spool Travel Direction.

$A_{orifice}$  saturates at  $A_{leak}$  when  $\Delta S$  is negative and saturates at  $A_{max}$  when the orifice is fully open. When the orifice is fully open,  $\Delta S$  is equal to the spool stroke, so  $\Delta S$  greater than the spool stroke does not further increase the orifice area.

- $\Delta S_{max}$  is the **Spool travel between closed and open orifice**.
- $A_{max}$  is the **Maximum orifice area**.
- $A_{leak}$  is the **Leakage area**.

When the valve is in a near-open or near-closed position in the linear parameterization, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the opening area between  $A_{leak}$  and  $A_{max}$ . For more information, see “Numerical Smoothing”.

- Tabulated data - Area vs. spool travel

Provide spool travel vectors for your system or for individual flow paths between ports **P**, **A**, **B**, and **T**. This data will be used to calculate the relationship between the orifice area and spool displacement. Interpolation is used to determine the opening area between given data points.  $A_{leak}$  and  $A_{max}$  are the first and last parameters of the opening area vector, respectively.

- Tabulated data - Volumetric flow rate vs. spool travel and pressure drop

Provide spool travel and pressure drop vectors and a dependent, 2-D volumetric flow rate array. Interpolation is used to determine flow rate between given data points. The mass flow rate is the product of the volumetric flow rate and the local density.

### Visualize Orifice Openings

To visualize spool offsets and maximum displacement, right-click on the block and select **Fluids > Plot Valve Characteristics**. The plot shows the orifices selected in the **Valve Configuration** tab settings. The axes are set by the orifice parameterization selection and are either:

- Orifice Area vs. Spool Position
- Volumetric Flow Rate vs. Spool Position, queried at a specific pressure differential

When the positive and negative settings in the **Valve Configuration** tab feature the same orifice, the orifice opening is displayed as a constant.

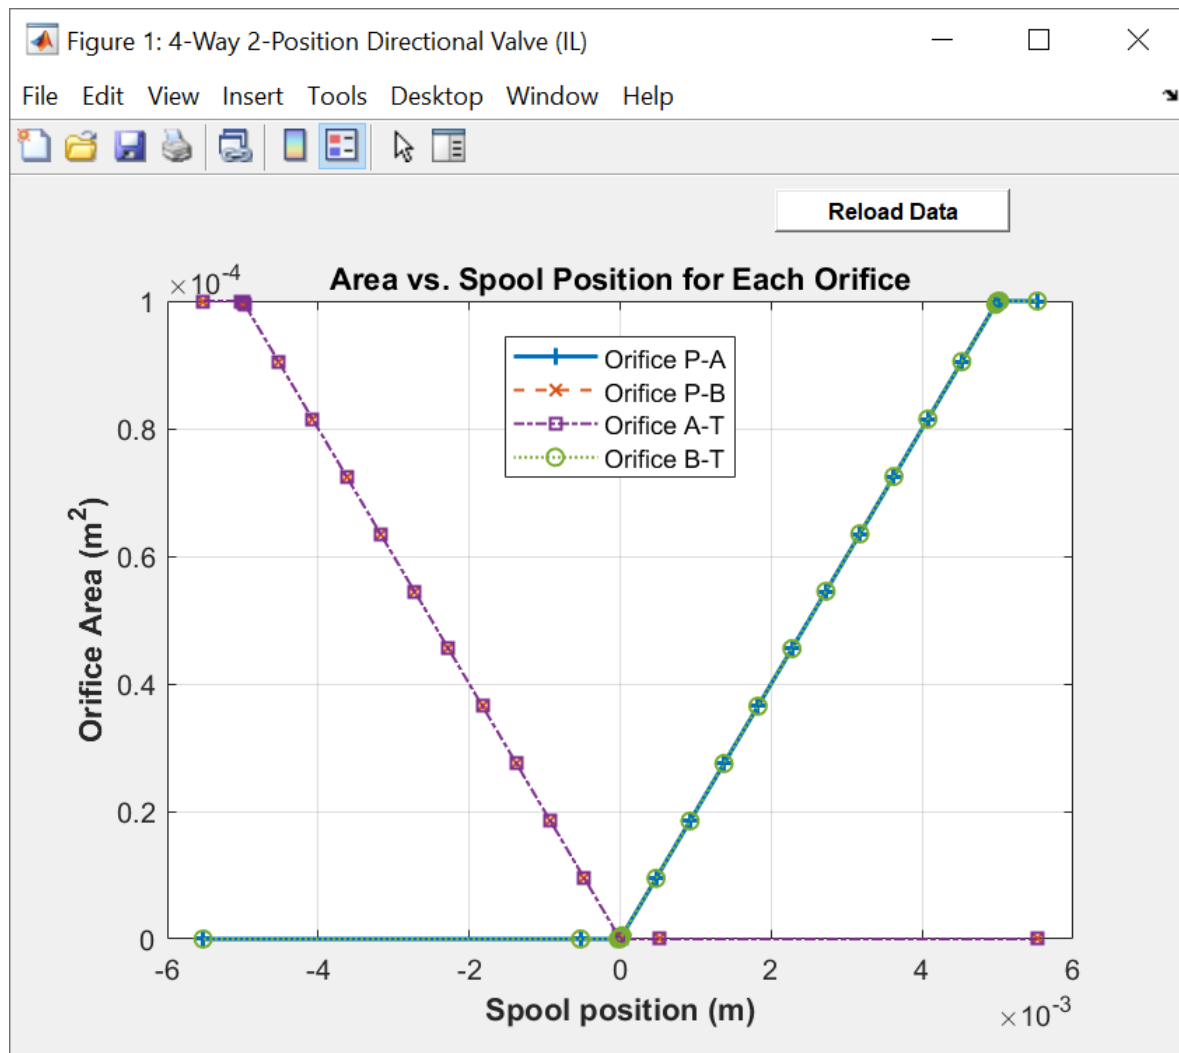

Each time you modify the block settings, click **Reload Data** on the figure window.

The image below shows the valve default configuration. On the **Valve Configuration** tab:

- **Positive spool position open connections** is set to P-A and B-T.
- **Negative spool position open connections** is set to P-B and A-T.

All other spool positions are at the default values.

### Example Spool Position Visualization

#### Faults

When faults are enabled, the valve open area becomes stuck at a specified spool position in response to one of these triggers:

- Simulation time — Faulting occurs at a specified time.
- Simulation behavior — Faulting occurs in response to an external trigger. This exposes port **Tr**.

Four fault options are available in the **Spool position when faulted** parameter:

- **Positive** — The spool position freezes in the positive position, opening the **Positive spool position open connections** flow paths to their maximum value. The flow paths that are only open in the **Negative spool position open connections** and **Neutral spool position open connections** are closed.
- **Negative** — The spool position freezes in the negative position, opening the **Negative spool position open connections** flow paths to their maximum value. The flow paths that are only open in the **Positive spool position open connections** and **Neutral spool position open connections** are closed.
- **Maintain last value** — The valve freezes at the spool position when the trigger occurs.

Due to numerical smoothing at the extremes of the valve area, in the linear parameterization, the minimum area applied is larger than the **Leakage area**, and the maximum is smaller than the **Maximum orifice area**, in proportion to the **Smoothing factor** value.

Once triggered, the valve remains at the faulted area for the rest of the simulation.

### Composite Structure

This block is a composite component comprising of multiple instances of the Orifice (IL) block. Refer to the Orifice (IL) block for more detail on the valve parameterizations and block calculations.

### Predefined Parameterization

You can populate the block with pre-parameterized manufacturing data, which allows you to model a specific supplier component.

To load a predefined parameterization:

- 1 In the block dialog box, next to **Selected part**, click the "<click to select>" hyperlink next to **Selected part** in the block dialogue box settings.
- 2 The Block Parameterization Manager window opens. Select a part from the menu and click **Apply all**. You can narrow the choices using the **Manufacturer** drop down menu.
- 3 You can close the **Block Parameterization Manager** menu. The block now has the parameterization that you specified.
- 4 You can compare current parameter settings with a specific supplier component in the Block Parameterization Manager window by selecting a part and viewing the data in the **Compare selected part with block** section.

---

**Note** Predefined block parameterizations use available data sources to supply parameter values. The block substitutes engineering judgement and simplifying assumptions for missing data. As a result, expect some deviation between simulated and actual physical behavior. To ensure accuracy, validate the simulated behavior against experimental data and refine your component models as necessary.

---

To learn more, see "List of Pre-Parameterized Components".

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Liquid entry or exit port to the valve.

**B** — Liquid port  
isothermal liquid

Liquid entry or exit port to the valve.

**P** — Liquid port  
isothermal liquid

Liquid entry or exit port to the valve.

**T** — Liquid port  
isothermal liquid

Liquid entry or exit port to the valve.

### Input

**S** — Spool displacement, m  
physical signal

Spool displacement, in m, specified as a physical signal.

**Tr** — External fault trigger  
physical signal

Physical signal port for an external fault trigger. Triggering occurs when the value is greater than 0.5. There is no unit associated with the trigger value.

### Dependencies

This port is visible when **Enable faults** is set to On and **Fault trigger** is set to External.

## Parameters

### Valve Configuration

**Positive spool position open connections** — Flow paths open when the spool is in a positive position

P-A and B-T (default) | P-A and P-B | P-B and A-T | P-A only | P-B only

Flow paths open when the spool is in a positive position. This parameter sets the valve configuration and defines the direction of spool movement according to the signal received at port **S**.

**Negative spool position open connections** — Flow paths open when the spool moves in the negative direction

P-B and A-T (default) | P-A and B-T | P-A and P-B | P-A only | P-B only

Flow paths open when the spool moves in the negative direction. This parameter sets the valve configuration and defines the direction of spool movement according to the signal received at port **S**.

### Model Parameterization

**Area characteristics** — Flow equations for orifices

Identical for all flow paths (default) | Different for each flow path

Applies uniform or individual flow equations for the valve orifice area. Identical for all flow paths uses the same orifice and spool geometries, flow rates, pressure, and area vectors for all valve orifices. When using Different for each flow path, these parameters are specified individually for each orifice. In both cases, orifices **A**, **B**, **P**, and **T** have the same cross-sectional areas, discharge coefficients, and Reynolds numbers in the Linear - Area vs. spool travel and Tabulated data - Area vs. spool travel parameterizations. The same **Orifice parameterization** is applied to all flow paths.

**Orifice parameterization** — Method of calculating opening area

Linear area vs. spool travel (default) | Tabulated data - Area vs. spool travel |  
Tabulated data - Volumetric flow rate vs. spool travel and pressure drop

Method of calculating the valve opening area. In the tabulated data parameterizations, you can provide your own valve area and spool travel data for nonlinear valve opening profiles, or you can provide data in terms of volumetric flow rate, spool travel, and pressure drop over the flow path.

**Spool travel between closed and open orifice** — Maximum spool stroke

0.005 m (default) | positive scalar

Maximum distance of spool travel.

#### **Dependencies**

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Linear - Area vs. spool travel.

**Maximum orifice area** — Maximum orifice opening area

1e-4 m<sup>2</sup> (default) | positive scalar

Largest open area of each orifice during the operation of the valve.

#### **Dependencies**

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Linear - Area vs. spool travel.

**Leakage area** — Open area when an orifice is fully closed

1e-9 m<sup>2</sup> (default) | positive scalar

Open area when an orifice is fully closed. Any area smaller than this value is maintained at the specified leakage area. This parameter contributes to numerical stability by maintaining continuity in the flow.

#### **Dependencies**

To enable this parameter, set **Orifice parameterization** to Linear - Area vs. spool travel.

**Spool travel vector** — Vector of spool opening distances relative to fully closed position

[0, .00125, .0025, .00375, .005] m (default) | 1-by-*n* vector

Vector of spool travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **Orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Tabulated data - Area vs. spool travel.

**Orifice area vector** — Vector of valve opening areas

[1e-09, 1e-05, 4e-05, 6e-05, .0001] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **Spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

**Dependencies**

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Tabulated data - Area vs. spool travel.

**Spool travel vector, ds** — Vector of spool opening distances relative to fully closed position

[0, .00125, .0025, .00375, .005] m (default) | 1-by-*n* vector

Vector of spool travel distances for the tabular parametrization of volumetric flow rate. The spool travel vector forms an independent axis with the **Pressure drop vector, dp** parameter for the 2-D dependent **Volumetric flow rate table, q(ds,dp)** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**Pressure drop vector, dp** — Vector of valve pressure drop values

[-.1, .3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of pressure drop values for the tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **Spool travel vector, ds** parameter for the 2-D dependent **Volumetric flow rate table, q(ds,dp)** parameter. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**Volumetric flow rate table, q(ds,dp)** — Array of volumetric flow rates

[-1e-08, 2.2e-08, 2.8e-08, 3.4e-08; -9e-06, .00015, .0002, .00024;  
-.00036, .00063, .00081, .00096; .00054, .00094, .0012, .0014;  
-.00091, .0016, .002, .0024] m<sup>3</sup>/s (default) | *M*-by-*N* matrix

*M*-by-*N* matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the correlated vectors:

- *M* is the number of vector elements in the **Pressure drop vector, dp** parameter.
- *N* is the number of vector elements in the **Spool travel vector, ds** parameter.

**Dependencies**

To enable this parameter, set **Area characteristics** to `Identical` for all flow paths and **Orifice parameterization** to `Tabulated data - Volumetric flow rate vs. spool travel and pressure drop`.

**Constant orifice area** — Orifice area for identical flow paths

`1e-4 m^2 (default) | positive scalar`

Orifice area when the positive and negative spool positions feature the same orifice.

**Dependencies**

To enable this parameter, set **Area characteristics** to `Identical` for all flow paths and **Orifice parameterization** to either:

- `Linear - area vs. spool travel`.
- `Tabulated data - Area vs. spool travel`

The same orifice must be selected in both of the **Valve Configuration** parameters:

- **Positive spool position open connections**
- **Negative spool position open connections**

**Constant orifice pressure drop vector** — Vector of pressure differential values for identical flow paths

`[-.1, .3, .5, .7] MPa (default) | 1-by-n vector`

Vector of pressure differential values over the valve when the positive and negative spool positions feature the same orifice. The vector elements correspond one-to-one with the elements in the **Constant orifice volumetric flow rate vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Area characteristics** to `Identical` for all flow paths and **Orifice parameterization** to `Tabulated data - Volumetric flow rate vs. spool travel and pressure drop`.

The same orifice must be selected in both of the **Valve Configuration** parameters:

- **Positive spool position open connections**
- **Negative spool position open connections**

**Constant orifice volumetric flow rate vector** — Vector of volumetric flow rate values for identical flow paths

`[-.0009, .0016, .002, .0024] m^3/s (default) | 1-by-n vector`

Vector of volumetric flow rate values for a constant orifice when the positive and negative spool positions feature the same orifice. The vector elements correspond one-to-one with the elements in the **Constant orifice pressure drop vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Area characteristics** to `Identical` for all flow paths and **Orifice parameterization** to `Tabulated data - Volumetric flow rate vs. spool travel and pressure drop`.

The same orifice must be selected in both of the **Valve Configuration** parameters:

- **Positive spool position open connections**
- **Negative spool position open connections**

**Cross-sectional area at ports P, T, A and B** — Area at conserving ports

`inf m^2` (default) | positive scalar

Maximum cross-sectional areas at the entry and exit ports **P**, **T**, **A**, and **B**, which are used in the pressure-flow rate equation that determines the mass flow rate through the valve.

**Dependencies**

To enable this parameter, set **Area characteristics** to `Identical` for all flow paths and **Orifice parameterization** to either:

- `Linear - area vs. spool travel`
- `Tabulated data - Area vs. spool travel`

**Discharge coefficient** — Discharge coefficient

`0.64` (default) | positive scalar

Correction factor that accounts for discharge losses in theoretical flows.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to either:

- `Linear - Area vs. spool travel`
- `Tabulated data - Area vs. spool travel`

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

`150` (default) | positive scalar

Upper Reynolds number limit for laminar flow through the orifice.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to:

- `Linear - area vs. spool travel`
- `Tabulated data - Area vs. spool travel`

**Smoothing factor** — Numerical smoothing factor

`0.01` (default) | positive scalar in the range of `[0,1]`

Continuous smoothing factor that introduces a layer of gradual change based to the flow response when the valve is in near-open and near-closed positions. To increase the stability of your simulation in these regimes, set this parameter to a nonzero value less than one.

**Dependencies**

To enable this parameter, set **Orifice parametrization** to Linear - area vs. spool travel.

**Pressure recovery** — Whether to account for pressure increase in area expansions  
off (default) | on

Whether to account for pressure increase when fluid flows from a region of smaller cross-sectional area to a region of larger cross-sectional area.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to:

- Linear - area vs. spool travel
- Tabulated data - Area vs. spool travel

**P-A Orifice**

**Spool position at maximum P-A orifice area** — Spool offset for fully open P-A orifice  
5e-3 m (default) | positive scalar

Spool offset from the neutral position for a fully open P-A orifice. To visualize the defined offsets, see “Visualize Orifice Openings” on page 1-256.

**Dependencies**

To enable this parameter, set one of the following parameters:

**Positive spool position open connections** to:

- P-A and B-T
- P-A and P-B
- P-A only

**Negative spool position open connections** to:

- P-A and B-T
- P-A and P-B
- P-A only

---

**Note:** This parameter is enabled only when the P-A orifice settings do not appear in both spool position parameters: **Positive spool position open connections** and **Negative spool position open connections**.

---

**P-A spool travel between closed and open orifice** — Maximum spool stroke  
0.005 m (default) | positive scalar

Maximum distance of spool travel. This value provides an upper limit to calculations so that simulations do not return unphysical values.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to:

- P-A and B-T
- P-A and P-B
- P-A only

**Negative spool position open connections** to:

- P-A and B-T
- P-A and P-B
- P-A only

**P-A maximum orifice area** — Maximum orifice opening area  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Largest open area of the P-A orifice during the operation of the valve.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to:

- P-A and B-T
- P-A and P-B
- P-A only

**Negative spool position open connections** to:

- P-A and B-T
- P-A and P-B
- P-A only

**P-A orifice spool travel vector** — Vector of spool opening distances relative to fully closed position  
 $[0, .00125, .0025, .00375, .005] \text{ m}$  (default) | 1-by- $n$  vector

Vector of spool travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **P-A orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections** to:

- P-A and B-T
- P-A and P-B
- P-A only

**Negative spool position open connections** to:

- P-A and B-T
- P-A and P-B
- P-A only

**P-A orifice area vector** — Vector of valve opening areas

[1e-10, 1e-05, 4e-05, 6e-05, .0001] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **P-A spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

#### **Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections** to:

- P-A and B-T
- P-A and P-B
- P-A only

**Negative spool position open connections** to:

- P-A and B-T
- P-A and P-B
- P-A only

**P-A orifice spool travel vector, ds** — Vector of spool opening distances relative to fully closed position

[0, .00125, .0025, .00375, .005] m (default) | 1-by-*n* vector

Vector of spool travel distances for the tabular parameterization of volumetric flow rates. The spool travel vector forms an independent axis with the **P-A orifice pressure drop vector, dp** parameter for the 2-D dependent **P-A orifice volumetric flow rate table, q(ds,dp)** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only

**Negative spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only

**P-A orifice pressure drop vector,  $dp$**  — Vector of pressure drop values  
 [ -.1, .3, .5, .7 ] MPa (default) | 1-by- $n$  vector

Vector of pressure drop values for the tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **P-A orifice spool travel vector,  $ds$**  parameter for the 2-D dependent **P-A orifice volumetric flow rate table,  $q(ds,dp)$**  parameter. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only

**Negative spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only

**P-A orifice volumetric flow rate table,  $q(ds,dp)$**  — Array of volumetric flow rate values  
[-1e-08, 2.2e-08, 2.8e-08, 3.4e-08; -9e-06, .00015, .0002, .00024;  
-.00036, .00063, .00081, .00096; -.00054, .00094, .0012, .0014;  
-.00091, .0016, .002, .0024] m<sup>3</sup>/s (default) | *M*-by-*N* matrix

*M*-by-*N* matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the correlated vectors:

- *M* is the number of vector elements in the **P-A orifice pressure drop vector,  $dp$**  parameter.
- *N* is the number of vector elements in the **P-A orifice spool travel vector,  $ds$**  parameter.

### Dependencies

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3** One of the following parameters:

**Positive spool position open connections** to:

- P-A and B-T
- P-A and P-B
- P-A only

**Negative spool position open connections** to:

- P-A and B-T
- P-A and P-B
- P-A only

**P-A constant orifice area** — Cross-sectional area for a constant orifice  
1e-4 m<sup>2</sup> (default) | positive scalar

Orifice area when the positive and negative spool positions feature the same orifice.

### Dependencies

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to either:
  - Linear - area vs. spool travel
  - Tabulated data - Area vs. spool travel
- 3** One of the following settings in each parameter:

**Positive spool position open connections** to:

- P-A and B-T
- P-A and P-B

- P-A only

**Negative spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only

**P-A Constant orifice pressure drop vector** — Vector of pressure differential values for a constant orifice

[-.1, .3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of pressure differential values over the valve when the positive and negative spool positions feature the same orifice. The vector elements correspond one-to-one with the elements in the **P-A Constant orifice volumetric flow rate vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following settings in each parameter:

**Positive spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only

**Negative spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only

**P-A Constant orifice volumetric flow rate vector** — Vector of volumetric flow rates for a constant orifice

[-.0009, .0016, .002, .0024] m<sup>3</sup>/s (default) | 1-by-*n* vector

Vector of pressure differential values over the valve when the positive and negative spool positions feature the same orifice. The vector elements correspond one-to-one with the elements in the **P-A Constant orifice pressure drop vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**3** One of the following settings in each parameter:

**Positive spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only

**Negative spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only

**P-B Orifice**

**Spool position at maximum P-B orifice area** — Spool offset from the neutral position for a fully open P-B orifice

-5e-3 (default) | positive scalar

Spool offset from the neutral position for a fully open P-B orifice. To visualize the defined offsets, see “Visualize Orifice Openings” on page 1-256.

**Dependencies**

To enable this parameter, set one of the following parameters:

**Positive spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only

**Negative spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only

---

**Note:** This parameter is enabled only when the P-B orifice settings do not appear in both spool position parameters: **Positive spool position open connections** and **Negative spool position open connections**.

---

**P-B spool travel between closed and open orifice** — Maximum spool stroke

0.005 m (default) | positive scalar

Maximum distance of spool travel. This value provides an upper limit to calculations so that simulations do not return unphysical values.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to:

- P-B and A-T
- P-A and P-B
- P-B only

or set **Negative spool position open connections** to:

- P-B and A-T
- P-A and P-B
- P-B only

**P-B maximum orifice area** — Maximum orifice opening area  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Largest open area of the P-B orifice during the operation of the valve.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to:

- P-B and A-T
- P-A and P-B
- P-B only

**Negative spool position open connections** to:

- P-B and A-T
- P-A and P-B
- P-B only

**P-B orifice spool travel vector** — Vector of spool opening distances relative to fully closed position  
 $[0, .00125, .0025, .00375, .005]$  m (default) | 1-by- $n$  vector

Vector of spool travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **P-B orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections** to:

- P-B and A-T
- P-A and P-B
- P-B only

**Negative spool position open connections** to:

- P-B and A-T
- P-A and P-B
- P-B only

**P-B orifice area vector** — Vector of valve opening areas

[1e-10, 1e-05, 4e-05, 6e-05, .0001] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **P-B spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

#### **Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections** to:

- P-B and A-T
- P-A and P-B
- P-B only

**Negative spool position open connections** to:

- P-B and A-T
- P-A and P-B
- P-B only

**P-B orifice spool travel vector, ds** — Vector of spool opening distances relative to fully closed position

[0, .00125, .0025, .00375, .005] m (default) | 1-by-*n* vector

Vector of spool travel distances for the tabular parameterization of volumetric flow rates. The spool travel vector forms an independent axis with the **P-T orifice pressure drop vector, dp** parameter for the 2-D dependent **P-T orifice volumetric flow rate table, q(ds,dp)** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only

**Negative spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only

**P-B orifice pressure drop vector,  $dp$**  — Vector of pressure differential values  
 [ -.1, .3, .5, .7] MPa (default) | 1-by-n vector

Vector of pressure drop values for tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **P-B orifice spool travel vector,  $ds$**  parameter for the 2-D dependent **P-B orifice volumetric flow rate table,  $q(ds,dp)$**  parameter. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only

**Negative spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only

**P-B orifice volumetric flow rate table,  $q(ds,dp)$**  — Array of volumetric flow rate values  
[-1e-08, 2.2e-08, 2.8e-08, 3.4e-08; -9e-06, .00015, .0002, .00024;  
-.00036, .00063, .00081, .00096; -.00054, .00094, .0012, .0014;  
-.00091, .0016, .002, .0024] m<sup>3</sup>/s (default) | *M*-by-*N* matrix

*M*-by-*N* matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the correlated vectors:

- *M* is the number of vector elements in the **P-B orifice pressure drop vector,  $dp$**  parameter.
- *N* is the number of vector elements in the **P-B orifice spool travel vector,  $ds$**  parameter.

### Dependencies

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3** One of the following parameters:

**Positive spool position open connections** to:

- P-B and A-T
- P-A and P-B
- P-B only

**Negative spool position open connections** to:

- P-B and A-T
- P-A and P-B
- P-B only

**P-B constant orifice area** — Cross-sectional area for a constant orifice  
1e-4 m<sup>2</sup> (default) | positive scalar

Orifice area when the positive and negative spool positions feature the same orifice.

### Dependencies

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to either:
  - Linear - area vs. spool travel
  - Tabulated data - Area vs. spool travel
- 3** One of the following settings in each parameter:

**Positive spool position open connections** to:

- P-B and A-T
- P-A and P-B

- P-B only

**Negative spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only

**P-B Constant orifice pressure drop vector** — Vector of pressure differential values for a constant orifice

[-.1, .3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of pressure differential values over the valve when the positive and negative spool positions feature the same orifice. The vector elements correspond one-to-one with the elements in the **P-B Constant orifice volumetric flow rate vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following settings in each parameter:

**Positive spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only

**Negative spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only

**P-B Constant orifice volumetric flow rate vector** — Vector of volumetric flow rate values for a constant orifice

[-.0009, .0016, .002, .0024] m<sup>3</sup>/s (default) | 1-by-*n* vector

Vector of volumetric flow rate values over the valve when the positive, neutral, and negative spool positions feature the same orifice. The vector elements correspond one-to-one with the elements in the **P-B Constant orifice pressure drop vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**3** One of the following settings in each parameter:

**Positive spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only

**Negative spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only

### **A-T Orifice**

**Spool position at maximum A-T orifice area** — Spool offset from the neutral position for a fully open A-T orifice

-5e-3 m (default) | positive scalar

Spool offset from the neutral position for a fully open A-T orifice. To visualize the defined offsets, see “Visualize Orifice Openings” on page 1-256.

#### **Dependencies**

To enable this parameter, set one of the following parameters:

- **Positive spool position open connections** to P-B and A-T.
- **Negative spool position open connections** to P-B and A-T.

---

**Note:** This parameter is enabled only when the A-T orifice settings do not appear in both spool position parameters: **Positive spool position open connections** and **Negative spool position open connections**.

---

**A-T spool travel between closed and open orifice** — Maximum spool stroke

0.005 m (default) | positive scalar

Maximum distance of spool travel. This value provides an upper limit to calculations so that simulations do not return unphysical values.

#### **Dependencies**

To enable this parameter, set:

- 1** **Area characteristics** to Different for each flow path.
- 2** **Orifice parameterization** to Linear - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections** to P-B and A-T

**Negative spool position open connections** to P-B and A-T.

**A-T maximum orifice area** — Maximum orifice opening area  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Largest open area of the A-T orifice during the operation of the valve.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to P-B and A-T

**Negative spool position open connections** to P-B and A-T.

**A-T orifice spool travel vector** — Vector of spool opening distances relative to fully closed position  
 $[0, .00125, .0025, .00375, .005]$  m (default) | 1-by- $n$  vector

Vector of spool travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **A-T orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to P-B and A-T.

**Negative spool position open connections** to P-B and A-T.

**A-T orifice spool travel vector** — Vector of spool opening distances relative to fully closed position  
 $[0, .00125, .0025, .00375, .005]$  m (default) | 1-by- $n$  vector

Vector of spool travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **A-T orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to P-B and A-T.

**Negative spool position open connections** to P-B and A-T.

**A-T orifice spool travel vector, ds** — Vector of spool opening distances relative to fully closed position

[0, .00125, .0025, .00375, .005] m (default) | 1-by-*n* vector

Vector of spool travel distances for the tabular parameterization of volumetric flow rates. The spool travel vector forms an independent axis with the **A-T orifice pressure drop vector, dp** parameter for the 2-D dependent **A-T orifice volumetric flow rate table, q(ds,dp)** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections** to P-B and A-T.

**Negative spool position open connections** to P-B and A-T.

**A-T orifice pressure drop vector, dp** — Vector of pressure differential values

[-.1, .3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of pressure drop values for tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **A-T orifice spool travel vector, ds** parameter for the 2-D dependent **A-T orifice volumetric flow rate table, q(ds,dp)** parameter. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections** to P-B and A-T.

**Negative spool position open connections** to P-B and A-T.

**A-T orifice volumetric flow rate table, q(ds,dp)** — Array of volumetric flow rate values

[-1e-08, 2.2e-08, 2.8e-08, 3.4e-08; -9e-06, .00015, .0002, .00024;  
-.00036, .00063, .00081, .00096; -.00054, .00094, .0012, .0014;  
-.00091, .0016, .002, .0024] m<sup>3</sup>/s (default) | *M*-by-*N* matrix

*M*-by-*N* matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the correlated vectors:

- $M$  is the number of vector elements in the **A-T orifice pressure drop vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **A-T orifice spool travel vector,  $ds$**  parameter.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections** to P-B and A-T.

**Negative spool position open connections** to P-B and A-T.

**A-T constant orifice area** — Cross-sectional area for a constant orifice  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Orifice area when the positive and negative spool positions feature the same orifice.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to either:
  - Linear - area vs. spool travel
  - Tabulated data - Area vs. spool travel
- 3 One of the following settings in each parameter:

**Positive spool position open connections** to P-B and A-T.

**Negative spool position open connections** to P-B and A-T.

**A-T Constant orifice pressure drop vector** — Vector of pressure differential values for a constant orifice

$[-.1, .3, .5, .7]$  MPa (default) | 1-by- $n$  vector

Vector of pressure differential values over the valve when the positive, neutral, and negative spool positions feature the same orifice. The vector elements correspond one-to-one with the elements in the **A-T Constant orifice volumetric flow rate vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following settings in each parameter:

**Positive spool position open connections** to P-B and A-T.

**Negative spool position open connections** to P-B and A-T.

**A-T Constant orifice volumetric flow rate vector** — Vector of volumetric flow rate values for a constant orifice

`[-.0009, .0016, .002, .0024]` m<sup>3</sup>/s (default) | 1-by-*n* vector

Vector of volumetric flow rate values when the positive, neutral, and negative spool positions feature the same orifice. The vector elements correspond one-to-one with the elements in the **Constant orifice volumetric flow rate vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following settings in each parameter:

**Positive spool position open connections** to P-B and A-T.

**Negative spool position open connections** to P-B and A-T.

#### B-T Orifice

**Spool position at maximum B-T orifice area** — Spool offset from the neutral position for a fully open B-T orifice

`5e-3` m (default) | positive scalar

Spool offset from the neutral position for a fully open B-T orifice. To visualize the defined offsets, see “Visualize Orifice Openings” on page 1-256.

#### Dependencies

To enable this parameter, set one of the following parameters:

- **Positive spool position open connections** to P-A and B-T.
- **Negative spool position open connections** to P-A and B-T.

---

**Note:** This parameter is enabled only when the B-T orifice settings do not appear in both spool position parameters: **Positive spool position open connections** and **Negative spool position open connections**.

---

**B-T spool travel between closed and open orifice** — Maximum spool stroke

`0.005` m (default) | positive scalar

Maximum distance of spool travel. This value provides an upper limit to calculations so that simulations do not return unphysical values.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to P-A and B-T.

**Negative spool position open connections** to P-A and B-T.

**B-T maximum orifice area** — Maximum orifice opening area  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Largest open area of the B-T orifice during the operation of the valve.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to P-A and B-T.

**Negative spool position open connections** to P-A and B-T.

**B-T orifice spool travel vector** — Vector of spool opening distances relative to fully closed position  
 $[0, .00125, .0025, .00375, .005] \text{ m}$  (default) | 1-by- $n$  vector

Vector of spool travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **B-T orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to P-A and B-T.

**Negative spool position open connections** to P-A and B-T.

**B-T orifice area vector** — Vector of valve opening areas  
 $[1e-10, 1e-05, 4e-05, 6e-05, .0001] \text{ m}^2$  (default) | 1-by- $n$  vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **B-T orifice spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to P-A and B-T.

**Negative spool position open connections** to P-A and B-T.

**B-T orifice spool travel vector, ds** — Vector of spool opening distances relative to fully closed position

[0, .00125, .0025, .00375, .005] m (default) | 1-by-*n* vector

Vector of control member travel distances for the tabular parameterization of volumetric flow rates. The spool travel vector forms an independent axis with the **B-T orifice pressure drop vector, dp** parameter for the 2-D dependent **B-T orifice volumetric flow rate table, q(ds,dp)** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections** to P-A and B-T.

**Negative spool position open connections** to P-A and B-T.

**B-T orifice pressure drop vector, dp** — Vector of pressure differential values

[-.1, .3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of pressure drop values for tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **B-T orifice spool travel vector, ds** parameter for the 2-D dependent **B-T orifice volumetric flow rate table, q(ds,dp)** parameter. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections** to P-A and B-T.

**Negative spool position open connections** to P-A and B-T.

**B-T orifice volumetric flow rate table,  $q(ds,dp)$**  — Array of volumetric flow rate values  
 [-1e-08, 2.2e-08, 2.8e-08, 3.4e-08; -9e-06, .00015, .0002, .00024;  
 -.00036, .00063, .00081, .00096; -.00054, .00094, .0012, .0014;  
 -.00091, .0016, .002, .0024] m<sup>3</sup>/s (default) | *M*-by-*N* matrix

*M*-by-*N* matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the correlated vectors:

- *M* is the number of vector elements in the **B-T orifice pressure drop vector,  $dp$**  parameter.
- *N* is the number of vector elements in the **B-T orifice spool travel vector,  $ds$**  parameter.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections** to P-A and B-T.

**Negative spool position open connections** to P-A and B-T.

**B-T constant orifice area** — Cross-sectional orifice area for constant orifices  
 1e-4 m<sup>2</sup> (default) | positive scalar

Orifice area when the positive and negative spool positions feature the same orifice.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to either:
  - Linear - area vs. spool travel
  - Tabulated data - Area vs. spool travel
- 3 One of the settings in each parameter:

**Positive spool position open connections** to P-A and B-T.

**Negative spool position open connections** to P-A and B-T.

**B-T Constant orifice pressure drop vector** — Vector of pressure differential values for a constant orifice  
 [-.1, .3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of pressure differential values over the valve when the positive and negative spool positions feature the same orifice. The vector elements correspond one-to-one with the elements in the **B-T Constant orifice volumetric flow rate vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the settings in each parameter:

**Positive spool position open connections** to P-A and B-T.

**Negative spool position open connections** to P-A and B-T.

**B-T Constant orifice volumetric flow rate vector** — Vector of volumetric flow rates for a constant orifice

[-.0009, .0016, .002, .0024] m<sup>3</sup>/s (default) | 1-by-n vector

Vector of pressure differential values over the valve when the positive and negative spool positions feature the same orifice. The vector elements correspond one-to-one with the elements in the **B-T Constant orifice pressure drop vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the settings in each parameter:

**Positive spool position open connections** to P-A and B-T.

**Negative spool position open connections** to P-A and B-T.

**Faults**

**Enable faults** — Fault option

Off (default) | On

Enable externally or temporally triggered faults. When faulting occurs, the valve area normally set by the opening parameterization will be set to the value specified in the **Spool position when faulted** parameter.

**Spool position when faulted** — Set faulted characteristics

Positive (default) | Negative | Maintain last value

Sets the faulted valve spool position. You can choose for the valve to seize when the spool is in the positive position, negative position, or at the position when faulting is triggered.

**Dependencies**

To enable this parameter, set **Enable faults** to On.

**Fault trigger** — External or temporal trigger option

Temporal (default) | External

Whether a fault trigger occurs due to an external event or at a specified time.

When set to External, port **Tr** is enabled. A physical signal at port **Tr** that is greater than 0.5 triggers faulting.

When set to Temporal, when the **Simulation time for fault event** is reached, the valve area will be set to the value specified in the **Spool position when faulted** parameter.

#### **Dependencies**

To enable this parameter, set **Enable faults** to On.

**Simulation time for fault event** — Time at which faulting is triggered

5 s (default) | positive scalar

When the **Simulation time for fault event** is reached, the valve area is set to the value specified in the **Spool position when faulted** parameter.

#### **Dependencies**

To enable this parameter, set **Enable faults** to On and **Fault trigger** to Temporal.

## **Version History**

Introduced in R2021a

## 4-Way 3-Position Directional Valve (IL)

4-way, 3-position directional valve in an isothermal liquid system

### Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Directional Control Valves

### Description

The 4-Way 3-Position Directional Valve (IL) block models a valve with four openings in an isothermal liquid network, typically between an actuator, pump, and tank. The valve operation is controlled by a single spool displaced according to the signal at port **S**. You can set the baseline configuration of your valve by specifying the orifices that are open when the spool is in the neutral position (centered at 0 m) in the **Neutral spool position open connections** parameter, when the spool moves in the positive direction in the **Positive spool position open connections** parameter, and when the spool moves in the negative direction in the **Negative spool position open connections**.

You can set the model for valve opening in the **Orifice parameterization** parameter as a linear relationship or function of user-provided data, which can be applied to one or all flow paths in the valve.

### Example Valve Setup

In this example configuration, **Neutral spool position open connections** is set to All closed. When the spool is in the neutral position, all orifices are closed to flow:

In this configuration, **Negative spool position open connections** is set to P-A and B-T. When the signal at port **S** moves the spool to a negative position, the paths between ports **P** and **A** and between ports **B** and **T** are open to flow. The paths between ports **P** and **B** and ports **A** and **T** are closed to flow:

In this configuration, **Positive spool position open connections** is set to P-B and A-T. When the signal at port **S** moves the spool to a positive position, the paths between ports **P** and **B** and between ports **A** and **T** are open to flow and the paths between ports **P** and **A** and between ports **B** and **T** are closed:

Schematically, this configuration is shown as:

The left-hand side corresponds to the positive position and the right-hand side corresponds to the negative position.

### Spool Displacement and Valve Configuration

The *spool stroke* is the amount of spool travel an orifice takes to fully open from a closed position and is defined for each orifice selected on the **Valve Configuration** tab. The table below shows how the stroke is calculated in accordance with the valve orifice parameterization and flow path characteristics.

#### Spool Stroke Based on Parameterization and Flow Path

Orifice Parameterization	Identical for All Flow Paths	Different for Each Flow Path
Linear - Area vs. spool travel	Defined by the <b>Spool travel between closed and open orifice</b> parameter	Defined by the Spool travel between closed and open orifice parameter, for each orifice
Tabulated data - Area vs. spool travel	The difference between the first and last element of the <b>Spool travel vector</b> parameter	The difference between the first and last element of the spool travel vector parameter for each orifice
Tabulated data - Volumetric flow rate vs. spool travel and pressure drop	The difference between the first and last element of the <b>Spool travel vector, ds</b> parameter	The difference between the first and last element of the spool travel vector, ds parameter for each orifice

The section “Visualize Orifice Openings” on page 1-256 details how to see the orientation of all valve orifices.

The direction of spool movement signaled at port **S** depends on the spool stroke and the orifice orientation:

#### Orifice Definition and Spool Travel Direction

Spool Position when Orifice is Open	Spool Travel, $\Delta S$
Always closed (orifice is not selected in any spool position configuration)	N/A
Always open (orifice is selected in positive, neutral, and negative spool position configurations)	N/A
Negative	$S_{\text{orifice\_max}} + \text{spool stroke} - \mathbf{S}$
Negative and Neutral	$S_{\text{orifice\_max}} + \text{spool stroke} - \mathbf{S}$
Positive	$S_{\text{orifice\_max}} - \text{spool stroke} + \mathbf{S}$
Positive and Neutral	$S_{\text{orifice\_max}} - \text{spool stroke} + \mathbf{S}$
Neutral	$ S_{\text{orifice\_max}}  + \text{spool stroke} -  \mathbf{S} $
Positive and Negative	$- S_{\text{orifice\_max}}  + \text{spool stroke} -  \mathbf{S} $

Where  $S_{\text{orifice\_max}}$  is the spool position at the maximum orifice area defined for each orifice. The orifice area saturates at the leakage area when  $\Delta S$  is negative and saturates at the maximum orifice area when the orifice is fully open. When the orifice is fully open,  $\Delta S$  is equal to the spool stroke, so  $\Delta S$  greater than the spool stroke does not further increase the orifice area.

The **Consistency check for neutral spool position open connections** parameter verifies that

- Any orifice listed in **Neutral spool position open connections** is open when the signal at **S** is 0.
- Any orifice that is not listed in **Neutral spool position open connections** is closed when the signal at **S** is 0.

You can optionally choose to receive a warning or error when this check is violated.

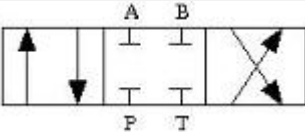

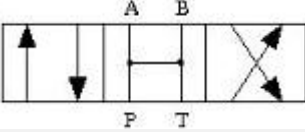

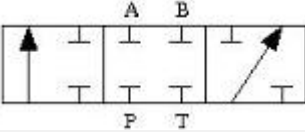

The possible configurations of the 4-Way 3-Position Directional Valve (IL) block are shown below.

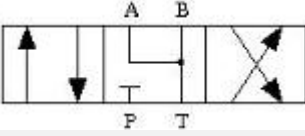

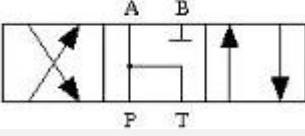

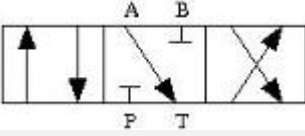

---

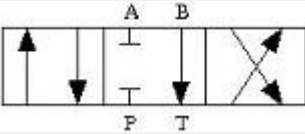

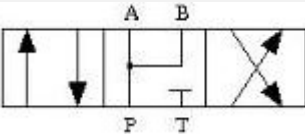

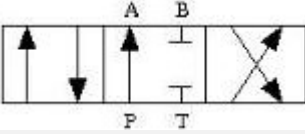

**Note** This block includes all configurations from the Hydraulic (Isothermal) library blocks 4-Way Directional Valve and the 4-Way Directional Valves A - K.

## Valve Orifice Parameterizations

The **Orifice parameterization** parameter sets the model for the open area or volumetric flow rate through one or all of the valve orifices. The block applies the same data for all flow paths if **Area characteristics** is set to **Identical** for all flow paths; otherwise, individual parameterizations are applied for the **Different** for all flow paths setting. You can model valve opening in three ways:

- Linear - area vs. spool travel

The opening area is a linear function of the spool position received as a signal at port **S**:

$$A_{orifice} = \frac{(A_{max} - A_{leak})}{\Delta S_{max}} \Delta S + A_{leak},$$

where:

- $\Delta S$  is the spool travel defined in Orifice Definition and Spool Travel Direction.
- $\Delta S_{max}$  is the **Spool travel between closed and open orifice**.
- $A_{max}$  is the **Maximum orifice area**.
- $A_{leak}$  is the **Leakage area**.

$A_{orifice}$  saturates at  $A_{leak}$  when  $\Delta S$  is negative and saturates at  $A_{max}$  when the orifice is fully open. When the orifice is fully open,  $\Delta S$  is equal to the spool stroke, so  $\Delta S$  greater than the spool stroke does not further increase the orifice area.

When the valve is in a near-open or near-closed position in the linear parameterization, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the opening area between  $A_{leak}$  and  $A_{max}$ . For more information, see "Numerical Smoothing".

- Tabulated data - Area vs. spool travel

Provide spool travel vectors for your system or for individual flow paths between ports **P**, **A**, **B**, and **T**. This data will be used to calculate the relationship between the orifice area and spool displacement. Interpolation is used to determine the opening area between given data points.  $A_{leak}$  and  $A_{max}$  are the first and last parameters of the opening area vector, respectively.

- Tabulated data - Volumetric flow rate vs. spool travel and pressure drop

Provide spool travel and pressure drop vectors and a dependent, 2-D volumetric flow rate array. Interpolation is used to determine flow rate between given data points. The mass flow rate is the product of the volumetric flow rate and the local density.

### Visualize Orifice Openings

To visualize spool offsets and maximum displacement, right-click the block and select **Fluids > Plot Valve Characteristics**. The plot shows the orifices selected in the **Valve Configuration** settings. The orifice parameterization sets the axes, which are either:

- Orifice area versus spool position
- Volumetric flow rate versus spool position, queried at a specific pressure differential

When the positive, neutral, and negative settings in the **Valve Configuration** feature the same orifice, the plot displays the orifice openings as a constant.

To update the data after changing the block parameters, click **Reload Data** on the figure window.

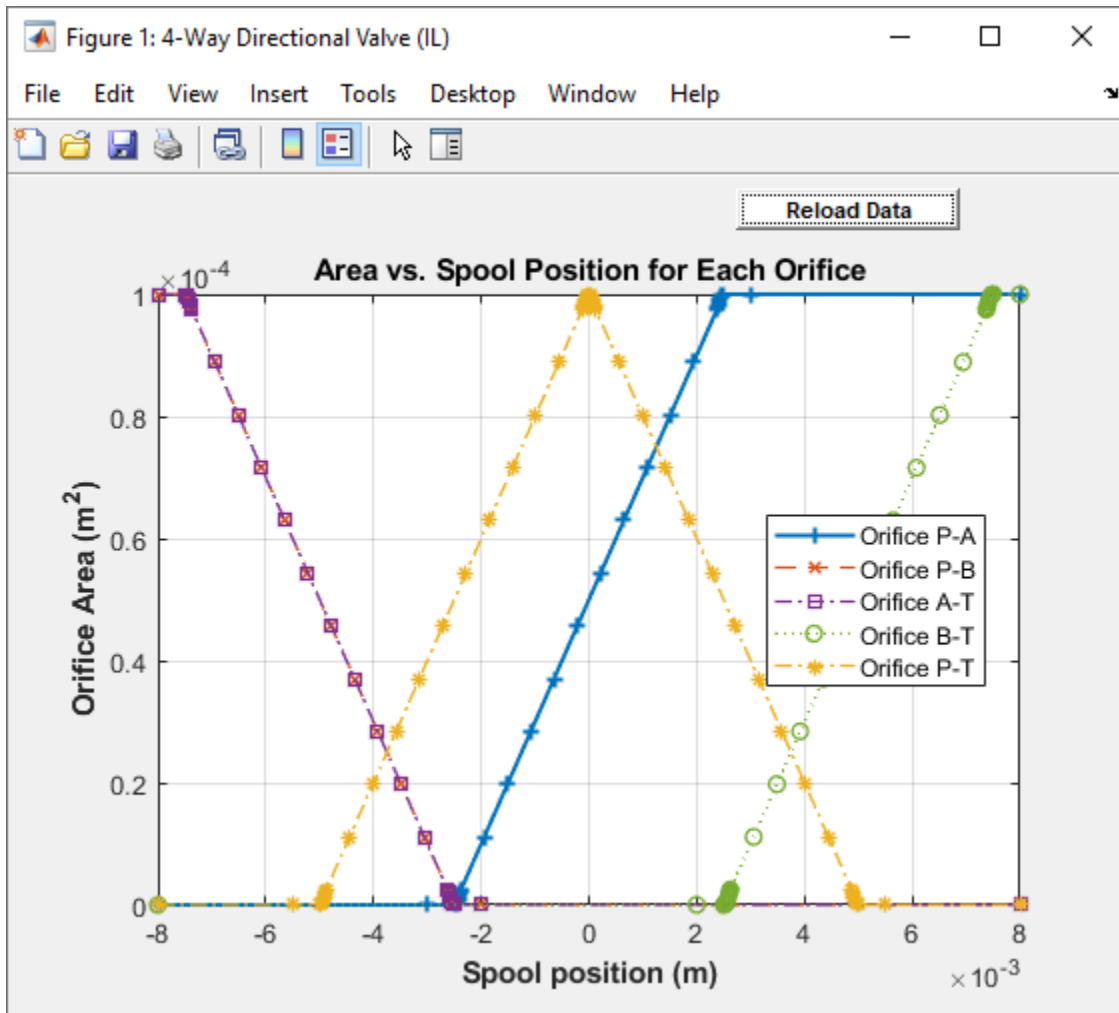

This image shows an example valve configuration. In the **Valve Configuration** settings:

- **Positive spool position open connections** is P-A and B-T.
- **Neutral spool position open connections** is P-T only.
- **Negative spool position open connections** is P-B and A-T.

In the **P-A Orifice** settings:

- **Spool position at maximum P-A orifice area** is  $2.5e-3$  m.

All other spool positions are at the default values.

### Example Spool Position Visualization

The visualization shows that the P-A orifice is open between the spool position at  $-2.53e-3$  and  $2.53e-3$  m. Because the P-A orifice is open only when the spool is displaced in the positive direction, setting the **Consistency check for neutral spool and position open connections** parameter to Warning returns:

Warning: P-A orifice must be closed when the spool is in the neutral position. Adjust Spool position at maximum P-A orifice area, Neutral spool position open connections, or Consistency check for neutral spool position open connections. Right-click on the block and select Fluids > Plot Valve Characteristics to view the area or flow of each connection versus spool position.

To resolve this warning, you can change:

- **Spool position at maximum P-A orifice area** to a value larger than 0.005 m.
- **Consistency check for neutral spool position open connections** to None.
- The valve configuration by setting **Neutral spool position open connections** to P-A only.

## Faults

When faults are enabled, the valve open area becomes stuck at a specified spool position in response to one of these triggers:

- Simulation time — Faulting occurs at a specified time.
- Simulation behavior — Faulting occurs in response to an external trigger. This exposes port **Tr**.

Four fault options are available in the **Spool position when faulted** parameter:

- **Positive** — The spool position freezes in the positive position, opening the **Positive spool position open connections** flow paths to their maximum value. The flow paths that are only open in the **Negative spool position open connections** and **Neutral spool position open connections** are closed.
- **Neutral** — The spool position freezes in the neutral position, opening all flow paths to their specified values at 0 m.
- **Negative** — The spool position freezes in the negative position, opening the **Negative spool position open connections** flow paths to their maximum value. The flow paths that are only open in the **Positive spool position open connections** and **Neutral spool position open connections** are closed.
- **Maintain last value** — The valve freezes at the spool position when the trigger occurs.

Due to numerical smoothing at the extremes of the valve area, in the linear parameterization, the minimum area applied is larger than the **Leakage area**, and the maximum is smaller than the **Maximum orifice area**, in proportion to the **Smoothing factor** value.

Once triggered, the valve remains at the faulted area for the rest of the simulation.

## Composite Structure

This block is a composite component comprising of multiple instances of the Orifice (IL) block. Refer to the Orifice (IL) block for more detail on the valve parameterizations and block calculations.

## Predefined Parameterization

You can populate the block with pre-parameterized manufacturing data, which allows you to model a specific supplier component.

To load a predefined parameterization:

- 1** In the block dialog box, next to **Selected part**, click the "<click to select>" hyperlink next to **Selected part** in the block dialogue box settings.
- 2** The Block Parameterization Manager window opens. Select a part from the menu and click **Apply all**. You can narrow the choices using the **Manufacturer** drop down menu.
- 3** You can close the **Block Parameterization Manager** menu. The block now has the parameterization that you specified.
- 4** You can compare current parameter settings with a specific supplier component in the Block Parameterization Manager window by selecting a part and viewing the data in the **Compare selected part with block** section.

---

**Note** Predefined block parameterizations use available data sources to supply parameter values. The block substitutes engineering judgement and simplifying assumptions for missing data. As a result,

expect some deviation between simulated and actual physical behavior. To ensure accuracy, validate the simulated behavior against experimental data and refine your component models as necessary.

To learn more, see “List of Pre-Parameterized Components”.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Liquid entry or exit port to the valve.

**B** — Liquid port  
isothermal liquid

Liquid entry or exit port to the valve.

**P** — Liquid port  
isothermal liquid

Liquid entry or exit port to the valve.

**T** — Liquid port  
isothermal liquid

Liquid entry or exit port to the valve.

### Input

**S** — Spool displacement, m  
physical signal

Spool displacement, in m, specified as a physical signal.

**Tr** — External fault trigger  
physical signal

Physical signal port for an external fault trigger. Triggering occurs when the value is greater than 0.5. There is no unit associated with the trigger value.

### Dependencies

This port is visible when **Enable faults** is set to On and **Fault trigger** is set to External.

## Parameters

### Valve Configuration

**Positive spool position open connections** — Flow paths open when the spool is in a positive position

P-A and B-T (default) | P-A and P-B | P-B and A-T | P-A only | P-B only | P-A, P-B, and A-B

Flow paths open when the spool is in a positive position. This parameter sets the valve configuration and defines the direction of spool movement according to the signal received at port **S**. The settings for this parameter can be checked against the definitions for the other orifices for consistency when the **Consistency check for neutral spool position open connections** is set to Warning or Error.

**Neutral spool position open connections** — Flow paths open when the spool is in the neutral position

All closed (default) | P-A, P-B, A-T, and B-T | A-T and B-T | P-A and A-T | P-A and B-T | P-A and P-B | P-B and A-T | P-B and B-T | A-T only | B-T only | P-A only | P-B only | P-T only | P-A, A-T, and P-T | P-A, P-B, and A-B | P-B, B-T, and P-T | P-A, P-B, A-T, B-T, P-T

Flow paths open when the spool is in the neutral position. This parameter sets the valve configuration and defines the direction of spool movement according to the signal received at port **S**. The settings for this parameter can be checked against the definitions for the other orifices for consistency when the **Consistency check for neutral spool position open connections** is set to Warning or Error.

**Negative spool position open connections** — Flow paths open when the spool moves in the negative direction

P-A and B-T (default) | P-A and P-B | P-B and A-T | P-A only | P-B only | P-A, P-B, and A-B

Flow paths open when the spool moves in the negative direction. This parameter sets the valve configuration and defines the direction of spool movement according to the signal received at port **S**. The settings for this parameter can be checked against the definitions for the other orifices for consistency when the **Consistency check for neutral spool position open connections** is set to Warning or Error.

**Consistency check for neutral spool position open connections** — Whether to check if the orifice settings are consistent with the specified spool position for maximum orifice opening

Warning (default) | Error | None

Whether to check if the neutral spool position open settings on the **Valve Configuration** tab are consistent with the specified spool position at the maximum orifice area. For each enabled orifice, the actual offset at the spool neutral position should be commensurate with the specified spool offset for each individual orifice.

## Model Parameterization

**Area characteristics** — Flow equations for orifices

Identical for all flow paths (default) | Different for each flow path

Applies uniform or individual flow equations for the valve orifice area. **Identical for all flow paths** uses the same orifice and spool geometries, flow rates, pressure, and area vectors for all valve orifices. When using **Different for each flow path**, these parameters are specified individually for each orifice. In both cases, orifices **A**, **B**, **P**, and **T** have the same cross-sectional areas, discharge coefficients, and Reynolds numbers in the **Linear - Area vs. spool travel** and **Tabulated data - Area vs. spool travel** parameterizations. The same **Orifice parameterization** is applied to all flow paths.

**Orifice parameterization** — Method of calculating opening area

Linear area vs. spool travel (default) | Tabulated data - Area vs. spool travel | Tabulated data - Volumetric flow rate vs. spool travel and pressure drop

Method of calculating the valve opening area. In the tabulated data parameterizations, you can provide your own valve area and spool travel data for nonlinear valve opening profiles, or you can provide data in terms of volumetric flow rate, spool travel, and pressure drop over the flow path.

**Spool travel between closed and open orifice** — Maximum spool stroke

0.005 m (default) | positive scalar

Maximum distance of spool travel.

#### Dependencies

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Linear - Area vs. spool travel.

**Maximum orifice area** — Maximum orifice opening area

1e-4 m<sup>2</sup> (default) | positive scalar

Largest open area of each orifice during the operation of the valve.

#### Dependencies

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Linear - Area vs. spool travel.

**Leakage area** — Open area when an orifice is fully closed

1e-9 m<sup>2</sup> (default) | positive scalar

Open area when an orifice is fully closed. Any area smaller than this value is maintained at the specified leakage area. This parameter contributes to numerical stability by maintaining continuity in the flow.

#### Dependencies

To enable this parameter, set **Orifice parameterization** to Linear - Area vs. spool travel.

**Spool travel vector** — Vector of spool opening distances relative to fully closed position

[0, .00125, .0025, .00375, .005] m (default) | 1-by-n vector

Vector of spool travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **Orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Tabulated data - Area vs. spool travel.

**Orifice area vector** — Vector of valve opening areas

[1e-09, 1e-05, 4e-05, 6e-05, .0001] m<sup>2</sup> (default) | 1-by-n vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **Spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

**Dependencies**

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Tabulated data - Area vs. spool travel.

**Spool travel vector, ds** — Vector of spool opening distances relative to fully closed position  
[0, .00125, .0025, .00375, .005] m (default) | 1-by-*n* vector

Vector of spool travel distances for the tabular parametrization of volumetric flow rate. The spool travel vector forms an independent axis with the **Pressure drop vector, dp** parameter for the 2-D dependent **Volumetric flow rate table, q(ds,dp)** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**Pressure drop vector, dp** — Vector of valve pressure drop values  
[-.1, .3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of pressure drop values for the tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **Spool travel vector, ds** parameter for the 2-D dependent **Volumetric flow rate table, q(ds,dp)** parameter. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**Volumetric flow rate table, q(ds,dp)** — Array of volumetric flow rates  
[-1e-08, 2.2e-08, 2.8e-08, 3.4e-08; -9e-06, .00015, .0002, .00024;  
-.00036, .00063, .00081, .00096; .00054, .00094, .0012, .0014;  
-.00091, .0016, .002, .0024] m<sup>3</sup>/s (default) | *M*-by-*N* matrix

*M*-by-*N* matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the correlated vectors:

- *M* is the number of vector elements in the **Spool travel vector, ds** parameter.
- *N* is the number of vector elements in the **Pressure drop vector, dp** parameter.

**Dependencies**

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**Constant orifice area** — Orifice area for identical flow paths  
1e-4 m<sup>2</sup> (default) | positive scalar

Orifice area when the positive, neutral, and negative spool positions feature the same orifice.

**Dependencies**

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to either:

- Linear - area vs. spool travel.
- Tabulated data - Area vs. spool travel

The same orifice must be selected in all three of the **Valve Configuration** parameters:

- **Positive spool position open connections**
- **Neutral spool position open connections**
- **Negative spool position open connections**

**Constant orifice pressure drop vector** — Vector of pressure differential values for identical flow paths

[-.1, .3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of pressure differential values over the valve when the positive, neutral, and negative spool positions feature the same orifice. The vector elements correspond one-to-one with the elements in the **Constant orifice volumetric flow rate vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

The same orifice must be selected in all three of the **Valve Configuration** parameters:

- **Positive spool position open connections**
- **Neutral spool position open connections**
- **Negative spool position open connections**

**Constant orifice volumetric flow rate vector** — Vector of volumetric flow rate values for identical flow paths

[-.0009, .0016, .002, .0024] m<sup>3</sup>/s (default) | 1-by-*n* vector

Vector of volumetric flow rate values for a constant orifice when the positive, neutral, and negative spool positions feature the same orifice. The vector elements correspond one-to-one with the elements in the **Constant orifice pressure drop vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

The same orifice must be selected in all three of the **Valve Configuration** parameters:

- **Positive spool position open connections**
- **Neutral spool position open connections**

- **Negative spool position open connections**

**Cross-sectional area at ports P, T, A and B** — Area at conserving ports

inf m<sup>2</sup> (default) | positive scalar

Maximum cross-sectional areas at the entry and exit ports **P**, **T**, **A**, and **B**, which are used in the pressure-flow rate equation that determines the mass flow rate through the valve.

**Dependencies**

To enable this parameter, set **Area characteristics** to `Identical` for all flow paths and **Orifice parameterization** to either:

- Linear - area vs. spool travel
- Tabulated data - Area vs. spool travel

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Correction factor that accounts for discharge losses in theoretical flows.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to either:

- Linear - Area vs. spool travel
- Tabulated data - Area vs. spool travel

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the orifice.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to:

- Linear - area vs. spool travel
- Tabulated data - Area vs. spool travel

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range of [0,1]

Continuous smoothing factor that introduces a layer of gradual change based to the flow response when the valve is in near-open and near-closed positions. To increase the stability of your simulation in these regimes, set this parameter to a nonzero value less than one.

**Dependencies**

To enable this parameter, set **Orifice parametrization** to `Linear - area vs. spool travel`.

**Pressure recovery** — Whether to account for pressure increase in area expansions

off (default) | on

Whether to account for pressure increase when fluid flows from a region of smaller cross-sectional area to a region of larger cross-sectional area.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to:

- Linear - area vs. spool travel
- Tabulated data - Area vs. spool travel

**P-A Orifice**

**Spool position at maximum P-A orifice area** — Spool offset for fully open P-A orifice  
 $7.5e-3$  m (default) | positive scalar

Spool offset from the neutral position for a fully open P-A orifice. The **Consistency check for neutral spool position open connections** parameter will notify you if the values set for this spool position are inconsistent or unphysical according to other orifice spool positions. To visualize the defined offsets, see “Visualize Orifice Openings” on page 1-256.

**Dependencies**

To enable this parameter, set one of the following parameters:

**Positive spool position open connections** to:

- P-A and B-T
- P-A and P-B
- P-A only

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only

**Negative spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only

---

**Note:** This parameter is enabled only when the P-A orifice settings do not appear in all three spool position parameters: **Positive spool position open connections**, **Neutral spool position open connections**, and **Negative spool position open connections**.

---

**P-A spool travel between closed and open orifice** — Maximum spool stroke  
 $0.005$  m (default) | positive scalar

Maximum distance of spool travel. This value provides an upper limit to calculations so that simulations do not return unphysical values.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Linear - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only

**P-A maximum orifice area** — Maximum orifice opening area  
1e-4 m<sup>2</sup> (default) | positive scalar

Largest open area of the P-A orifice during the operation of the valve.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Linear - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections to:**

- P-A and B-T
- P-A and P-B

- P-A only

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only

**P-A orifice spool travel vector** — Vector of spool opening distances relative to fully closed position  
[0, .00125, .0025, .00375, .005] m (default) | 1-by-*n* vector

Vector of spool travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **P-A orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only

**P-A orifice area vector** — Vector of valve opening areas

[1e-10, 1e-05, 4e-05, 6e-05, .0001] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **P-A spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

#### Dependencies

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only

**P-A orifice spool travel vector, ds** — Vector of spool opening distances relative to fully closed position

[0, .00125, .0025, .00375, .005] m (default) | 1-by-*n* vector

Vector of spool travel distances for the tabular parameterization of volumetric flow rates. The spool travel vector forms an independent axis with the **P-A orifice pressure drop vector, dp** parameter for the 2-D dependent **P-A orifice volumetric flow rate table, q(ds,dp)** parameter. The values are

listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

#### Positive spool position open connections to:

- P-A and B-T
- P-A and P-B
- P-A only

#### Neutral spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only

#### Negative spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only

**P-A orifice pressure drop vector,  $dp$**  — Vector of pressure drop values  
[ -.1, .3, .5, .7] MPa (default) | 1-by- $n$  vector

Vector of pressure drop values for the tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **P-A orifice spool travel vector,  $ds$**  parameter for the 2-D dependent **P-A orifice volumetric flow rate table,  $q(ds,dp)$**  parameter. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only

**P-A orifice volumetric flow rate table,  $q(ds,dp)$**  — Array of volumetric flow rate values  
[-1e-08, 2.2e-08, 2.8e-08, 3.4e-08; -9e-06, .00015, .0002, .00024;  
-.00036, .00063, .00081, .00096; -.00054, .00094, .0012, .0014;  
-.00091, .0016, .002, .0024] m<sup>3</sup>/s (default) | *M*-by-*N* matrix

*M*-by-*N* matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the correlated vectors:

- *M* is the number of vector elements in the **P-A orifice spool travel vector,  $ds$**  parameter.
- *N* is the number of vector elements in the **P-A orifice pressure drop vector,  $dp$**  parameter.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3** One of the following parameters:

**Positive spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only

**P-A constant orifice area** — Cross-sectional area for a constant orifice  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Orifice area when the positive, neutral, and negative spool positions feature the same orifice.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to either:
  - Linear - area vs. spool travel
  - Tabulated data - Area vs. spool travel
- 3** One of the following settings in each parameter:

**Positive spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T

- P-A and P-B
- P-A only

**P-A Constant orifice pressure drop vector** — Vector of pressure differential values for a constant orifice

[ -.1, .3, .5, .7 ] MPa (default) | 1-by-*n* vector

Vector of pressure differential values over the valve when the positive, neutral, and negative spool positions feature the same orifice. The vector elements correspond one-to-one with the elements in the **P-A Constant orifice volumetric flow rate vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3** One of the following settings in each parameter:

**Positive spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only

**P-A Constant orifice volumetric flow rate vector** — Vector of volumetric flow rates for a constant orifice

[ -.0009, .0016, .002, .0024 ] m<sup>3</sup>/s (default) | 1-by-*n* vector

Vector of pressure differential values over the valve when the positive, neutral, and negative spool positions feature the same orifice. The vector elements correspond one-to-one with the elements in the **P-A Constant orifice pressure drop vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following settings in each parameter:

**Positive spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only

**P-B Orifice**

**Spool position at maximum P-B orifice area** — Spool offset from the neutral position for a fully open P-B orifice

7.5e-3 m (default) | positive scalar

Spool offset from the neutral position for a fully open P-B orifice. The **Consistency check for neutral spool position open connections** parameter will notify you if the values set for this spool position are inconsistent or unphysical according to other orifice spool positions. To visualize the defined offsets, see “Visualize Orifice Openings” on page 1-256.

**Dependencies**

To enable this parameter, set one of the following parameters:

**Positive spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

---

**Note:** This parameter is enabled only when the P-B orifice settings do not appear in all three spool position parameters: **Positive spool position open connections**, **Neutral spool position open connections**, and **Negative spool position open connections**.

---

**P-B spool travel between closed and open orifice** — Maximum spool stroke

0.005 m (default) | positive scalar

Maximum distance of spool travel. This value provides an upper limit to calculations so that simulations do not return unphysical values.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Linear - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only

or set **Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

or set **Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

**P-B maximum orifice area** — Maximum orifice opening area  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Largest open area of the P-B orifice during the operation of the valve.

#### Dependencies

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Linear - Area vs. spool travel.
- 3** One of the following parameters:

#### Positive spool position open connections to:

- P-B and A-T
- P-A and P-B
- P-B only

#### Neutral spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

#### Negative spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

**P-B orifice spool travel vector** — Vector of spool opening distances relative to fully closed position  
 $[0, .00125, .0025, .00375, .005] \text{ m}$  (default) | 1-by- $n$  vector

Vector of spool travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **P-B orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections** to:

- P-B and A-T
- P-A and P-B
- P-B only

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

**Negative spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

**P-B orifice area vector** — Vector of valve opening areas

[1e-10, 1e-05, 4e-05, 6e-05, .0001] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **P-B spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections** to:

- P-B and A-T
- P-A and P-B
- P-B only

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

**P-B orifice spool travel vector,  $ds$**  — Vector of spool opening distances relative to fully closed position

[0, .00125, .0025, .00375, .005] m (default) | 1-by- $n$  vector

Vector of spool travel distances for the tabular parameterization of volumetric flow rates. The spool travel vector forms an independent axis with the **P-T orifice pressure drop vector,  $dp$**  parameter for the 2-D dependent **P-T orifice volumetric flow rate table,  $q(ds,dp)$**  parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only.

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

**P-B orifice pressure drop vector,  $dp$**  — Vector of pressure differential values  
[-.1, .3, .5, .7] MPa (default) | 1-by- $n$  vector

Vector of pressure drop values for tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **P-B orifice spool travel vector,  $ds$**  parameter for the 2-D dependent **P-B orifice volumetric flow rate table,  $q(ds,dp)$**  parameter. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

#### Positive spool position open connections to:

- P-B and A-T
- P-A and P-B
- P-B only

#### Neutral spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

#### Negative spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

**P-B orifice volumetric flow rate table,  $q(ds,dp)$**  — Array of volumetric flow rate values  
[-1e-08, 2.2e-08, 2.8e-08, 3.4e-08; -9e-06, .00015, .0002, .00024;  
-.00036, .00063, .00081, .00096; -.00054, .00094, .0012, .0014;  
-.00091, .0016, .002, .0024] m<sup>3</sup>/s (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance.  $M$  and  $N$  are the sizes of the correlated vectors:

- $M$  is the number of vector elements in the **P-B orifice spool travel vector, ds** parameter.
- $N$  is the number of vector elements in the **P-B orifice pressure drop vector, dp** parameter.

### Dependencies

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3** One of the following parameters:

#### Positive spool position open connections to:

- P-B and A-T
- P-A and P-B
- P-B only

#### Neutral spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

#### Negative spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

**P-B constant orifice area** — Cross-sectional area for a constant orifice  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Orifice area when the positive, neutral, and negative spool positions feature the same orifice.

### Dependencies

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to either:
  - Linear - area vs. spool travel
  - Tabulated data - Area vs. spool travel

- 3** One of the following settings in each parameter:

**Positive spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

**P-B Constant orifice pressure drop vector** — Vector of pressure differential values for a constant orifice

[-.1, .3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of pressure differential values over the valve when the positive, neutral, and negative spool positions feature the same orifice. The vector elements correspond one-to-one with the elements in the **P-B Constant orifice volumetric flow rate vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3** One of the following settings in each parameter:

**Positive spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T

- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

**P-B Constant orifice volumetric flow rate vector** — Vector of volumetric flow rate values for a constant orifice

[-.0009, .0016, .002, .0024] m<sup>3</sup>/s (default) | 1-by-*n* vector

Vector of volumetric flow rate values over the valve when the positive, neutral, and negative spool positions feature the same orifice. The vector elements correspond one-to-one with the elements in the **P-B Constant orifice pressure drop vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3** One of the following settings in each parameter:

**Positive spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T

- P-B and B-T
- P-A and P-B
- P-B only

**A-T Orifice**

**Spool position at maximum A-T orifice area** — Spool offset from the neutral position for a fully open A-T orifice

7.5e-3 m (default) | positive scalar

Spool offset from the neutral position for a fully open A-T orifice. The **Consistency check for neutral spool position open connections** parameter will notify you if the values set for this spool position are inconsistent or unphysical according to other orifice spool positions. To visualize the defined offsets, see “Visualize Orifice Openings” on page 1-256.

**Dependencies**

To enable this parameter, set one of the following parameters:

- **Positive spool position open connections** to P-B and A-T.
- **Neutral spool position open connections** to:
  - P-A, P-B, A-T, and B-T
  - P-B and A-T
  - A-T and B-T
  - P-A and A-T
  - A-T only
- **Negative spool position open connections** to P-B and A-T.

---

**Note:** This parameter is enabled only when the A-T orifice settings do not appear in all three spool position parameters: **Positive spool position open connections**, **Neutral spool position open connections**, and **Negative spool position open connections**.

---

**A-T spool travel between closed and open orifice** — Maximum spool stroke

0.005 m (default) | positive scalar

Maximum distance of spool travel. This value provides an upper limit to calculations so that simulations do not return unphysical values.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to P-B and A-T

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- A-T and B-T
- P-A and A-T
- A-T only

**Negative spool position open connections** to P-B and A-T.

**A-T maximum orifice area** — Maximum orifice opening area  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Largest open area of the A-T orifice during the operation of the valve.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to P-B and A-T

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- A-T and B-T
- P-A and A-T
- A-T only

**Negative spool position open connections** to P-B and A-T.

**A-T orifice spool travel vector** — Vector of spool opening distances relative to fully closed position  
 $[0, .00125, .0025, .00375, .005] \text{ m}$  (default) | 1-by- $n$  vector

Vector of spool travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **A-T orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to P-B and A-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- A-T and B-T
- P-A and A-T
- A-T only

**Negative spool position open connections** to P-B and A-T.

**A-T orifice area vector** — Vector of valve opening areas  
 $[1e-10, 1e-05, 4e-05, 6e-05, .0001]$  m<sup>2</sup> (default) | 1-by-*n* vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **A-T spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to P-B and A-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- A-T and B-T
- P-A and A-T
- A-T only

**Negative spool position open connections** to P-B and A-T.

**A-T orifice spool travel vector, ds** — Vector of spool opening distances relative to fully closed position  
 $[0, .00125, .0025, .00375, .005]$  m (default) | 1-by-*n* vector

Vector of spool travel distances for the tabular parameterization of volumetric flow rates. The spool travel vector forms an independent axis with the **A-T orifice pressure drop vector, dp** parameter for the 2-D dependent **A-T orifice volumetric flow rate table, q(ds,dp)** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

3 One of the following parameters:

**Positive spool position open connections** to P-B and A-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- A-T and B-T
- P-A and A-T
- A-T only

**Negative spool position open connections** to P-B and A-T.

**A-T orifice pressure drop vector,  $dp$**  — Vector of pressure differential values  
[-.1, .3, .5, .7] MPa (default) | 1-by- $n$  vector

Vector of pressure drop values for tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **A-T orifice spool travel vector,  $ds$**  parameter for the 2-D dependent **A-T orifice volumetric flow rate table,  $q(ds,dp)$**  parameter. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections** to P-B and A-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- A-T and B-T
- P-A and A-T
- A-T only

**Negative spool position open connections** to P-B and A-T.

**A-T orifice volumetric flow rate table,  $q(ds,dp)$**  — Array of volumetric flow rate values  
[-1e-08, 2.2e-08, 2.8e-08, 3.4e-08; -9e-06, .00015, .0002, .00024;  
-.00036, .00063, .00081, .00096; -.00054, .00094, .0012, .0014;  
-.00091, .0016, .002, .0024] m<sup>3</sup>/s (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance.  $M$  and  $N$  are the sizes of the correlated vectors:

- $M$  is the number of vector elements in the **A-T orifice spool travel vector,  $ds$**  parameter.
- $N$  is the number of vector elements in the **A-T orifice pressure drop vector,  $dp$**  parameter.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3** One of the following parameters:

**Positive spool position open connections** to P-B and A-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- A-T and B-T
- P-A and A-T
- A-T only

**Negative spool position open connections** to P-B and A-T.

**A-T constant orifice area** — Cross-sectional area for a constant orifice  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Orifice area when the positive, neutral, and negative spool positions feature the same orifice.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to either:
  - Linear - area vs. spool travel
  - Tabulated data - Area vs. spool travel
- 3** One of the following settings in each parameter:

**Positive spool position open connections** to P-B and A-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- A-T and B-T
- P-A and A-T
- A-T only

**Negative spool position open connections** to P-B and A-T.

**A-T Constant orifice pressure drop vector** — Vector of pressure differential values for a constant orifice

[-.1, .3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of pressure differential values over the valve when the positive, neutral, and negative spool positions feature the same orifice. The vector elements correspond one-to-one with the elements in the **A-T Constant orifice volumetric flow rate vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following settings in each parameter:

**Positive spool position open connections** to P-B and A-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- A-T and B-T
- P-A and A-T
- A-T only

**Negative spool position open connections** to P-B and A-T.

**A-T Constant orifice volumetric flow rate vector** — Vector of volumetric flow rate values for a constant orifice

[-.0009, .0016, .002, .0024] m<sup>3</sup>/s (default) | 1-by-*n* vector

Vector of volumetric flow rate values when the positive, neutral, and negative spool positions feature the same orifice. The vector elements correspond one-to-one with the elements in the **Constant orifice volumetric flow rate vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following settings in each parameter:

**Positive spool position open connections** to P-B and A-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T

- P-B and A-T
- A-T and B-T
- P-A and A-T
- A-T only

**Negative spool position open connections** to P-B and A-T.

### **B-T Orifice**

**Spool position at maximum B-T orifice area** — Spool offset from the neutral position for a fully open B-T orifice

7.5e-3 m (default) | positive scalar

Spool offset from the neutral position for a fully open B-T orifice. The **Consistency check for neutral spool position open connections** parameter will notify you if the values set for this spool position are inconsistent or unphysical according to other orifice spool positions. To visualize the defined offsets, see “Visualize Orifice Openings” on page 1-256.

### **Dependencies**

To enable this parameter, set one of the following parameters:

- **Positive spool position open connections** to P-A and B-T.
- **Neutral spool position open connections** to:
  - P-A, P-B, A-T, and B-T
  - A-T and B-T
  - P-A and B-T
  - P-B and B-T
  - B-T only
- **Negative spool position open connections** to P-A and B-T.

---

**Note:** This parameter is enabled only when the B-T orifice settings do not appear in all three spool position parameters: **Positive spool position open connections**, **Neutral spool position open connections**, and **Negative spool position open connections**.

---

**B-T spool travel between closed and open orifice** — Maximum spool stroke

0.005 m (default) | positive scalar

Maximum distance of spool travel. This value provides an upper limit to calculations so that simulations do not return unphysical values.

### **Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to P-A and B-T.

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- A-T and B-T
- P-A and B-T
- P-B and B-T
- B-T only

**Negative spool position open connections to P-A and B-T.**

**B-T maximum orifice area** — Maximum orifice opening area  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Largest open area of the B-T orifice during the operation of the valve.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections to P-A and B-T.****Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- A-T and B-T
- P-A and B-T
- P-B and B-T
- B-T only

**Negative spool position open connections to P-A and B-T.**

**B-T orifice spool travel vector** — Vector of spool opening distances relative to fully closed position  
 $[0, .00125, .0025, .00375, .005]$  m (default) | 1-by- $n$  vector

Vector of spool travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **B-T orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections to P-A and B-T.**

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- A-T and B-T
- P-A and B-T
- P-B and B-T
- B-T only

**Negative spool position open connections to P-A and B-T.****B-T orifice area vector** — Vector of valve opening areas

[1e-10, 1e-05, 4e-05, 6e-05, .0001] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **B-T orifice spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections to P-A and B-T.****Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- A-T and B-T
- P-A and B-T
- P-B and B-T
- B-T only

**Negative spool position open connections to P-A and B-T.****B-T orifice spool travel vector, ds** — Vector of spool opening distances relative to fully closed position

[0, .00125, .0025, .00375, .005] m (default) | 1-by-*n* vector

Vector of control member travel distances for the tabular parameterization of volumetric flow rates. The spool travel vector forms an independent axis with the **B-T orifice pressure drop vector, dp** parameter for the 2-D dependent **B-T orifice volumetric flow rate table, q(ds,dp)** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.

**2 Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**3** One of the following parameters:

**Positive spool position open connections** to P-A and B-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- A-T and B-T
- P-A and B-T
- P-B and B-T
- B-T only

**Negative spool position open connections** to P-A and B-T.

**B-T orifice pressure drop vector,  $dp$**  — Vector of pressure differential values  
[-.1, .3, .5, .7] MPa (default) | 1-by- $n$  vector

Vector of pressure drop values for tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **B-T orifice spool travel vector,  $ds$**  parameter for the 2-D dependent **B-T orifice volumetric flow rate table,  $q(ds,dp)$**  parameter. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

**1 Area characteristics** to Different for each flow path.

**2 Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**3** One of the following parameters:

**Positive spool position open connections** to P-A and B-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- A-T and B-T
- P-A and B-T
- P-B and B-T
- B-T only

**Negative spool position open connections** to P-A and B-T.

**B-T orifice volumetric flow rate table,  $q(ds,dp)$**  — Array of volumetric flow rate values  
[-1e-08, 2.2e-08, 2.8e-08, 3.4e-08; -9e-06, .00015, .0002, .00024;  
-.00036, .00063, .00081, .00096; -.00054, .00094, .0012, .0014;  
-.00091, .0016, .002, .0024] m<sup>3</sup>/s (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance.  $M$  and  $N$  are the sizes of the correlated vectors:

- $M$  is the number of vector elements in the **B-T orifice spool travel vector, ds** parameter.
- $N$  is the number of vector elements in the **B-T orifice pressure drop vector, dp** parameter.

### Dependencies

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3** One of the following parameters:

**Positive spool position open connections** to P-A and B-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- A-T and B-T
- P-A and B-T
- P-B and B-T
- B-T only

**Negative spool position open connections** to P-A and B-T.

**B-T constant orifice area** — Cross-sectional orifice area for constant orifices  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Orifice area when the positive, neutral, and negative spool positions feature the same orifice.

### Dependencies

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to either:
  - Linear - area vs. spool travel
  - Tabulated data - Area vs. spool travel
- 3** One of the settings in each parameter:

**Positive spool position open connections** to P-A and B-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- A-T and B-T
- P-A and B-T
- P-B and B-T

- B-T only

**Negative spool position open connections** to P-A and B-T.

**B-T Constant orifice pressure drop vector** — Vector of pressure differential values for a constant orifice

[-.1, .3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of pressure differential values over the valve when the positive, neutral, and negative spool positions feature the same orifice. The vector elements correspond one-to-one with the elements in the **B-T Constant orifice volumetric flow rate vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the settings in each parameter:

**Positive spool position open connections** to P-A and B-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- A-T and B-T
- P-A and B-T
- P-B and B-T
- B-T only

**Negative spool position open connections** to P-A and B-T.

**B-T Constant orifice volumetric flow rate vector** — Vector of volumetric flow rates for a constant orifice

[-.0009, .0016, .002, .0024] m<sup>3</sup>/s (default) | 1-by-*n* vector

Vector of pressure differential values over the valve when the positive, neutral, and negative spool positions feature the same orifice. The vector elements correspond one-to-one with the elements in the **B-T Constant orifice pressure drop vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the settings in each parameter:

**Positive spool position open connections** to P-A and B-T.

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- A-T and B-T
- P-A and B-T
- P-B and B-T
- B-T only

**Negative spool position open connections** to P-A and B-T.

**P-T Orifice**

**Spool position at maximum P-T orifice area** — Spool offset from the neutral position for a fully open P-T orifice

0 m (default) | positive scalar

Spool offset from the neutral position for a fully open P-T orifice. The **Consistency check for neutral spool position open connections** parameter will notify you if the values set for this spool position are inconsistent or unphysical according to other orifice spool positions. To visualize the defined offsets, see “Visualize Orifice Openings” on page 1-256.

**Dependencies**

To enable this parameter, set **Neutral spool position open connections** to P-T only.

**P-T spool travel between closed and open orifice** — Maximum spool stroke

0.005 m (default) | positive scalar

Maximum distance of spool travel. This value provides an upper limit to calculations so that simulations do not return unphysical values.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 **Neutral spool position open connections** to P-T only.

**P-T maximum orifice area** — Maximum orifice opening area

1e-4 m<sup>2</sup> (default) | positive scalar

Largest open area of the P-T orifice during the operation of the valve.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 **Neutral spool position open connections** to P-T only.

**P-T orifice spool travel vector** — Vector of spool opening distances relative to fully closed position

[0, .00125, .0025, .00375, .005] m (default) | 1-by-n vector

Vector of control member travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **P-T orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3 **Neutral spool position open connections** to P-T only.

**P-T orifice spool travel vector, ds** — Vector of spool opening distances relative to fully-closed position

[0, .00125, .0025, .00375, .005] m (default) | 1-by-*n* vector

Vector of control member travel distances for the tabular parameterization of volumetric flow rate. The spool travel vector forms an independent axis with the **P-T orifice pressure drop vector, dp** parameter for the 2-D dependent **P-T orifice volumetric flow rate table, q(ds,dp)** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3 **Neutral spool position open connections** to P-T only.

**P-T orifice pressure drop vector, dp** — Vector of pressure differential values

[-.1, .3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of pressure drop values for tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **P-T orifice spool travel vector, ds** parameter for the 2-D dependent **P-T orifice volumetric flow rate table, q(ds,dp)** parameter. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3 **Neutral spool position open connections** to P-T only.

**P-T orifice volumetric flow rate table, q(ds,dp)** — Array of volumetric flow rates

[-1e-08, 2.2e-08, 2.8e-08, 3.4e-08; -9e-06, .00015, .0002, .00024; -.00036, .00063, .00081, .00096; -.00054, .00094, .0012, .0014; -.00091, .0016, .002, .0024] m<sup>3</sup>/s (default) | *M*-by-*N* matrix

$M$ -by- $N$  matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance.  $M$  and  $N$  are the sizes of the correlated vectors:

- $M$  is the number of vector elements in the **P-T orifice spool travel vector,  $ds$**  parameter.
- $N$  is the number of vector elements in the **P-T orifice pressure drop vector,  $dp$**  parameter.

### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3 **Neutral spool position open connections** to P-T only.

### Faults

**Enable faults** — Fault option

Off (default) | On

Enable externally or temporally triggered faults. When faulting occurs, the valve area normally set by the opening parameterization will be set to the value specified in the **Spool position area when faulted** parameter.

**Spool position when faulted** — Set faulted characteristics

Positive (default) | Neutral | Negative | Maintain last value

Sets the faulted valve spool position. You can choose for the valve to seize when the spool is in the positive position, negative position, or at the position when faulting is triggered.

### Dependencies

To enable this parameter, set **Enable faults** to On.

**Fault trigger** — External or temporal trigger option

Temporal (default) | External

Whether a fault trigger occurs due to an external event or at a specified time.

When set to External, port **Tr** is enabled. A physical signal at port **Tr** that is greater than 0.5 triggers faulting.

When set to Temporal, when the **Simulation time for fault event** is reached, the valve area will be set to the value specified in the **Spool position when faulted** parameter.

### Dependencies

To enable this parameter, set **Enable faults** to On.

**Simulation time for fault event** — Time at which faulting is triggered

5 s (default) | positive scalar

When the **Simulation time for fault event** is reached, the valve area is set to the value specified in the **Spool position when faulted** parameter.

### Dependencies

To enable this parameter, set **Enable faults** to On and **Fault trigger** to Temporal.

## 4-Way 3-Position Directional Valve (TL)

Valve for routing flow at the junction of four lines in a thermal liquid network

### Libraries:

Simscape / Fluids / Thermal Liquid / Valves & Orifices / Directional Control Valves

### Description

The 4-Way 3-Position Directional Valve (TL) block models a valve with four openings in a thermal liquid network, typically between an actuator, pump, and tank. The valve operation is controlled by a single spool displaced according to the signal at port **S**. You can set the baseline configuration of your valve by specifying the orifices that are open when the spool is in the neutral position (centered at 0 m) in the **Neutral spool position open connections** parameter, when the spool moves in the positive direction in the **Positive spool position open connections** parameter, and when the spool moves in the negative direction in the **Negative spool position open connections**.

You can set the model for valve opening in the **Orifice parameterization** parameter as a linear relationship or function of user-provided data, which can be applied to one or all flow paths in the valve.

### Example Valve Setup

In this example configuration, **Neutral spool position open connections** is set to All closed. When the spool is in the neutral position, all orifices are closed to flow:

In this configuration, **Negative spool position open connections** is set to P-A and B-T. When the signal at port **S** moves the spool to a negative position, the paths between ports **P** and **A** and between ports **B** and **T** are open to flow. The paths between ports **P** and **B** and ports **A** and **T** are closed to flow:

In this configuration, **Positive spool position open connections** is set to P-B and A-T. When the signal at port **S** moves the spool to a positive position, the paths between ports **P** and **B** and between ports **A** and **T** are open to flow and the paths between ports **P** and **A** and between ports **B** and **T** are closed:

Schematically, this configuration is shown as:

The left-hand side corresponds to the positive position and the right-hand side corresponds to the negative position.

### Spool Displacement and Valve Configuration

The *spool stroke* is the amount of spool travel an orifice takes to fully open from a closed position and is defined for each orifice selected on the **Valve Configuration** tab. The table below shows how the stroke is calculated in accordance with the valve orifice parameterization and flow path characteristics.

The direction of spool movement signaled at port **S** depends on the spool stroke and the orifice orientation:

### Orifice Definition and Spool Travel Direction

Spool Position when Orifice is Open	Spool Travel, $\Delta S$
Always closed (orifice is not selected in any spool position configuration)	N/A
Always open (orifice is selected in positive, neutral, and negative spool position configurations)	N/A
Negative	$S_{\text{orifice\_max}} + \text{spool stroke} - \mathbf{S}$
Negative and Neutral	$S_{\text{orifice\_max}} + \text{spool stroke} - \mathbf{S}$
Positive	$S_{\text{orifice\_max}} - \text{spool stroke} + \mathbf{S}$
Positive and Neutral	$S_{\text{orifice\_max}} - \text{spool stroke} + \mathbf{S}$
Neutral	$ S_{\text{orifice\_max}}  + \text{spool stroke} -  \mathbf{S} $
Positive and Negative	$- S_{\text{orifice\_max}}  + \text{spool stroke} -  \mathbf{S} $

Where  $S_{\text{orifice\_max}}$  is the spool position at the maximum orifice area defined for each orifice. The orifice area saturates at the leakage area when  $\Delta S$  is negative and saturates at the maximum orifice area when the orifice is fully open. When the orifice is fully open,  $\Delta S$  is equal to the spool stroke, so  $\Delta S$  greater than the spool stroke does not further increase the orifice area.

The **Consistency check for neutral spool position open connections** parameter verifies that

- Any orifice listed in **Neutral spool position open connections** is open when the signal at **S** is 0.
- Any orifice that is not listed in **Neutral spool position open connections** is closed when the signal at **S** is 0.

You can optionally choose to receive a warning or error when this check is violated.

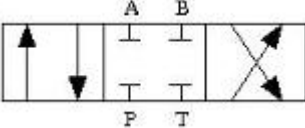

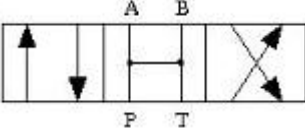

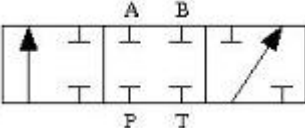

The possible configurations of the 4-Way 3-Position Directional Valve (TL) block are shown below.

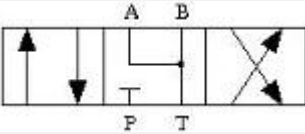

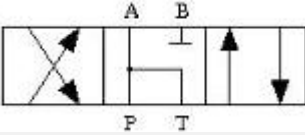

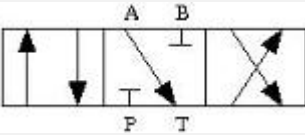

---

**Note** This block includes all configurations from the Hydraulic (Isothermal) library blocks 4-Way Directional Valve and the 4-Way Directional Valves A - K.

## Valve Orifice Parameterizations

The **Orifice parameterization** parameter sets the model for the open area or volumetric flow rate through one or all of the valve orifices. The block applies the same data for all flow paths if **Area characteristics** is set to **Identical** for all flow paths; otherwise, individual parameterizations are applied for the **Different** for all flow paths setting. You can model valve opening in three ways:

- Linear - Area vs. spool travel

The opening area is a linear function of the spool position received as a signal at port **S**:

$$A_{orifice} = \frac{(A_{max} - A_{leak})}{\Delta S_{max}} \Delta S + A_{leak},$$

where:

- $\Delta S$  is the spool travel defined in “Spool Displacement and Valve Configuration” on page 1-300.

$A_{orifice}$  saturates at  $A_{leak}$  when  $\Delta S$  is negative and saturates at  $A_{max}$  when the orifice is fully open. When the orifice is fully open,  $\Delta S$  is equal to the spool stroke, so  $\Delta S$  greater than the spool stroke does not further increase the orifice area.

- $\Delta S_{max}$  is the **Spool travel between closed and open orifice**.
- $A_{max}$  is the **Maximum orifice area**.
- $A_{leak}$  is the **Leakage area**.

When the valve is in a near-open or near-closed position in the linear parameterization, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the opening area between  $A_{leak}$  and  $A_{max}$ . For more information, see “Numerical Smoothing”.

- Tabulated data - Area vs. spool travel

Provide spool travel vectors for your system or for individual flow paths between ports **P**, **A**, **B**, and **T**. This data will be used to calculate the relationship between the orifice area and spool displacement. Interpolation is used to determine the opening area between given data points.  $A_{leak}$  and  $A_{max}$  are the first and last parameters of the opening area vector, respectively.

- Tabulated data - Volumetric flow rate vs. spool travel and pressure drop

Provide spool travel and pressure drop vectors and a dependent, 2-D volumetric flow rate array. Interpolation is used to determine flow rate between given data points. The mass flow rate is the product of the volumetric flow rate and the local density.

- Tabulated data - Mass flow rate vs. spool travel and pressure drop

Calculate the mass flow rate directly from the control member position and the pressure drop across the valve. The relationship between the three variables can be nonlinear; the block calculates it from the tabulated data in the **Spool travel vector, ds**, **Pressure drop vector, dp**, and **Mass flow rate table, mdot(ds,dp)** parameters.

### Visualize Orifice Openings

To visualize spool offsets and maximum displacement, right-click the block and select **Fluids > Plot Valve Characteristics**. The plot shows the orifices selected in the **Valve Configuration** settings. The orifice parameterization sets the axes, which are either:

- Orifice area versus spool position
- Volumetric flow rate versus spool position, queried at a specific pressure differential
- Mass flow rate versus spool position for the reference inflow temperature and reference inflow pressure, queried at a specific pressure differential

When the positive, neutral, and negative settings in the **Valve Configuration** feature the same orifice, the plot displays the orifice openings as a constant.

To update the data after changing the block parameters, click **Reload Data** on the figure window.

This image shows an example valve configuration. In the **Valve Configuration** settings:

- **Positive spool position open connections** is P-A and B-T.
- **Neutral spool position open connections** is P-T only.
- **Negative spool position open connections** is P-B and A-T.

In the **P-A Orifice** settings:

- **Spool position at maximum P-A orifice area** is  $2.53 \times 10^{-3}$  m.

All other spool positions are at the default values.

The visualization shows that the P-A orifice is open between the spool position at  $-2.53 \times 10^{-3}$  and  $2.53 \times 10^{-3}$  m. Because the P-A orifice is open only when the spool is displaced in the positive direction, setting the **Consistency check for neutral spool and position open connections** parameter to Warning returns:

Warning: P-A orifice must be closed when the spool is in the neutral position. Adjust Spool position at maximum P-A orifice area, Neutral spool position open connections, or Consistency check for neutral spool position open connections. Right-click on the block and select Fluids > Plot Valve Characteristics to view the area or flow of each connection versus spool position.

To resolve this warning, you can change:

- **Spool position at maximum P-A orifice area** to a value larger than 0.005 m.

- **Consistency check for neutral spool position open connections** to None.
- The valve configuration by setting **Neutral spool position open connections** to P-A only.

### Composite Structure

This block is a composite component comprising of multiple instances of the Orifice (TL) block. Refer to the Orifice (TL) block for more detail on the valve parameterizations and block calculations.

### Leakage Flow

The primary purpose of the leakage flow rate of a closed valve is to ensure that at no time a portion of the thermal liquid network becomes isolated from the remainder of the model. Such isolated portions reduce the numerical robustness of the model and can slow down simulation or cause it to fail. Leakage flow is generally present in real valves but in a model its exact value is less important than its being a small number greater than zero. The leakage flow rate is determined from the **Leakage area** block parameter.

### Predefined Parameterization

You can populate the block with pre-parameterized manufacturing data, which allows you to model a specific supplier component.

To load a predefined parameterization:

- 1 In the block dialog box, next to **Selected part**, click the "<click to select>" hyperlink next to **Selected part** in the block dialogue box settings.
- 2 The Block Parameterization Manager window opens. Select a part from the menu and click **Apply all**. You can narrow the choices using the **Manufacturer** drop down menu.
- 3 You can close the **Block Parameterization Manager** menu. The block now has the parameterization that you specified.
- 4 You can compare current parameter settings with a specific supplier component in the Block Parameterization Manager window by selecting a part and viewing the data in the **Compare selected part with block** section.

---

**Note** Predefined block parameterizations use available data sources to supply parameter values. The block substitutes engineering judgement and simplifying assumptions for missing data. As a result, expect some deviation between simulated and actual physical behavior. To ensure accuracy, validate the simulated behavior against experimental data and refine your component models as necessary.

---

To learn more, see "List of Pre-Parameterized Components".

## Ports

### Input

**S** — Spool or valve control member, unitless  
physical signal

Instantaneous displacement of the valve control member.

## Conserving

**P** — Flow passage  
thermal liquid

Opening through which the flow can enter or exit the valve. This port is typically connected to a fluid supply line.

**T** — Flow passage  
thermal liquid

Opening through which the flow can enter or exit the valve. This port is typically connected to a fluid return line.

**A** — Flow passage  
thermal liquid

Opening through which the flow can enter or exit the valve. This port is typically connected to an actuation line.

**B** — Flow passage  
thermal liquid

Opening through which the flow can enter or exit the valve. This port is typically connected to an actuation line.

## Parameters

### Valve Configuration

**Positive spool position open connections** — Flow paths open when the spool is in a positive position

P-A and B-T (default) | P-A and P-B | P-B and A-T | P-A only | P-B only | P-A, P-B, and A-B

Flow paths open when the spool is in a positive position. This parameter sets the valve configuration and defines the direction of spool movement according to the signal received at port **S**. To check the parameter settings for consistency with other orifices, set **Consistency check for neutral spool position open connections** to Warning or Error.

**Neutral spool position open connections** — Flow paths open when the spool is in the neutral position

All closed (default) | P-A, P-B, A-T, and B-T | A-T and B-T | P-A and A-T | P-A and B-T | P-A and P-B | P-B and A-T | P-B and B-T | A-T only | B-T only | P-A only | P-B only | P-T only | P-A, A-T, and P-T | P-A, P-B, and A-B | P-B, B-T, and P-T | P-A, P-B, A-T, B-T, P-T

Flow paths open when the spool is in the neutral position. This parameter sets the valve configuration and defines the direction of spool movement according to the signal received at port **S**. To check the parameter settings for consistency with other orifices, set **Consistency check for neutral spool position open connections** to Warning or Error.

**Negative spool position open connections** — Flow paths open when the spool moves in the negative direction

P-A and B-T (default) | P-A and P-B | P-B and A-T | P-A only | P-B only | P-A, P-B, and A-B

Flow paths open when the spool moves in the negative direction. This parameter sets the valve configuration and defines the direction of spool movement according to the signal received at port **S**. To check the parameter settings for consistency with other orifices, set **Consistency check for neutral spool position open connections** to Warning or Error.

**Consistency check for neutral spool position open connections** — Whether to check if the orifice settings are consistent with the specified spool position for maximum orifice opening

Warning (default) | Error | None

Whether to check if the neutral spool position open settings on the **Valve Configuration** tab are consistent with the specified spool position at the maximum orifice area. For each enabled orifice, the actual offset at the spool neutral position should be commensurate with the specified spool offset for each individual orifice.

### Model Parameterization

**Area characteristics** — Flow equations for orifices

Identical for all flow paths (default) | Different for each flow path

Applies uniform or individual flow equations for the valve orifice area. **Identical for all flow paths** uses the same orifice and spool geometries, flow rates, pressure, and area vectors for all valve orifices. When using **Different for each flow path**, these parameters are specified individually for each orifice. In both cases, all orifices have the same cross-sectional areas, discharge coefficients, and Reynolds numbers in the **Linear - Area vs. spool travel** and **Tabulated data - Area vs. spool travel** parameterizations. The same **Orifice parameterization** is applied to all flow paths.

**Orifice parameterization** — Method of calculating opening area

Linear - Area vs. spool travel (default) | Tabulated data - Area vs. spool travel |  
Tabulated data - Volumetric flow rate vs. spool travel and pressure drop |  
Tabulated data - Mass flow rate vs. spool travel and pressure drop

Method of calculating the valve opening area. In the tabulated data parameterizations, you can provide your own valve area and spool travel data for nonlinear valve opening profiles, or you can provide data in terms of volumetric flow rate, spool travel, and pressure drop over the flow path.

**Spool travel between closed and open orifice** — Maximum spool stroke

0.005 m (default) | positive scalar

Maximum distance of spool travel.

### Dependencies

To enable this parameter, set **Area characteristics** to **Identical for all flow paths** and **Orifice parameterization** to **Linear - Area vs. spool travel**.

**Maximum orifice area** — Maximum orifice opening area

1e-4 m<sup>2</sup> (default) | positive scalar

Largest open area of each orifice during the operation of the valve.

**Dependencies**

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Linear - Area vs. spool travel.

**Leakage area** — Open area when an orifice is fully closed

1e-9 m<sup>2</sup> (default) | positive scalar

Open area when an orifice is fully closed. Any area smaller than this value is maintained at the specified leakage area. This parameter contributes to numerical stability by maintaining continuity in the flow.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to Linear - Area vs. spool travel.

**Spool travel vector** — Vector of spool opening distances relative to fully closed position

[0, .00125, .0025, .00375, .005] m (default) | 1-by-*n* vector

Vector of spool travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **Orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Tabulated data - Area vs. spool travel.

**Orifice area vector** — Vector of valve opening areas

[1e-09, 1e-05, 4e-05, 6e-05, .0001] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **Spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

**Dependencies**

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Tabulated data - Area vs. spool travel.

**Spool travel vector, ds** — Vector of spool opening distances relative to fully closed position

[0, .00125, .0025, .00375, .005] m (default) | 1-by-*n* vector

Vector of spool travel distances for the tabular parametrization of volumetric flow rate. The spool travel vector forms an independent axis with the **Pressure drop vector, dp** parameter for the 2-D dependent **Volumetric flow rate table, q(ds,dp)** or **Mass flow rate table, mdot(ds,dp)** parameters. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Volumetric flow rate vs. spool travel and pressure drop or Tabulated data - Mass flow rate vs. spool travel and pressure drop.

**Pressure drop vector, dp** — Vector of valve pressure drop values  
[-.1, .3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of pressure drop values for the tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **Spool travel vector, ds** parameter for the 2-D dependent **Volumetric flow rate table, q(ds,dp)** or **Mass flow rate table, mdot(ds,dp)** parameters. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Volumetric flow rate vs. spool travel and pressure drop or Tabulated data - Mass flow rate vs. spool travel and pressure drop.

**Volumetric flow rate table, q(ds,dp)** — Array of volumetric flow rates  
[-1e-08, 2.2e-08, 2.8e-08, 3.4e-08; -9e-06, .00015, .0002, .00024;  
-.00036, .00063, .00081, .00096; .00054, .00094, .0012, .0014;  
-.00091, .0016, .002, .0024] m<sup>3</sup>/s (default) | *M*-by-*N* matrix

*M*-by-*N* matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the correlated vectors:

- *M* is the number of vector elements in the **Spool travel vector, ds** parameter.
- *N* is the number of vector elements in the **Pressure drop vector, dp** parameter.

#### Dependencies

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**Mass flow rate table, mdot(ds,dp)** — Mass flow rate  
[-1e-05, 1.7e-05, 2e-05, 2.6e-05; -.009, .0035, .0045, .0053; -.36, .7, .9,  
1.06; -.54, 1.96, 2.5, 3; -.91, 6, 7.7, 9.13] kg/s (default) | *M*-by-*N* matrix

*M*-by-*N* matrix of mass flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the correlated vectors:

- *M* is the number of vector elements in the **Spool travel vector, ds** parameter.
- *N* is the number of vector elements in the **Pressure drop vector, dp** parameter.

#### Dependencies

To enable this parameter, set **Orifice parameterization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop.

**Constant orifice area** — Orifice area for identical flow paths  
1e-4 m<sup>2</sup> (default) | positive scalar

Orifice area when the positive, neutral, and negative spool positions feature the same orifice.

#### Dependencies

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to either:

- Linear - Area vs. spool travel.
- Tabulated data - Area vs. spool travel

The same orifice must be selected in all three of the **Valve Configuration** parameters:

- **Positive spool position open connections**
- **Neutral spool position open connections**
- **Negative spool position open connections**

**Constant orifice pressure drop vector** — Vector of pressure differential values for identical flow paths

[-.1, .3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of pressure differential values over the valve when the positive, neutral, and negative spool positions feature the same orifice. The vector elements correspond one-to-one with the elements in the **Constant orifice volumetric flow rate vector** or **Constant orifice mass flow rate table,  $\dot{m}(\text{ds}, \text{dp})$**  parameters. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### **Dependencies**

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop or Tabulated data - Mass flow rate vs. spool travel and pressure drop.

The same orifice must be selected in all three of the **Valve Configuration** parameters:

- **Positive spool position open connections**
- **Neutral spool position open connections**
- **Negative spool position open connections**

**Constant orifice volumetric flow rate vector** — Vector of volumetric flow rate values for identical flow paths

[-.0009, .0016, .002, .0024] m<sup>3</sup>/s (default) | 1-by-*n* vector

Vector of volumetric flow rate values for a constant orifice when the positive, neutral, and negative spool positions use the same orifice. The vector elements correspond one-to-one with the elements in the **Constant orifice pressure drop vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### **Dependencies**

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

The same orifice must be selected in all three of the **Valve Configuration** parameters:

- **Positive spool position open connections**
- **Neutral spool position open connections**
- **Negative spool position open connections**

**Constant orifice mass flow rate vector** — Vector of mass flow rates for a constant orifice  
[-.9, 1.6, 2, 2.4] kg/s (default) | 1-by-*n* vector

Vector of mass flow rate values over the valve when the positive, neutral, and negative spool positions use the same orifice. The vector elements correspond one-to-one with the elements in the **Constant orifice pressure drop vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Area characteristics** to Identical for all flow paths and **Orifice parameterization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop.

The same orifice must be selected in all three of the **Valve Configuration** parameters:

- **Positive spool position open connections**
- **Neutral spool position open connections**
- **Negative spool position open connections**

**Reference inflow temperature** — Temperature at which mass flow rate data is specified  
293.15 K (default) | positive scalar

Temperature at which the tabulated mass flow rate data is specified.

#### Dependencies

To enable this parameter, set **Orifice parameterization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop.

**Reference inflow pressure** — Pressure at which mass flow rate tabulated data is specified  
0.101325 MPa (default) | positive scalar

Pressure at which the tabulated mass flow rate data is specified. The block uses this parameter to calculate a third reference parameter, the reference density. The reference that it uses to scale the tabulated pressure drop data for pressures and temperatures deviating from the reference conditions.

#### Dependencies

To enable this parameter, set **Orifice parameterization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop.

**Cross-sectional area at ports P, T, A and B** — Area at conserving ports  
0.01 m<sup>2</sup> (default) | positive scalar

Maximum cross-sectional areas at the entry and exit ports **P**, **T**, **A**, and **B**, which are used in the pressure-flow rate equation that determines the mass flow rate through the valve and energy flow rate smoothing.

**Discharge coefficient** — Discharge coefficient  
0.64 (default) | positive scalar

Correction factor that accounts for discharge losses in theoretical flows.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to either:

- Linear - Area vs. spool travel
- Tabulated data - Area vs. spool travel

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the orifice.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to:

- Linear - Area vs. spool travel
- Tabulated data - Area vs. spool travel

**Smoothing factor** — Numerical smoothing factor  
0.01 (default) | positive scalar in the range of [0,1]

Continuous smoothing factor that introduces a layer of gradual change based to the flow response when the valve is in near-open and near-closed positions. To increase the stability of your simulation in these regimes, set this parameter to a nonzero value less than one.

**Dependencies**

To enable this parameter, set **Orifice parametrization** to Linear - Area vs. spool travel.

**Pressure recovery** — Whether to account for pressure increase in area expansions  
off (default) | on

Whether to account for pressure increase when fluid flows from a region of smaller cross-sectional area to a region of larger cross-sectional area.

**Dependencies**

To enable this parameter, set **Orifice parameterization** to:

- Linear - Area vs. spool travel
- Tabulated data - Area vs. spool travel

**P-A Orifice**

**Spool position at maximum P-A orifice area** — Spool offset for fully open P-A orifice  
7.5e-3 m (default) | positive scalar

Spool offset from the neutral position for a fully open P-A orifice. The **Consistency check for neutral spool position open connections** parameter will notify you if the values set for this spool position are inconsistent or unphysical according to other orifice spool positions.

**Dependencies**

To enable this parameter, set one of the following parameters:

**Positive spool position open connections** to:

- P-A and B-T
- P-A and P-B
- P-A only
- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only
- P-A, A-T, and P-T
- P-A, P-B, and A-B
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only
- P-A, P-B, and A-B

---

**Note:** This parameter is enabled only when the P-A orifice settings do not appear in all three spool position parameters: **Positive spool position open connections**, **Neutral spool position open connections**, and **Negative spool position open connections**.

---

**P-A spool travel between closed and open orifice** — Maximum spool stroke

0.005 m (default) | positive scalar

Maximum distance of spool travel. This value provides an upper limit to calculations so that simulations do not return unphysical values.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections to:**

- P-A and B-T
- P-A and P-B

- P-A only
- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only
- P-A, A-T, and P-T
- P-A, P-B, and A-B
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only
- P-A, P-B, and A-B

**P-A maximum orifice area** — Maximum orifice opening area  
1e-4 m<sup>2</sup> (default) | positive scalar

Largest open area of the P-A orifice during the operation of the valve.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Linear - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only
- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T

- P-A and P-B
- P-A only
- P-A, A-T, and P-T
- P-A, P-B, and A-B
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only
- P-A, P-B, and A-B

**P-A orifice area vector** — Vector of valve opening areas

[1e-10, 1e-05, 4e-05, 6e-05, .0001] m<sup>2</sup> (default) | 1-by-n vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **P-A spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only
- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only
- P-A, A-T, and P-T
- P-A, P-B, and A-B
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only
- P-A, P-B, and A-B

**P-A orifice spool travel vector,  $ds$**  — Vector of spool opening distances relative to fully closed position

[0, .00125, .0025, .00375, .005] m (default) | 1-by- $n$  vector

Vector of spool travel distances for the tabular parameterization of volumetric flow rates. The spool travel vector forms an independent axis with the **P-A orifice pressure drop vector,  $dp$**  parameter for the 2-D dependent **P-A orifice volumetric flow rate table,  $q(ds,dp)$**  or **P-A orifice mass flow rate table,  $\dot{m}(ds,dp)$**  parameters. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop or Tabulated data - Mass flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only
- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only
- P-A, A-T, and P-T
- P-A, P-B, and A-B
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T

- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only
- P-A, P-B, and A-B

**P-A orifice pressure drop vector,  $dp$**  — Vector of pressure drop values  
 [-.1, .3, .5, .7] MPa (default) | 1-by- $n$  vector

Vector of pressure drop values for the tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **P-A orifice spool travel vector,  $ds$**  parameter for the 2-D dependent **P-A orifice volumetric flow rate table,  $q(ds,dp)$**  or **P-A orifice mass flow rate table,  $\dot{m}(ds,dp)$**  parameters. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop or Tabulated data - Mass flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

#### Positive spool position open connections to:

- P-A and B-T
- P-A and P-B
- P-A only
- P-A, P-B, and A-B

#### Neutral spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only
- P-A, A-T, and P-T
- P-A, P-B, and A-B
- P-A, P-B, A-T, B-T, P-T

#### Negative spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T

- P-A and P-B
- P-A only
- P-A, P-B, and A-B

**P-A orifice volumetric flow rate table,  $q(ds,dp)$**  — Array of volumetric flow rate values  
[-1e-08, 2.2e-08, 2.8e-08, 3.4e-08; -9e-06, .00015, .0002, .00024;  
-.00036, .00063, .00081, .00096; -.00054, .00094, .0012, .0014;  
-.00091, .0016, .002, .0024] m<sup>3</sup>/s (default) | *M*-by-*N* matrix

*M*-by-*N* matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the correlated vectors:

- *M* is the number of vector elements in the **P-A orifice spool travel vector,  $ds$**  parameter.
- *N* is the number of vector elements in the **P-A orifice pressure drop vector,  $dp$**  parameter.

### Dependencies

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3** One of the following parameters:

**Positive spool position open connections** to:

- P-A and B-T
- P-A and P-B
- P-A only
- P-A, P-B, and A-B

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only
- P-A, A-T, and P-T
- P-A, P-B, and A-B
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B

- P-A only
- P-A, P-B, and A-B

**P-A orifice mass flow rate table,  $\dot{m}(ds,dp)$**  — Array of mass flow rate values  
 [-1e-05, 1.7e-05, 2e-05, 2.6e-05; -.009, .0035, .0045, .0053; -.36, .7, .9, 1.06; -.54, 1.96, 2.5, 3; -.91, 6, 7.7, 9.13] kg/s (default) | *M*-by-*N* matrix

*M*-by-*N* matrix of mass flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the correlated vectors:

- *M* is the number of vector elements in the **P-A orifice spool travel vector,  $ds$**  parameter.
- *N* is the number of vector elements in the **P-A orifice pressure drop vector,  $dp$**  parameter.

### Dependencies

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop.
- 3** One of the following parameters:

#### Positive spool position open connections to:

- P-A and B-T
- P-A and P-B
- P-A only
- P-A, P-B, and A-B

#### Neutral spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only
- P-A, A-T, and P-T
- P-A, P-B, and A-B
- P-A, P-B, A-T, B-T, P-T

#### Negative spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only
- P-A, P-B, and A-B

**P-A constant orifice area** — Cross-sectional area for a constant orifice  
1e-4 m<sup>2</sup> (default) | positive scalar

Orifice area when the positive, neutral, and negative spool positions use the same orifice.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to either:
  - Linear - Area vs. spool travel
  - Tabulated data - Area vs. spool travel
- 3** One of the following settings in each parameter:

**Positive spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only
- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only
- P-A, A-T, and P-T
- P-A, P-B, and A-B
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only
- P-A, P-B, and A-B

**P-A Constant orifice pressure drop vector** — Vector of pressure differential values for a constant orifice

[-.1, .3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of pressure differential values over the valve when the positive, neutral, and negative spool positions use the same orifice. The vector elements correspond one-to-one with the elements in the **P-**

**A Constant orifice volumetric flow rate vector** or **P-A Constant orifice mass flow rate table,  $\mathbf{mdot}(ds,dp)$**  parameters. The values are listed in ascending order. Linear interpolation is employed between table data points.

### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop or Tabulated data - Mass flow rate vs. spool travel and pressure drop.
- 3 One of the following settings in each parameter:

#### Positive spool position open connections to:

- P-A and B-T
- P-A and P-B
- P-A only
- P-A, P-B, and A-B

#### Neutral spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only
- P-A, A-T, and P-T
- P-A, P-B, and A-B
- P-A, P-B, A-T, B-T, P-T

#### Negative spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only
- P-A, P-B, and A-B

**P-A Constant orifice volumetric flow rate vector** — Vector of volumetric flow rates for a constant orifice

[-.0009, .0016, .002, .0024] m<sup>3</sup>/s (default) | 1-by-*n* vector

Vector of volumetric flow rate values over the valve when the positive, neutral, and negative spool positions use the same orifice. The vector elements correspond one-to-one with the elements in the **P-A Constant orifice pressure drop vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following settings in each parameter:

**Positive spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only
- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only
- P-A, A-T, and P-T
- P-A, P-B, and A-B
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only
- P-A, P-B, and A-B

**P-A Constant orifice mass flow rate vector** — Vector of mass flow rates for a constant orifice  
[-.9, 1.6, 2, 2.4] kg/s (default) | 1-by-*n* vector

Vector of mass flow rate values over the valve when the positive, neutral, and negative spool positions use the same orifice. The vector elements correspond one-to-one with the elements in the **P-A Constant orifice pressure drop vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.

2 **Orifice parameterization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop.

3 One of the following settings in each parameter:

**Positive spool position open connections to:**

- P-A and B-T
- P-A and P-B
- P-A only
- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only
- P-A, A-T, and P-T
- P-A, P-B, and A-B
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-A and A-T
- P-A and B-T
- P-A and P-B
- P-A only
- P-A, P-B, and A-B

**P-B Orifice**

**Spool position at maximum P-B orifice area** — Spool offset from the neutral position for a fully open P-B orifice

7.5e-3 m (default) | positive scalar

Spool offset from the neutral position for a fully open P-B orifice. The **Consistency check for neutral spool position open connections** parameter will notify you if the values set for this spool position are inconsistent or unphysical according to other orifice spool positions.

**Dependencies**

To enable this parameter, set one of the following parameters:

**Positive spool position open connections to:**

- P-B and A-T
- P-A and P-B

- P-B only
- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

---

**Note:** This parameter is enabled only when the P-B orifice settings do not appear in all three spool position parameters: **Positive spool position open connections**, **Neutral spool position open connections**, and **Negative spool position open connections**.

---

**P-B spool travel between closed and open orifice** — Maximum spool stroke

0.005 m (default) | positive scalar

Maximum distance of spool travel. This value provides an upper limit to calculations so that simulations do not return unphysical values.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Linear - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

**P-B maximum orifice area** — Maximum orifice opening area  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Largest open area of the P-B orifice during the operation of the valve.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

- P-A, P-B, and A-B
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

**P-B orifice spool travel vector** — Vector of spool opening distances relative to fully closed position  
[0, .00125, .0025, .00375, .005] m (default) | 1-by-*n* vector

Vector of spool travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **P-B orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

**P-B orifice area vector** — Vector of valve opening areas

[1e-10, 1e-05, 4e-05, 6e-05, .0001] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **P-B spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3 One of the following parameters:

#### Positive spool position open connections to:

- P-B and A-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

#### Neutral spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

#### Negative spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only

- P-A, P-B, and A-B

**P-B orifice spool travel vector, ds** — Vector of spool opening distances relative to fully closed position

[0, .00125, .0025, .00375, .005] m (default) | 1-by-*n* vector

Vector of spool travel distances for the tabular parameterization of volumetric flow rates. The spool travel vector forms an independent axis with the **P-B orifice pressure drop vector, dp** parameter for the 2-D dependent **P-B orifice volumetric flow rate table, q(ds,dp)** or **P-B orifice mass flow rate table, mdot(ds,dp)** parameters. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop or Tabulated data - Mass flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

**P-B orifice pressure drop vector,  $dp$**  — Vector of pressure differential values  
 [-.1, .3, .5, .7] MPa (default) | 1-by- $n$  vector

Vector of pressure drop values for tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **P-B orifice spool travel vector,  $ds$**  parameter for the 2-D dependent **P-B orifice volumetric flow rate table,  $q(ds,dp)$**  or **P-B orifice mass flow rate table,  $m\dot{d}(ds,dp)$**  parameters. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop or Tabulated data - Mass flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

#### Positive spool position open connections to:

- P-B and A-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

#### Neutral spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

#### Negative spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

**P-B orifice volumetric flow rate table,  $q(ds,dp)$**  — Array of volumetric flow rate values  
 [-1e-08, 2.2e-08, 2.8e-08, 3.4e-08; -9e-06, .00015, .0002, .00024;  
 -.00036, .00063, .00081, .00096; -.00054, .00094, .0012, .0014;  
 -.00091, .0016, .002, .0024]  $m^3/s$  (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance.  $M$  and  $N$  are the sizes of the correlated vectors:

- $M$  is the number of vector elements in the **P-B orifice spool travel vector, ds** parameter.
- $N$  is the number of vector elements in the **P-B orifice pressure drop vector, dp** parameter.

### Dependencies

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3** One of the following parameters:

#### Positive spool position open connections to:

- P-B and A-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

#### Neutral spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

#### Negative spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

**P-B orifice mass flow rate table, mdot(ds,dp)** — Array of mass flow rate values  
[-1e-05, 1.7e-05, 2e-05, 2.6e-05; -.009, .0035, .0045, .0053; -.36, .7, .9, 1.06; -.54, 1.96, 2.5, 3; -.91, 6, 7.7, 9.13] kg/s (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of mass flow rates based on independent values of pressure drop and spool travel distance.  $M$  and  $N$  are the sizes of the correlated vectors:

- $M$  is the number of vector elements in the **P-B orifice spool travel vector,  $ds$**  parameter.
- $N$  is the number of vector elements in the **P-B orifice pressure drop vector,  $dp$**  parameter.

### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

#### Positive spool position open connections to:

- P-B and A-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

#### Neutral spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

#### Negative spool position open connections to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

**P-B constant orifice area** — Cross-sectional area for a constant orifice  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Orifice area when the positive, neutral, and negative spool positions use the same orifice.

### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.

**2 Orifice parameterization** to either:

- Linear - Area vs. spool travel
- Tabulated data - Area vs. spool travel

**3** One of the following settings in each parameter:**Positive spool position open connections** to:

- P-B and A-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

**P-B Constant orifice pressure drop vector** — Vector of pressure differential values for a constant orifice

[-.1, .3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of pressure differential values over the valve when the positive, neutral, and negative spool positions use the same orifice. The vector elements correspond one-to-one with the elements in the **P-B Constant orifice volumetric flow rate vector** or **P-B Constant orifice mass flow rate table**, **mdot(ds,dp)** parameters. The values are listed in ascending order. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.

- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop or Tabulated data - Mass flow rate vs. spool travel and pressure drop.
- 3 One of the following settings in each parameter:

**Positive spool position open connections** to:

- P-B and A-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

**P-B Constant orifice volumetric flow rate vector** — Vector of volumetric flow rate values for a constant orifice

[-.0009, .0016, .002, .0024] m<sup>3</sup>/s (default) | 1-by-n vector

Vector of volumetric flow rate values over the valve when the positive, neutral, and negative spool positions use the same orifice. The vector elements correspond one-to-one with the elements in the **P-B Constant orifice pressure drop vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**3** One of the following settings in each parameter:

**Positive spool position open connections to:**

- P-B and A-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

**P-B Constant orifice mass flow rate vector** — Vector of mass flow rates for a constant orifice  
[-.9, 1.6, 2, 2.4] kg/s (default) | 1-by-*n* vector

Vector of mass flow rate values over the valve when the positive, neutral, and negative spool positions use the same orifice. The vector elements correspond one-to-one with the elements in the **P-B Constant orifice pressure drop vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop.
- 3** One of the following settings in each parameter:

**Positive spool position open connections to:**

- P-B and A-T

- P-A and P-B
- P-B only
- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- P-B and B-T
- P-A and P-B
- P-B only
- P-A, P-B, and A-B

**A-B Orifice**

**Spool position at maximum A-B orifice area** — Spool offset from the neutral position for a fully open A-B orifice

7.5e-3 m (default) | positive scalar

Spool offset from the neutral position for a fully open A-B orifice. The **Consistency check for neutral spool position open connections** parameter will notify you if the values set for this spool position are inconsistent or unphysical according to other orifice spool positions.

**Dependencies**

To enable this parameter, set one of the following parameters:

**Positive spool position open connections to:**

- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, and A-B

**Negative spool position open connections to:**

- P-A, P-B, and A-B

**Note:** This parameter is enabled only when the P-A orifice settings do not appear in all three spool position parameters: **Positive spool position open connections**, **Neutral spool position open connections**, and **Negative spool position open connections**.

---

**A-B spool travel between closed and open orifice** — Maximum spool stroke

0.005 m (default) | positive scalar

Maximum distance of spool travel. This value provides an upper limit to calculations so that simulations do not return unphysical values.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to:

- P-A, P-B, and A-B

**Neutral spool position open connections** to:

- P-A, P-B, and A-B

**Negative spool position open connections** to:

- P-A, P-B, and A-B

**A-B maximum orifice area** — Maximum orifice opening area

1e-4 m<sup>2</sup> (default) | positive scalar

Largest open area of the A-B orifice during the operation of the valve.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to:

- P-A, P-B, and A-B

**Neutral spool position open connections** to:

- P-A, P-B, and A-B

**Negative spool position open connections** to:

- P-A, P-B, and A-B

**A-B orifice spool travel vector** — Vector of spool opening distances relative to fully closed position  
 [0, .00125, .0025, .00375, .005] m (default) | 1-by-*n* vector

Vector of spool travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **A-B orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to:

- P-A, P-B, and A-B

**Neutral spool position open connections** to:

- P-A, P-B, and A-B

**Negative spool position open connections** to:

- P-A, P-B, and A-B

**A-B orifice area vector** — Vector of valve opening areas  
 [1e-10, 1e-05, 4e-05, 6e-05, .0001] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **A-B spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to:

- P-A, P-B, and A-B

**Neutral spool position open connections** to:

- P-A, P-B, and A-B

**Negative spool position open connections** to:

- P-A, P-B, and A-B

**A-B orifice spool travel vector,  $ds$**  — Vector of spool opening distances relative to fully closed position

[0, .00125, .0025, .00375, .005] m (default) | 1-by- $n$  vector

Vector of spool travel distances for the tabular parameterization of volumetric flow rates. The spool travel vector forms an independent axis with the **A-B orifice pressure drop vector,  $dp$**  parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections to:**

- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, and A-B

**Negative spool position open connections to:**

- P-A, P-B, and A-B

**A-B orifice pressure drop vector,  $dp$**  — Vector of pressure differential values

[-.1, .3, .5, .7] MPa (default) | 1-by- $n$  vector

Vector of pressure drop values for tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **A-B orifice spool travel vector,  $ds$**  parameter for the 2-D dependent **A-B orifice volumetric flow rate table,  $q(ds,dp)$**  or **A-B orifice mass flow rate table,  $\dot{m}(ds,dp)$**  parameters. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections to:**

- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, and A-B

**Negative spool position open connections to:**

- P-A, P-B, and A-B

**A-B orifice volumetric flow rate table,  $q(ds,dp)$**  — Array of volumetric flow rate values  
 [-1e-08, 2.2e-08, 2.8e-08, 3.4e-08; -9e-06, .00015, .0002, .00024;  
 -.00036, .00063, .00081, .00096; -.00054, .00094, .0012, .0014;  
 -.00091, .0016, .002, .0024] m<sup>3</sup>/s (default) | *M*-by-*N* matrix

*M*-by-*N* matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the correlated vectors:

- *M* is the number of vector elements in the **A-B orifice spool travel vector,  $ds$**  parameter.
- *N* is the number of vector elements in the **A-B orifice pressure drop vector,  $dp$**  parameter.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to:

- P-A, P-B, and A-B

**Neutral spool position open connections** to:

- P-A, P-B, and A-B

**Negative spool position open connections** to:

- P-A, P-B, and A-B

**A-B orifice mass flow rate table,  $\dot{m}(ds,dp)$**  — Array of mass flow rate values  
 [-1e-05, 1.7e-05, 2e-05, 2.6e-05; -.009, .0035, .0045, .0053; -.36, .7, .9,  
 1.06; -.54, 1.96, 2.5, 3; -.91, 6, 7.7, 9.13] kg/s (default) | *M*-by-*N* matrix

*M*-by-*N* matrix of mass flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the correlated vectors:

- *M* is the number of vector elements in the **A-B orifice spool travel vector,  $ds$**  parameter.
- *N* is the number of vector elements in the **A-B orifice pressure drop vector,  $dp$**  parameter.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to:

- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, and A-B

**Negative spool position open connections to:**

- P-A, P-B, and A-B

**A-B constant orifice area** — Cross-sectional area for a constant orifice  
1e-4 m<sup>2</sup> (default) | positive scalar

Orifice area when the positive, neutral, and negative spool positions use the same orifice.

#### **Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Linear - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections to:**

- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, and A-B

**Negative spool position open connections to:**

- P-A, P-B, and A-B

**A-B Constant orifice pressure drop vector** — Vector of pressure differential values for a constant orifice  
[-.1, .3, .5, .7] MPa (default) | 1-by-n vector

Vector of pressure differential values over the valve when the positive, neutral, and negative spool positions use the same orifice. The vector elements correspond one-to-one with the elements in the **A-B Constant orifice volumetric flow rate vector** or **A-B Constant orifice mass flow rate table,  $\dot{m}$ (ds,dp)** parameters. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### **Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Linear - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections to:**

- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, and A-B

**Negative spool position open connections to:**

- P-A, P-B, and A-B

**A-B Constant orifice volumetric flow rate vector** — Vector of volumetric flow rate values for a constant orifice

[-.0009, .0016, .002, .0024] m<sup>3</sup>/s (default) | 1-by-*n* vector

Vector of volumetric flow rate values over the valve when the positive, neutral, and negative spool positions use the same orifice. The vector elements correspond one-to-one with the elements in the **A-B Constant orifice pressure drop vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections to:**

- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, and A-B

**Negative spool position open connections to:**

- P-A, P-B, and A-B

**A-B Constant orifice mass flow rate vector** — Vector of mass flow rates for a constant orifice

[-.9, 1.6, 2, 2.4] kg/s (default) | 1-by-*n* vector

Vector of mass flow rate values over the valve when the positive, neutral, and negative spool positions use the same orifice. The vector elements correspond one-to-one with the elements in the **A-B Constant orifice pressure drop vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections to:**

- P-A, P-B, and A-B

**Neutral spool position open connections to:**

- P-A, P-B, and A-B

**Negative spool position open connections** to:

- P-A, P-B, and A-B

### **A-T Orifice**

**Spool position at maximum A-T orifice area** — Spool offset from the neutral position for a fully open A-T orifice

7.5e-3 m (default) | positive scalar

Spool offset from the neutral position for a fully open A-T orifice. The **Consistency check for neutral spool position open connections** parameter will notify you if the values set for this spool position are inconsistent or unphysical according to other orifice spool positions.

### **Dependencies**

To enable this parameter, set one of the following parameters:

- **Positive spool position open connections** to P-B and A-T.
- **Neutral spool position open connections** to:
  - P-A, P-B, A-T, and B-T
  - P-B and A-T
  - A-T and B-T
  - P-A and A-T
  - A-T only
  - P-A, A-T, and P-T
  - P-A, P-B, A-T, B-T, P-T
- **Negative spool position open connections** to P-B and A-T.

---

**Note:** This parameter is enabled only when the A-T orifice settings do not appear in all three spool position parameters: **Positive spool position open connections**, **Neutral spool position open connections**, and **Negative spool position open connections**.

---

**A-T spool travel between closed and open orifice** — Maximum spool stroke

0.005 m (default) | positive scalar

Maximum distance of spool travel. This value provides an upper limit to calculations so that simulations do not return unphysical values.

### **Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Linear - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections** to P-B and A-T

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- A-T and B-T
- P-A and A-T
- A-T only
- P-A, A-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections to P-B and A-T.**

**A-T maximum orifice area** — Maximum orifice opening area  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Largest open area of the A-T orifice during the operation of the valve.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections to P-B and A-T****Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- P-B and A-T
- A-T and B-T
- P-A and A-T
- A-T only
- P-A, A-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections to P-B and A-T.**

**A-T orifice spool travel vector** — Vector of spool opening distances relative to fully closed position  
 $[0, .00125, .0025, .00375, .005] \text{ m}$  (default) | 1-by- $n$  vector

Vector of spool travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **A-T orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections** to P-B and A-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- A-T and B-T
- P-A and A-T
- A-T only
- P-A, A-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to P-B and A-T.

**A-T orifice area vector** — Vector of valve opening areas

[1e-10, 1e-05, 4e-05, 6e-05, .0001] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **A-T spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

#### **Dependencies**

To enable this parameter, set:

- 1 Area characteristics** to Different for each flow path.
- 2 Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3** One of the following parameters:

**Positive spool position open connections** to P-B and A-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- A-T and B-T
- P-A and A-T
- A-T only
- P-A, A-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to P-B and A-T.

**A-T orifice spool travel vector, ds** — Vector of spool opening distances relative to fully closed position

[0, .00125, .0025, .00375, .005] m (default) | 1-by-*n* vector

Vector of spool travel distances for the tabular parameterization of volumetric flow rates. The spool travel vector forms an independent axis with the **A-T orifice pressure drop vector,  $dp$**  parameter for the 2-D dependent **A-T orifice volumetric flow rate table,  $q(ds,dp)$**  or **A-T orifice mass flow rate table,  $\dot{m}(ds,dp)$**  parameters. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop or Tabulated data - Mass flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections** to P-B and A-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- A-T and B-T
- P-A and A-T
- A-T only
- P-A, A-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to P-B and A-T.

**A-T orifice pressure drop vector,  $dp$**  — Vector of pressure differential values  
[ -.1, .3, .5, .7 ] MPa (default) | 1-by- $n$  vector

Vector of pressure drop values for tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **A-T orifice spool travel vector,  $ds$**  parameter for the 2-D dependent **A-T orifice volumetric flow rate table,  $q(ds,dp)$**  or **A-T orifice mass flow rate table,  $\dot{m}(ds,dp)$**  parameters. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop or Tabulated data - Mass flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections** to P-B and A-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- A-T and B-T
- P-A and A-T
- A-T only
- P-A, A-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to P-B and A-T.

**A-T orifice volumetric flow rate table,  $q(ds,dp)$**  — Array of volumetric flow rate values  
 [-1e-08, 2.2e-08, 2.8e-08, 3.4e-08; -9e-06, .00015, .0002, .00024;  
 -.00036, .00063, .00081, .00096; -.00054, .00094, .0012, .0014;  
 -.00091, .0016, .002, .0024] m<sup>3</sup>/s (default) | *M*-by-*N* matrix

*M*-by-*N* matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the correlated vectors:

- *M* is the number of vector elements in the **A-T orifice spool travel vector,  $ds$**  parameter.
- *N* is the number of vector elements in the **A-T orifice pressure drop vector,  $dp$**  parameter.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections** to P-B and A-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- A-T and B-T
- P-A and A-T
- A-T only
- P-A, A-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to P-B and A-T.

**A-T orifice mass flow rate table,  $\dot{m}(ds,dp)$**  — Array of mass flow rate values  
 [-1e-05, 1.7e-05, 2e-05, 2.6e-05; -.009, .0035, .0045, .0053; -.36, .7, .9,  
 1.06; -.54, 1.96, 2.5, 3; -.91, 6, 7.7, 9.13] kg/s (default) | *M*-by-*N* matrix

*M*-by-*N* matrix of mass flow rates based on independent values of pressure drop and spool travel distance. *M* and *N* are the sizes of the correlated vectors:

- $M$  is the number of vector elements in the **A-T orifice spool travel vector,  $ds$**  parameter.
- $N$  is the number of vector elements in the **A-T orifice pressure drop vector,  $dp$**  parameter.

### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections** to P-B and A-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- A-T and B-T
- P-A and A-T
- A-T only
- P-A, A-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to P-B and A-T.

**A-T constant orifice area** — Cross-sectional area for a constant orifice  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Orifice area when the positive, neutral, and negative spool positions use the same orifice.

### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to either:
  - Linear - Area vs. spool travel
  - Tabulated data - Area vs. spool travel
- 3 One of the following settings in each parameter:

**Positive spool position open connections** to P-B and A-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- A-T and B-T
- P-A and A-T

- A-T only
- P-A, A-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to P-B and A-T.

**A-T Constant orifice pressure drop vector** — Vector of pressure differential values for a constant orifice

[-.1, .3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of pressure differential values over the valve when the positive, neutral, and negative spool positions use the same orifice. The vector elements correspond one-to-one with the elements in the **A-T Constant orifice volumetric flow rate vector** or **A-T Constant orifice mass flow rate table,  $\mathbf{mdot(ds,dp)}$**  parameters. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop or Tabulated data - Mass flow rate vs. spool travel and pressure drop.
- 3 One of the following settings in each parameter:

**Positive spool position open connections** to P-B and A-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- A-T and B-T
- P-A and A-T
- A-T only
- P-A, A-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to P-B and A-T.

**A-T Constant orifice volumetric flow rate vector** — Vector of volumetric flow rate values for a constant orifice

[-.0009, .0016, .002, .0024] m<sup>3</sup>/s (default) | 1-by-*n* vector

Vector of volumetric flow rate values when the positive, neutral, and negative spool positions use the same orifice. The vector elements correspond one-to-one with the elements in the **Constant orifice volumetric flow rate vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following settings in each parameter:

**Positive spool position open connections** to P-B and A-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- A-T and B-T
- P-A and A-T
- A-T only
- P-A, A-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to P-B and A-T.

**A-T Constant orifice mass flow rate vector** — Vector of mass flow rates for a constant orifice  
[-.9, 1.6, 2, 2.4] kg/s (default) | 1-by-*n* vector

Vector of mass flow rate values over the valve when the positive, neutral, and negative spool positions use the same orifice. The vector elements correspond one-to-one with the elements in the **P-B Constant orifice pressure drop vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop.
- 3 One of the following settings in each parameter:

**Positive spool position open connections** to P-B and A-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- P-B and A-T
- A-T and B-T
- P-A and A-T
- A-T only
- P-A, A-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to P-B and A-T.

## B-T Orifice

**Spool position at maximum B-T orifice area** — Spool offset from the neutral position for a fully open B-T orifice

7.5e-3 m (default) | positive scalar

Spool offset from the neutral position for a fully open B-T orifice. The **Consistency check for neutral spool position open connections** parameter will notify you if the values set for this spool position are inconsistent or unphysical according to other orifice spool positions.

### Dependencies

To enable this parameter, set one of the following parameters:

- **Positive spool position open connections** to P-A and B-T.
- **Neutral spool position open connections** to:
  - P-A, P-B, A-T, and B-T
  - A-T and B-T
  - P-A and B-T
  - P-B and B-T
  - B-T only
  - P-B, B-T, and P-T
  - P-A, P-B, A-T, B-T, P-T
- **Negative spool position open connections** to P-A and B-T.

---

**Note:** This parameter is enabled only when the B-T orifice settings do not appear in all three spool position parameters: **Positive spool position open connections**, **Neutral spool position open connections**, and **Negative spool position open connections**.

---

**B-T spool travel between closed and open orifice** — Maximum spool stroke

0.005 m (default) | positive scalar

Maximum distance of spool travel. This value provides an upper limit to calculations so that simulations do not return unphysical values.

### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to P-A and B-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- A-T and B-T

- P-A and B-T
- P-B and B-T
- B-T only
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to P-A and B-T.

**B-T maximum orifice area** — Maximum orifice opening area  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Largest open area of the B-T orifice during the operation of the valve.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to P-A and B-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- A-T and B-T
- P-A and B-T
- P-B and B-T
- B-T only
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to P-A and B-T.

**B-T orifice spool travel vector** — Vector of spool opening distances relative to fully closed position  
 $[0, .00125, .0025, .00375, .005] \text{ m}$  (default) | 1-by- $n$  vector

Vector of spool travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **B-T orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections** to P-A and B-T.

**Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- A-T and B-T
- P-A and B-T
- P-B and B-T
- B-T only
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections to P-A and B-T.****B-T orifice area vector** — Vector of valve opening areas

[1e-10, 1e-05, 4e-05, 6e-05, .0001] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of opening areas for the tabular parameterization of valve opening area. The vector elements must correspond one-to-one with the elements in the **B-T orifice spool travel vector** parameter. The elements are listed in ascending order and must be greater than 0.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3 One of the following parameters:

**Positive spool position open connections to P-A and B-T.****Neutral spool position open connections to:**

- P-A, P-B, A-T, and B-T
- A-T and B-T
- P-A and B-T
- P-B and B-T
- B-T only
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections to P-A and B-T.****B-T orifice spool travel vector, ds** — Vector of spool opening distances relative to fully closed position

[0, .00125, .0025, .00375, .005] m (default) | 1-by-*n* vector

Vector of control member travel distances for the tabular parameterization of volumetric flow rates. The spool travel vector forms an independent axis with the **B-T orifice pressure drop vector, dp** parameter for the 2-D dependent **B-T orifice volumetric flow rate table, q(ds,dp)** or **B-T orifice mass flow rate table, mdot(ds,dp)** parameters. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop or Tabulated data - Mass flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections** to P-A and B-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- A-T and B-T
- P-A and B-T
- P-B and B-T
- B-T only
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to P-A and B-T.

**B-T orifice pressure drop vector,  $dp$**  — Vector of pressure differential values  
[ -.1, .3, .5, .7] MPa (default) | 1-by- $n$  vector

Vector of pressure drop values for tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **B-T orifice spool travel vector,  $ds$**  parameter for the 2-D dependent **B-T orifice volumetric flow rate table,  $q(ds,dp)$**  or **B-T orifice mass flow rate table,  $m\dot{m}(ds,dp)$**  parameters. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop or Tabulated data - Mass flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections** to P-A and B-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- A-T and B-T
- P-A and B-T

- P-B and B-T
- B-T only
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to P-A and B-T.

**B-T orifice volumetric flow rate table,  $q(ds,dp)$**  — Array of volumetric flow rate values  
 $[-1e-08, 2.2e-08, 2.8e-08, 3.4e-08; -9e-06, .00015, .0002, .00024;$   
 $-.00036, .00063, .00081, .00096; -.00054, .00094, .0012, .0014;$   
 $-.00091, .0016, .002, .0024]$  m<sup>3</sup>/s (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance.  $M$  and  $N$  are the sizes of the correlated vectors:

- $M$  is the number of vector elements in the **B-T orifice spool travel vector,  $ds$**  parameter.
- $N$  is the number of vector elements in the **B-T orifice pressure drop vector,  $dp$**  parameter.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections** to P-A and B-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- A-T and B-T
- P-A and B-T
- P-B and B-T
- B-T only
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to P-A and B-T.

**B-T orifice mass flow rate table,  $\dot{m}(ds,dp)$**  — Array of mass flow rate values  
 $[-1e-05, 1.7e-05, 2e-05, 2.6e-05; -.009, .0035, .0045, .0053; -.36, .7, .9,$   
 $1.06; -.54, 1.96, 2.5, 3; -.91, 6, 7.7, 9.13]$  kg/s (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of mass flow rates based on independent values of pressure drop and spool travel distance.  $M$  and  $N$  are the sizes of the correlated vectors:

- $M$  is the number of vector elements in the **B-T orifice spool travel vector,  $ds$**  parameter.
- $N$  is the number of vector elements in the **B-T orifice pressure drop vector,  $dp$**  parameter.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop.
- 3 One of the following parameters:

**Positive spool position open connections** to P-A and B-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- A-T and B-T
- P-A and B-T
- P-B and B-T
- B-T only
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to P-A and B-T.

**B-T constant orifice area** — Cross-sectional orifice area for constant orifices  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Orifice area when the positive, neutral, and negative spool positions use the same orifice.

**Dependencies**

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to either:
  - Linear - Area vs. spool travel
  - Tabulated data - Area vs. spool travel
- 3 One of the settings in each parameter:

**Positive spool position open connections** to P-A and B-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- A-T and B-T
- P-A and B-T
- P-B and B-T
- B-T only
- P-B, B-T, and P-T

- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to P-A and B-T.

**B-T Constant orifice pressure drop vector** — Vector of pressure differential values for a constant orifice

[-.1, .3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of pressure differential values over the valve when the positive, neutral, and negative spool positions use the same orifice. The vector elements correspond one-to-one with the elements in the **B-T Constant orifice volumetric flow rate vector** or **B-T Constant orifice mass flow rate table, *mdot(ds,dp)*** parameters. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop or Tabulated data - Mass flow rate vs. spool travel and pressure drop.
- 3 One of the settings in each parameter:

**Positive spool position open connections** to P-A and B-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- A-T and B-T
- P-A and B-T
- P-B and B-T
- B-T only
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to P-A and B-T.

**B-T Constant orifice volumetric flow rate vector** — Vector of volumetric flow rates for a constant orifice

[-.0009, .0016, .002, .0024] m<sup>3</sup>/s (default) | 1-by-*n* vector

Vector of volumetric flow rate values over the valve when the positive, neutral, and negative spool positions use the same orifice. The vector elements correspond one-to-one with the elements in the **B-T Constant orifice pressure drop vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.

**2 Orifice parameterization** to Tabulated data - Volumetric flow rate vs. spool travel and pressure drop.

**3** One of the settings in each parameter:

**Positive spool position open connections** to P-A and B-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- A-T and B-T
- P-A and B-T
- P-B and B-T
- B-T only
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to P-A and B-T.

**B-T Constant orifice mass flow rate vector** — Vector of mass flow rates for a constant orifice  
[-.9, 1.6, 2, 2.4] kg/s (default) | 1-by-*n* vector

Vector of mass flow rate values over the valve when the positive, neutral, and negative spool positions use the same orifice. The vector elements correspond one-to-one with the elements in the **P-B Constant orifice pressure drop vector** parameter. The values are listed in ascending order. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

**1 Area characteristics** to Different for each flow path.

**2 Orifice parameterization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop.

**3** One of the settings in each parameter:

**Positive spool position open connections** to P-A and B-T.

**Neutral spool position open connections** to:

- P-A, P-B, A-T, and B-T
- A-T and B-T
- P-A and B-T
- P-B and B-T
- B-T only
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**Negative spool position open connections** to P-A and B-T.

## P-T Orifice

**Spool position at maximum P-T orifice area** — Spool offset from the neutral position for a fully open P-T orifice

0 m (default) | positive scalar

Spool offset from the neutral position for a fully open P-T orifice. The **Consistency check for neutral spool position open connections** parameter will notify you if the values set for this spool position are inconsistent or unphysical according to other orifice spool positions.

### Dependencies

To enable this parameter, set **Neutral spool position open connections** to:

- P-T only
- P-A, A-T, and P-T
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**P-T spool travel between closed and open orifice** — Maximum spool stroke

0.005 m (default) | positive scalar

Maximum distance of spool travel. This value provides an upper limit to calculations so that simulations do not return unphysical values.

### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 **Neutral spool position open connections** to:
  - P-T only
  - P-A, A-T, and P-T
  - P-B, B-T, and P-T
  - P-A, P-B, A-T, B-T, P-T

**P-T maximum orifice area** — Maximum orifice opening area

1e-4 m<sup>2</sup> (default) | positive scalar

Largest open area of the P-T orifice during the operation of the valve.

### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Linear - Area vs. spool travel.
- 3 **Neutral spool position open connections** to:
  - P-T only

- P-A, A-T, and P-T
- P-B, B-T, and P-T
- P-A, P-B, A-T, B-T, P-T

**P-T orifice spool travel vector** — Vector of spool opening distances relative to fully closed position  
[0, .00125, .0025, .00375, .005] m (default) | 1-by-*n* vector

Vector of control member travel distances for the tabular parameterization of valve area. The vector elements must correspond one-to-one with the elements in the **P-T orifice area vector** parameter. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3 **Neutral spool position open connections** to:
  - P-T only
  - P-A, A-T, and P-T
  - P-B, B-T, and P-T
  - P-A, P-B, A-T, B-T, P-T

**P-T orifice spool travel vector, ds** — Vector of spool opening distances relative to fully-closed position  
[0, .00125, .0025, .00375, .005] m (default) | 1-by-*n* vector

Vector of control member travel distances for the tabular parameterization of volumetric flow rate. The spool travel vector forms an independent axis with the **P-T orifice pressure drop vector, dp** parameter for the 2-D dependent **P-T orifice volumetric flow rate table, q(ds,dp)** or **P-T orifice mass flow rate table, mdot(ds,dp)** parameters. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3 **Neutral spool position open connections** to:
  - P-T only
  - P-A, A-T, and P-T
  - P-B, B-T, and P-T
  - P-A, P-B, A-T, B-T, P-T

**P-T orifice pressure drop vector, dp** — Vector of pressure differential values  
[-.1, .3, .5, .7] MPa (default) | 1-by-*n* vector

Vector of pressure drop values for tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **P-T orifice spool travel vector,  $ds$**  parameter for the 2-D dependent **P-T orifice volumetric flow rate table,  $q(ds,dp)$**  or **P-T orifice mass flow rate table,  $\dot{m}(ds,dp)$**  parameters. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3 **Neutral spool position open connections** to:
  - P-T only
  - P-A, A-T, and P-T
  - P-B, B-T, and P-T
  - P-A, P-B, A-T, B-T, P-T

**P-T orifice volumetric flow rate table,  $q(ds,dp)$**  — Array of volumetric flow rates  
 $[-1e-08, 2.2e-08, 2.8e-08, 3.4e-08; -9e-06, .00015, .0002, .00024;$   
 $-.00036, .00063, .00081, .00096; -.00054, .00094, .0012, .0014;$   
 $-.00091, .0016, .002, .0024]$  m<sup>3</sup>/s (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance.  $M$  and  $N$  are the sizes of the correlated vectors:

- $M$  is the number of vector elements in the **P-T orifice spool travel vector,  $ds$**  parameter.
- $N$  is the number of vector elements in the **P-T orifice pressure drop vector,  $dp$**  parameter.

### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Area vs. spool travel.
- 3 **Neutral spool position open connections** to:
  - P-T only
  - P-A, A-T, and P-T
  - P-B, B-T, and P-T
  - P-A, P-B, A-T, B-T, P-T

**P-T orifice mass flow rate table,  $\dot{m}(ds,dp)$**  — Array of mass flow rate values  
 $[-1e-05, 1.7e-05, 2e-05, 2.6e-05; -.009, .0035, .0045, .0053; -.36, .7, .9,$   
 $1.06; -.54, 1.96, 2.5, 3; -.91, 6, 7.7, 9.13]$  kg/s (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of mass flow rates based on independent values of pressure drop and spool travel distance.  $M$  and  $N$  are the sizes of the correlated vectors:

- $M$  is the number of vector elements in the **P-T orifice pressure drop vector,  $dp$**  parameter.

- $N$  is the number of vector elements in the **P-T orifice spool travel vector, ds** parameter.

### Dependencies

To enable this parameter, set:

- 1 **Area characteristics** to Different for each flow path.
- 2 **Orifice parameterization** to Tabulated data - Mass flow rate vs. spool travel and pressure drop.
- 3 **Neutral spool position open connections** to:
  - P-T only
  - P-A, A-T, and P-T
  - P-B, B-T, and P-T
  - P-A, P-B, A-T, B-T, P-T

## Version History

Introduced in R2016a

### R2022b: Right-click blocks to view opening characteristic plots

You can view the plot of the area or volumetric flow rate with respect to spool position for each orifice by right-clicking the block and selecting **Fluids > Plot Valve Characteristics**.

## Library

Directional Valves

### Description

The 4-Way Ideal Valve block represents a 4-way critically-centered valve, where initial openings of all four variable orifices are equal to zero. This significantly simplifies the model of a 4-way directional valve and makes it especially suitable for real-time and HIL (hardware-in-the-loop) simulation, where such assumption is applicable.

The flow rate is computed with the equation:

$$q = x C_D b \sqrt{\frac{1}{\rho} (p_S - \text{abs}(p_A - p_B)) \text{sign}(p_A - p_B)}$$

where

$q$	Flow rate
$x$	Valve displacement, $-x_{max} \leq x \leq x_{max}$
$b$	Orifice width, $b = A_{max} / x_{max}$
$A_{max}$	Maximum orifice area
$x_{max}$	Valve maximum opening
$C_D$	Flow discharge coefficient
$\rho$	Fluid density
$p_S$	Pressure supply
$p_A, p_B$	Pressures at the load ports A and B, respectively

Connections A and B are conserving hydraulic ports associated with the valve load ports. Connections P and S are the physical signal input ports that provide supply pressure and valve displacement values, respectively.

## Basic Assumptions and Limitations

- The valve is of a critically-centered type, that is, all initial openings are equal to zero.
- The return pressure is assumed to be very low and can be treated as a zero pressure.
- All the orifices are assumed to have the same shape and size, that is, the valve is symmetrical.

## Parameters

### Valve passage maximum area

Specify the area of a fully opened valve. The parameter value must be greater than zero. The default value is  $5e-5 \text{ m}^2$ .

### Valve maximum opening

Specify the maximum displacement of the control member. The parameter value must be greater than zero. The default value is  $0.005 \text{ m}$ .

### Flow discharge coefficient

Semi-empirical parameter for valve capacity characterization. Its value depends on the geometrical properties of the valve, and usually is provided in textbooks or manufacturer data sheets. The default value is  $0.7$ .

## Global Parameters

Parameter determined by the type of working fluid:

- **Fluid density**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the actuator connection port.

B

Hydraulic conserving port associated with the actuator connection port.

P

Physical signal port that controls the supply pressure.

S

Physical signal port that controls spool displacement.

## Examples

The “Closed-Loop Hydraulic Actuator Model for Real-Time Simulation” example is an example of using this valve, along with other blocks optimized for real-time and HIL simulation.

## Version History

**Introduced in R2010a**

**R2023a: To be removed**

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

Directional Valves

### Description

The 6-Way Directional Valve A block simulates a configuration of hydraulic continuous 6-way directional valve with pump port P, two return ports T and T1, and three actuator ports A, B, and C. Use the valve for applications with two actuators, each being controlled by a valve of this type. When both valves are in neutral position, the pump is unloaded. If any of the valves is shifted from neutral, the diverting line is cut off and the respective actuator is fed at fuel pump pressure. For more details, see the “Front-Loader Actuation System” example, which uses a similar system of two valves.

The 6-Way Directional Valve A block has six hydraulic connections, corresponding to the valve hydraulic ports (A, B, C, P, T, and T1), and one physical signal port connection (S), which controls the spool position. The block is built of six Variable Orifice blocks, connected as shown in the following diagram.

All blocks are controlled by the same position signal, provided through the physical signal port S, but the **Orifice orientation** parameter in the block instances is set in such a way that positive signal at port S opens the orifices colored blue in the block diagram (orifices P-A, B-T, and P-C2 ) and closes the orifices colored yellow (orifices A-T1, P-B, and P-C1). As a result, the openings of the orifices are computed as follows:

$$h_{PA} = h_{PA0} + x$$

$$h_{PB} = h_{PB0} - x$$

$$h_{AT1} = h_{AT10} - x$$

$$h_{BT} = h_{BT0} + x$$

$$h_{PC1} = h_{PC10} - x$$

$$h_{PC2} = h_{PC20} + x$$

where

$h_{PA}$	Orifice opening for the Variable Orifice P-A block
$h_{PB}$	Orifice opening for the Variable Orifice P-B block
$h_{AT1}$	Orifice opening for the Variable Orifice A-T1 block
$h_{BT}$	Orifice opening for the Variable Orifice B-T block
$h_{PC1}$	Orifice opening for the Variable Orifice P-C1 block
$h_{PC2}$	Orifice opening for the Variable Orifice P-C2 block
$h_{PA0}$	Initial opening for the Variable Orifice P-A block

$h_{PB0}$	Initial opening for the Variable Orifice P-B block
$h_{AT10}$	Initial opening for the Variable Orifice A-T1 block
$h_{BT0}$	Initial opening for the Variable Orifice B-T block
$h_{PC10}$	Initial opening for the Variable Orifice P-C1 block
$h_{PC20}$	Initial opening for the Variable Orifice P-C2 block
$x$	Control member displacement from initial position

For information on the block parameterization options, basic parameter descriptions, assumptions and limitations, global and restricted parameters, see the 4-Way Directional Valve block reference page.

## Parameters

- “Basic Parameters Tab” on page 1-373
- “Valve Opening Offsets Tab” on page 1-375

### Basic Parameters Tab

#### Model parameterization

Select one of the following methods for specifying the valve:

- **By maximum area and opening** — Provide values for the maximum valve passage area and the maximum valve opening. The passage area is linearly dependent on the control member displacement, that is, the valve is closed at the initial position of the control member (zero displacement), and the maximum opening takes place at the maximum displacement. This is the default method.
- **By area vs. opening table** — Provide tabulated data of valve openings and corresponding valve passage areas. The passage area is determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.
- **By pressure-flow characteristic** — Provide tabulated data of valve openings, pressure differentials, and corresponding flow rates. The flow rate is determined by two-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.

#### Valve passage maximum area

Specify the area of a fully opened valve. The parameter value must be greater than zero. The default value is  $5e-5 \text{ m}^2$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

#### Valve maximum opening

Specify the maximum displacement of the control member. The parameter value must be greater than zero. The default value is  $5e-3 \text{ m}$ . This parameter is used if **Model parameterization** is set to **By maximum area and opening**.

#### Valve opening vector, $s$

Specify the vector of input values for valve openings as a one-dimensional array. The input values vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in meters, are  $[-0.002 \ 0 \ 0.002 \ 0.005 \ 0.015]$ . If **Model parameterization** is set to **By area vs. opening table**, the **Tabulated valve openings** values will be used together with **Tabulated**

**valve passage area** values for one-dimensional table lookup. If **Model parameterization** is set to By pressure-flow characteristic, the **Tabulated valve openings** values will be used together with **Tabulated pressure differentials** and **Tabulated flow rates** for two-dimensional table lookup.

#### Valve passage area vector

Specify the vector of output values for valve passage area as a one-dimensional array. The valve passage area vector must be of the same size as the valve openings vector. All the values must be positive. The default values, in  $m^2$ , are [1e-09 2.0352e-07 4.0736e-05 0.00011438 0.00034356]. This parameter is used if **Model parameterization** is set to By area vs. opening table.

#### Pressure differential vector, dp

Specify the vector of input values for pressure differentials as a one-dimensional array. The vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in Pa, are [-1e+07 -5e+06 -2e+06 2e+06 5e+06 1e+07]. This parameter is used if **Model parameterization** is set to By pressure-flow characteristic.

#### Volumetric flow rate table, q(s,dp)

Specify the flow rates as an m-by-n matrix, where m is the number of valve openings and n is the number of pressure differentials. Each value in the matrix specifies flow rate taking place at a specific combination of valve opening and pressure differential. The matrix size must match the dimensions defined by the input vectors. The default values, in  $m^3/s$ , are:

```
[-1e-07 -7.0711e-08 -4.4721e-08 4.4721e-08 7.0711e-08 1e-07;
-2.0352e-05 -1.4391e-05 -9.1017e-06 9.1017e-06 1.4391e-05 2.0352e-05;
-0.0040736 -0.0028805 -0.0018218 0.0018218 0.0028805 0.0040736;
-0.011438 -0.0080879 -0.0051152 0.0051152 0.0080879 0.011438;
-0.034356 -0.024293 -0.015364 0.015364 0.024293 0.034356;]
```

This parameter is used if **Model parameterization** is set to By pressure-flow characteristic.

#### Interpolation method

Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- **Linear** — Select this option to get the best performance.
- **Smooth** — Select this option to produce a continuous curve (By area vs. opening table) or surface (By pressure-flow characteristic) with continuous first-order derivatives.

For more information on interpolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

#### Extrapolation method

Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- **Linear** — Select this option to produce a curve or surface with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.
- **Nearest** — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

**Flow discharge coefficient**

Semi-empirical parameter for valve capacity characterization. Its value depends on the geometrical properties of the valve, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.7.

**Laminar transition specification**

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

**Laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

**Critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12, which corresponds to a round orifice in thin material with sharp edges. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

**Leakage area**

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is  $1e-12 \text{ m}^2$ .

**Valve Opening Offsets Tab****Between ports P and A**

Orifice opening of the **P-A** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

**Between ports P and B**

Orifice opening of the **P-B** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

**Between ports A and T1**

Orifice opening of the **A-T1** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

**Between ports B and T**

Orifice opening of the **B-T** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of 0 corresponds to a zero-lapped valve. The default value is  $-2.5e-3 \text{ m}$ .

**Between ports P and C1**

Orifice opening of the **P-C1** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $\theta$  corresponds to a zero-lapped valve. The default value is  $2.5e-3$  m.

**Between ports P and C2**

Orifice opening of the **P-C2** flow path at zero spool displacement. Specify a positive offset to model an underlapped valve or a negative offset to model an overlapped valve. The default value of  $\theta$  corresponds to a zero-lapped valve. The default value is  $2.5e-3$  m.

**Ports**

The block has the following ports:

P

Hydraulic conserving port associated with the pressure supply line inlet.

T

Hydraulic conserving port associated with the first return line connection.

T1

Hydraulic conserving port associated with the second return line connection.

A

Hydraulic conserving port associated with the actuator connection port.

B

Hydraulic conserving port associated with the actuator connection port.

C

Hydraulic conserving port associated with the actuator connection port.

S

Physical signal port to control spool displacement.

## Air Muscle Actuator (G)

Linear actuator with force characteristics of biological muscle

### Libraries:

Simscape / Fluids / Gas / Actuators

### Description

The Air Muscle Actuator (G) block models a linear actuator popular in robotics for its characteristics reminiscent of biological muscle. The actuator comprises an expandable bladder in a braided shell. When the bladder is pressurized, the pair widens and simultaneously shortens, producing at their end caps a contractile force. The bladder is pressurized at Gas port **A**; the force is exerted at Mechanical Translational ports **R** and **C**.

### Air Muscle in Relaxed State

Air muscles are often installed in pairs—one muscle serving as agonist, the other as antagonist. Pairs of this sort are common in the human body, where the biceps (in the arm) accompanies the triceps, and the quadriceps (in the leg) accompanies the hamstrings. The muscles attach at one end to a joint, but at an offset so as to produce a torque. When the net torque is other than zero, and if loading conditions allow, the joint rotates.

### Actuator Force

The mass and energy balances of the actuator are as described for the Translational Mechanical Converter (G) block. The actuator force, however, is based on the standard Chou-Hannaford equation (with two corrections made for the simplifying assumptions of the original model). In its original form, the Chou-Hannaford equation gives:

$$F_{C-H} = \frac{\pi D_M^2 P}{4} \left[ 3 \left( \frac{L}{l} \right)^2 - 1 \right],$$

where:

- $F$  is the contractile force exerted by the actuator on its ends. The subscript C-H denotes the theoretical value of the original Chou-Hannaford model.
- $D$  is the diameter of the bladder and shell assembly. The subscript M denotes its maximum theoretical value—that in which the braids of the shell are at right angles to its longitudinal axis.
- $P$  is the gauge pressure in the bladder (measured against the environment external to the actuator).
- $L$  is the length of the actuator (the distance between the mechanical ports **R** and **C**).

- $l$  is the natural length of a braid (before it is stretched in a pressurized bladder). The braids, as they are wound about the longitudinal axis of the actuator, are always longer than the actuator itself).

The maximum theoretical diameter of the actuator is defined as:

$$D_M = \frac{l}{n\pi},$$

where  $n$  is the number of turns that a braid makes about the longitudinal axis of the actuator.

Implicit in the Chou-Hannaford equation are the assumptions of infinitely thin bladder and shell and of inelastic braids incapable of stretching. Both assumptions can lower the accuracy of the model and are corrected for in this block. The correction for the stretching in a braid replaces the constant length  $l$  with the variable length  $l^*$ :

$$l^* = \frac{Cl + \sqrt{(Cl)^2 + 12L^2(C + 1)}}{2(C + 1)} + \frac{2nPD^2}{Ed},$$

where  $l$  is the natural length of a braid used in the original Chou-Hannaford equation and:

- $C$  is a correction term for braid stretching.
- $E$  is Young's modulus of elasticity for the material of the braids.
- $d$  is the diameter of a strand in a braid (each braid being a bundle of tightly intertwined strands).

The correction term for braid stretching is defined as:

$$C = \frac{n^2\pi^2Ed^2N}{PlL},$$

where  $N$  is the total number strands in the braided shell. The correction for the thickness of the bladder and shell adds to the total actuator force the factor:

$$F_T = \pi P \left[ t \left( 2D - \frac{D_M^2}{D} \right) - t^2 \right]$$

where  $t$  is the aggregate thickness of the bladder and shell and the subscript T denotes the correction for thickness. The total actuator force is:

$$F = F_{H-F} + F_T,$$

where the strand length used in the calculation of the Chou-Hannaford term is the variable  $l^*$ . This force is counteracted at the limits of extension and contraction by translational hard stops. These are modeled as described for the Translational Hard Stop block.

### Modeling Assumptions

- There is no flow resistance between the gas entrance (port **A**) and the interior of the actuator.
- There is no thermal resistance between the actuator wall (port **H**) and the gas that it encloses.
- The actuator is hermetic and does not leak.
- The effects of friction and inertia are ignored.
- The bladder and shell are perfectly cylindrical no matter their inflation level.

- The longitudinal elasticity of the bladder is ignored.

## Ports

### Conserving

**A** — Actuator inlet  
gas

Gas opening for pressurizing the actuator. Connect this port to the pressure source for the actuator. The pressure at this port controls the force generated by the actuator.

**R** — Actuator end cap  
mechanical translational

One of two end caps at which the actuator force is applied. Connect this port to the fixture on which the actuator is to be mounted or to the load that the actuator is to move.

**C** — Actuator end cap  
mechanical translational

One of two end caps at which the actuator force is applied. Connect this port to the fixture on which the actuator is to be mounted or to the load that the actuator is to move.

**H** — Actuator wall  
thermal

Thermal boundary condition between the gas volume of the actuator and its surroundings. Connect this port to blocks in the Thermal domain to capture heat transfer by conduction, convection, or radiation, for example, or to insulate the actuator from the environment.

## Parameters

**Initial actuator length** — Distance between end caps when unloaded and unpressurized  
0.575 m (default) | positive scalar in units of length

Distance between the end caps of the actuator in the relaxed state, when it is both unloaded and unpressurized. Inflating the actuator during simulation causes it to widen and simultaneously to shorten. The actuator is shorter than its braids, which is to say that its initial length should be less than the **Unstretched braid length** parameter.

**Unstretched braid length** — Length of straightened braid when unloaded  
0.65 m (default) | positive scalar in units of length

Length of a braid as measured with its turns straightened and any loads removed. If the braids are elastic, their (common) length will vary with during simulation pressure and load. As the braids are wound about the longitudinal axis of the actuator, their length is always greater than the **Initial actuator length** parameter.

**Number of turns per braid** — Number of turns in a braid about the actuator length axis  
4.7 (default) | positive unitless scalar

Number of turns that a braid makes about the longitudinal axis of the actuator from one end cap to the second.

**Braid stretching** — Choice of whether to model the stretching of a braid  
 Inelastic braids (default) | Elastic braids

Choice of whether to model the stretching of a braid. The default option, **Inelastic braids**, treats the braids as flexible but inextensible. This is the assumption implicit in the original Chou-Hannaford equation. The length of a braid is then constant during simulation.

The alternative option, **Elastic braids**, allows the braids to extend with actuator load and pressure. The length of the braid is then treated as variable during simulation. This change adds a correction to the Chou-Hannaford equation for force.

**Thickness of braided shell and bladder** — Combined thickness of shell and bladder  
 0.075 m (default) | positive scalar in units of length

Sum of the thicknesses of the braided shell and of the bladder inside it. A finite thickness adds to the Chou-Hannaford equation for force a correction term. (In the original Chou-Hannaford equation, the shell and bladder are assumed to be infinitely thin.)

**Cross-sectional area at port A** — Area normal to flow at the gas port  
 0.01 m (default) | positive scalar in units of length

Area normal to flow at the gas port of the actuator.

**Total number of braids** — Number of braids in the braided shell  
 80 (default) | positive unitless scalar

Number of braids in the shell surrounding the bladder. As the braids are each a bundle of intertwined strands, the number of braids is not generally the same as the number of strands.

#### Dependencies

This parameter is active when the **Braid stretching** option is set to **Elastic Braids**.

**Number of strands per braid** — Number of individual strands in a braid  
 3 (default) | positive unitless scalar

Number of strands in a braid. The product of this number and the **Total number of braids** parameter gives the total number of strands in the shell.

#### Dependencies

This parameter is active when the **Braid stretching** option is set to **Elastic Braids**.

**Strand diameter** — Diameter of a strand  
 0.25 m (default) | positive scalar in units of length

Average diameter of a strand throughout its length.

#### Dependencies

This parameter is active when the **Braid stretching** option is set to **Elastic Braids**.

**Young's modulus of strands** — Degree to which the strands extend under pressure  
 3e9 GPA (default)

Young's modulus of elasticity for the material of the strands. This parameter determines the degree to which the strands extend under pressure.

### Dependencies

This parameter is active when the **Braid stretching** option is set to `Elastic Braids`.

**Environment pressure specification** — Pressure condition outside of the actuator  
`Atmospheric pressure (default)` | `Specified pressure`

Pressure condition in the immediate surroundings of the actuator. The gauge pressure in the actuator is obtained relative to this pressure. Select `Atmospheric pressure` to use the atmospheric value specified in the Two-Phase Fluid Properties (2P) block or `Specified pressure` to use a different pressure.

**Environment pressure** — Absolute pressure outside of the actuator  
`0.101325 (default)` | scalar in units of pressure

Absolute pressure in the immediate surroundings of the actuator. The actuator contracts when the gauge pressure at port **A** (measured against this value) is greater than zero.

### Dependencies

This parameter is active when the **Environment pressure specification** option is set to `Specified pressure`.

**Contact stiffness of braids at full muscle contraction or extension** — Stiffness coefficient for contact force at actuator motion limits  
`1e6 N/m (default)`

Stiffness coefficient for the contact force at the limits of the actuator's range of motion. The contact force keeps the actuator from extending or contracting beyond its physical limits. The contact force is modeled using a spring-damper system. The spring element adds a restorative force that pulls the end caps back once they reach either limit of motion.

For more information on the force model, see the Translational Hard Stop block.

**Contact damping of braids at full muscle contraction or extension** — Damping coefficient for contact force at actuator motion limits  
`1e4 N/(m/s) (default)`

Damping coefficient for the contact force at the limits of the actuator's range of motion. The contact force keeps the actuator from extending or contracting beyond its physical limits. This force is modeled using a spring-damper system. The damper adds a viscous force to the end caps once they reach a limit of motion, causing them to slow to a stop.

For more information on the force model, see the Translational Hard Stop.

## Angle Sensor

(To be removed) Ideal angle sensor with measuring range from 0 to 360 degrees

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

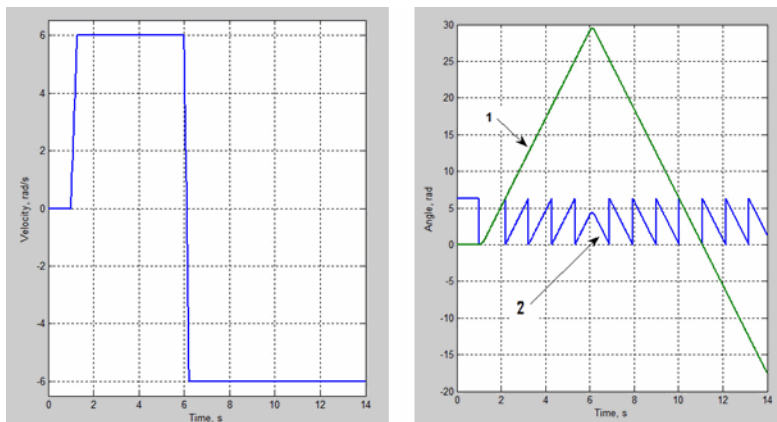

## Library

Pumps and Motors

## Description

The Angle Sensor block represents an ideal angle sensor with measuring range from 0 to 360 degrees. To measure an angular displacement, the sensor must be connected to a mechanical rotational port. No load is imposed on the measured object. The sensor output is kept within the range from 0 to  $2\pi$  radians (360 degrees) regardless of the number of revolutions performed by the object and the direction of rotation. The sensor is ideal because it does not account for inertia, friction, and so on.

The difference between the Angle Sensor block and the Ideal Rotational Motion Sensor block, available in the Simscape Foundation library, is demonstrated in the following figure.

In this example, the object is moving at 6 rad/s in the positive direction for the first 5 seconds, and then switches to the negative direction at the same speed. The Ideal Rotational Motion Sensor block

output (line 1) shows that the object turned forward by 30 rad and then turned back in the negative direction, continuing until -20 rad. The reading of the Angle Sensor block (line 2) stays in the range from 0 to  $2\pi$  rad.

Availability of the Angle Sensor block considerably simplifies development of models with complex relationship between model parameters and rotation angle, such as pumps and motors.

## Basic Assumptions and Limitations

- The sensor is assumed to be ideal. No load is imposed on the object.
- No inertial effects are considered.

## Parameters

### Phase angle

This parameter lets you account for angular shift between the object and the sensor input. The default value is 0.

## Ports

The block has the following ports:

W

Mechanical rotational conserving port associated with the probe of the sensor.

A

Physical signal port that outputs the angular displacement of the object.

## Examples

The “Hydraulic Axial-Piston Pump with Load-Sensing and Pressure-Limiting Control” example models a test rig designed to investigate interaction between an axial-piston pump and a typical control unit, simultaneously performing the load-sensing and pressure-limiting functions. To assure required accuracy, the model of the pump must account for such features as interaction between pistons, swash plate, and porting plate, which makes it necessary to build a detailed pump model.

The Angle Sensor block is used in each of the piston model subsystems (`Piston_1`, ..., `Piston_5`), where it provides the angular position of the respective piston as input to the Porting Plate Variable Orifice blocks.

## Annular Leakage (IL)

Models annular leakage between a circular tube and a round insert in an isothermal flow

### Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Orifices

### Description

The Annular Leakage (IL) block models annular leakage between a circular tube and a round insert in an isothermal liquid network. The insert can be located off-center from the tube and can have varying lengthwise overlap with the tube.

Ports **A** and **B** correspond with the orifice inlet and outlet. The input ports **L** and **E** are optional physical signal ports that model variable overlap length ( $L$ ) and variable eccentricity ( $E$ ).

### The Mass Flow Rate Equation

The leakage mass flow rate is calculated from the pressure-flow rate equation

$$\dot{m} = \frac{\pi(R-r)^3(R+r)(p_A - p_B)}{12\nu l} \left[ 1 + 3\varepsilon_{sat}^2 \frac{R}{(R+r)} + \frac{3}{8} \varepsilon^4 \frac{(R-r)}{(R+r)} \right]$$

where:

- $R$  is the annulus outer radius.
- $r$  is the annulus inner radius.
- $p_A$  is the pressure at port **A**.
- $p_B$  is the pressure at port **B**.
- $\nu$  is the fluid kinematic viscosity.
- $l$  is the overlap length.

- $\varepsilon$  is the eccentricity ratio,  $\varepsilon = \frac{e}{R-r}$ , where  $e$  is the eccentricity, which can be defined as a physical signal or constant value.
- $\varepsilon_{\text{sat}}$  is the saturated eccentricity ratio, which is  $\varepsilon$  for constant orifices, or the physical signal connected to port **L** for variable orifices. The eccentricity ratio is always between 0 and 1.

When modeling a variable overlap length, the user-defined minimum overlap length is used if the physical signal falls below the value of the **Minimum overlap length** parameter.

### Assumptions and Limitations

The pressure-flow equation is valid only for fully-developed, laminar flows. The flow Reynolds number can be determined using  $Re = \frac{\dot{m}D_h}{\mu\pi(R^2 - r^2)}$  or by checking the simulation log in the Results Explorer or the Simulation Data Inspector. For more information, see “Data Logging”.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Entry or exit port of the liquid to or from the orifice.

**B** — Liquid port  
isothermal liquid

Entry or exit port of the liquid to or from the orifice.

### Input

**L** — Variable overlap length  
physical signal

Optional physical signal port that provides the variable overlap length between the sleeve and annular insert.

### Dependencies

To expose this port, set **Overlap length specification** to Variable.

**E** — Variable eccentricity  
physical signal

Optional physical signal port that provides variable eccentricity of the annular insert to the sleeve.

### Dependencies

To expose this port, set **Eccentricity specification** to Variable.

## Parameters

**Overlap length specification** — Type of insert-sleeve overlap  
Constant (default) | Variable

Whether the length-wise sleeve-insert overlap is constant or variable.

**Overlap length** — Overlap between tube and insert  
 $1e-3$  m (default) | positive scalar

Length-wise overlap between the insert and tube.

### Dependencies

To enable this parameter, set **Overlap length specification** to Constant.

**Minimum overlap length** — Minimum overlap between tube and insert  
 $1e-6$  m (default) | positive scalar

Lower limit to the length-wise overlap between the insert and tube. Any length shorter than this value will be set to the specified minimum.

### Dependencies

To enable this parameter, set **Overlap length specification** to Variable.

**Eccentricity specification** — Eccentricity variability  
Constant (default) | Variable

Whether the orifice eccentricity changes or remains at a set value.

**Eccentricity** — Center of insert offset with respect to sleeve center  
 $0$  m (default) | positive scalar

The distance between the center of the orifice and the center of the insert.

### Dependencies

To enable this parameter, set **Eccentricity specification** to Constant.

**Inner radius** — Radius of insert  
 $9.8e-3$  m (default) | positive scalar

Insert radius  $r$ .

**Outer radius** — Radius of tube  
 $1e-2$  m (default) | positive scalar

Tube radius  $R$ , measured from the tube center to the inner wall.

# Annular Orifice

(To be removed) Hydraulic variable orifice created by circular tube and round insert

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Orifices

## Description

The Annular Orifice block annular leakage in a fully-developed laminar flow created by a circular tube and a round insert in an isothermal liquid network. The insert can be located off-center from the tube by an eccentricity value.

The flow rate is computed using the Hagen-Poiseuille equation (see [1]):

$$q = \frac{\pi R(R-r)^3}{6\nu\rho L} \cdot \left(1 + \frac{3}{2}\varepsilon^2\right) \cdot p$$

$$\varepsilon = \frac{e}{R-r}$$

where

$q$	Flow rate
-----	-----------

$\rho$	Pressure differential
$R$	Orifice radius
$r$	Insert radius
$L$	Overlap length
$\varepsilon$	Eccentricity ratio
$e$	Eccentricity
$\rho$	Fluid density
$\nu$	Fluid kinematic viscosity

Use this block to simulate leakage path in plungers, valves, and cylinders.

The block positive direction is from port A to port B. This means that the flow rate is positive if it flows from A to B and the pressure differential is determined as  $\Delta p = p_A - p_B$ . Positive signal at the physical signal port S increases or decreases the overlap, depending on the value of the parameter **Orifice orientation**.

## Assumptions and Limitations

Fluid inertia is not taken into account.

## Ports

### Input

**S** — Physical signal port that controls the insert displacement, m  
physical signal

Physical signal port that controls the insert displacement.

### Conserving

**A** — Hydraulic conserving port associated with the orifice inlet  
hydraulic

Hydraulic conserving port associated with the orifice inlet.

**B** — Hydraulic conserving port associated with the orifice outlet  
hydraulic

Hydraulic conserving port associated with the orifice outlet.

## Parameters

**Orifice radius** — Radius of the tube  
0.01 m (default) | positive scalar

The radius of the tube.

**Insert radius** — Radius of the insert  
0.0098 m (default) | positive scalar

The radius of the insert.

**Eccentricity** — Distance between the central axes of the insert and the tube  
 $\theta$  (default) | nonnegative scalar

The distance between the central axes of the insert and the tube. The parameter can be a positive value, smaller than the difference between the radius of the tube and the radius of the insert, or equal to zero for coaxial configuration.

**Initial length** — Initial overlap between the tube and the insert  
 $0.003$  m (default) | positive scalar

Initial overlap between the tube and the insert. The parameter must be positive. The value of the initial length does not depend on the orifice orientation.

**Orifice orientation** — Specifies the effect of the control signal on the orifice overlap  
 Positive signal increases overlap (default) | Negative signal increases overlap

Specifies the effect of the control signal on the orifice overlap.

## Area Change (IL)

Area expansion or contraction along a pipe in an isothermal liquid network

### Libraries:

Simscape / Fluids / Isothermal Liquid / Pipes & Fittings

### Description

The Area Change (IL) block models a sudden or a gradual area change along a pipe with fixed areas and variable flow direction. When the fluid moves from port **A** to port **B**, it experiences an area contraction. When the fluid flows from port **B** to port **A**, it experiences an area expansion. The inlet and outlet areas can be equal.

Both semi-empirical and tabular formulations are available for correlating flows to losses.

### Semi-Empirical Formulation

In the semi-empirical, analytical formulation, losses in pressure and velocity are characterized by a *Hydraulic loss coefficient*,  $K$ , in terms of a user-defined **Contraction correction factor**,  $C_{\text{contraction}}$ , and **Expansion correction factor**,  $C_{\text{expansion}}$ , from Crane [1]. The coefficient that characterizes area change is calculated from both expansion and contraction loss factors and based on the flow rate through the block.

For gradual conical area contractions between 0 and 45 degrees, the contraction loss factor is:

$$K_{\text{contraction}} = 0.8C_{\text{contraction}}\sin\left(\frac{\theta}{2}\right)(1 - R),$$

where  $R$  is the port area ratio  $\frac{A_{\text{smaller}}}{A_{\text{bigger}}}$ . For gradual area contraction between 45 and 180 degrees:

$$K_{\text{contraction}} = \frac{C_{\text{contraction}}}{2}\sqrt{\sin\left(\frac{\theta}{2}\right)}(1 - R),$$

where  $\theta$  is the **Cone angle**. A sudden area change has an angle of 180 degrees. In this case, the loss factor is calculated as  $K_{\text{contraction}} = \frac{C}{2}(1 - R)$ .

For gradual conical area expansions between 0 and 45 degrees, the expansion loss factor is:

$$K_{\text{expansion}} = 2.6C_{\text{expansion}}\sin\left(\frac{\theta}{2}\right)(1 - R)^2,$$

and for gradual area expansion between 45 and 180 degrees:

$$K_{\text{expansion}} = C_{\text{expansion}}(1 - R)^2.$$

The hydraulic loss coefficient for the pipe change segment is calculated from these values as:

$$K = K_{expansion} + \frac{K_{contraction} - K_{expansion}}{2} \left( \tanh\left(\frac{3\dot{m}_A}{\dot{m}_{th}}\right) + 1 \right),$$

where:

- $\dot{m}_A$  is the mass flow rate through port **A**. Mass is conserved through the segment:  $\dot{m}_A + \dot{m}_B = 0$ .
- $\dot{m}_{th}$  is the threshold mass flow rate for flow reversal, which is based on the **Critical Reynolds number**,  $Re_c$ :

$$\dot{m}_{th} = \frac{Re_c A_R \nu \bar{\rho}}{D_h},$$

where:

- $A_R$  is the smallest segment area (either the **Cross-sectional area at port A** or the **Cross-sectional area at port B**.)
- $\nu$  is the fluid kinematic viscosity.
- $\bar{\rho}$  is the average fluid density.
- $D_h$  is the hydraulic diameter at  $A_R$ :  $D_h = \sqrt{\frac{4A_R}{\Pi}}$ .

### Tabulated Data Parameterization

The loss factor can also be parameterized with user-provided data interpolated from the Reynolds number at the smallest area, which in turn is a function of the **Critical Reynolds number**:

$$K = TLU(Re_c).$$

Linear interpolation is employed between data points, and nearest-neighbor extrapolation is employed beyond the table boundaries.

### Pressure Differential

The pressure differential over the area change is

$$p_A - p_B = \frac{\dot{m}^2}{2\bar{\rho}A_R^2} (1 - R^2) + \Delta p_{loss},$$

where the pressure loss is:

$$\Delta p_{loss} = \frac{K}{2\bar{\rho}A_R^2} \dot{m}_A \sqrt{\dot{m}_A^2 + \dot{m}_{th}^2}.$$

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Liquid entry port.

**B** — Liquid port  
isothermal liquid

Liquid exit port.

## Parameters

**Cone angle** — Gradual area change angle  
30 (default) | positive scalar

Angle of expansion for a gradual area change parameterized as a cone.

### Dependencies

To enable this parameter, set **Local loss parameterization** to Semi-empirical correlation - gradual area change.

**Local loss parameterization** — Model of hydraulic losses  
Semi-empirical correlation - sudden area change (default) | Semi-empirical correlation - gradual area change | Tabulated data - loss coefficient vs. Reynolds number

Model of hydraulic losses due to area change. You can choose from two analytical, semi-empirical formulations or you can provide your own data by selecting Tabulated data - loss coefficient vs. Reynolds number.

**Cross-sectional area at port A** — Area at port A  
0.02 m<sup>2</sup> (default) | positive scalar

Area at the section entrance, port **A**.

**Cross-sectional area at port B** — area at port B  
0.01 m<sup>2</sup> (default) | positive scalar

Area at the section exit, port **B**.

**Reynolds number vector** — Vector of Reynolds number values for tabular parameterization  
[10, 20, 30, 40, 50, 100, 200, 500, 1000, 2000] (default) | 1-by- $n$  vector

Vector of Reynolds number values for the tabular parameterization of the area change. The elements must correspond one-to-one with the elements of the **Contraction loss coefficient vector** and the **Expansion loss coefficient vector** parameters. The vector values are listed in ascending order.

### Dependencies

To enable this parameter, set **Local loss parameterization** to Tabulated data - loss coefficient vs. Reynolds number.

**Contraction loss coefficient vector** — Vector of loss coefficients for an area contraction  
[5, 2.7, 1.8, 1.46, 1.3, .9, .65, .42, .3, .2] (default) | 1-by- $n$  vector

Vector of loss coefficients for an area contraction corresponding to the **Reynolds number vector** parameter, where  $n$  is the length of the **Reynolds number vector**. The elements are listed in descending order and must be greater than 0.

**Dependencies**

To enable this parameter, set **Local loss parameterization** to Tabulated data - loss coefficient vs. Reynolds number.

**Expansion loss coefficient vector** — Vector of loss coefficients for an area expansion  
[3.1, 2.3, 1.65, 1.35, 1.15, .9, .75, .65, .9, .65] (default) | 1-by- $n$  vector

Vector of loss coefficients for an area expansion corresponding to the **Reynolds number vector** parameter, where  $n$  is the length of the **Reynolds number vector**. The elements are listed in descending order and must be greater than 0.

**Dependencies**

To enable this parameter, set **Local loss parameterization** to Tabulated data - loss coefficient vs. Reynolds number.

**Expansion correction factor** — Coefficient in semi-empirical loss factor equation  
1 (default) | positive scalar

Coefficient used in the semi-empirical calculation of the area expansion loss factor.

**Dependencies**

To enable this parameter, set **Local loss parameterization** to either:

- Semi-empirical correlation - sudden area change
- Semi-empirical correlation - gradual area change

**Contraction correction factor** — Coefficient in semi-empirical loss factor equation  
1 (default) | positive scalar

Coefficient used in the semi-empirical calculation of the area contraction loss factor.

**Dependencies**

To enable this parameter, set **Local loss parameterization** to either:

- Semi-empirical correlation - sudden area change
- Semi-empirical correlation - gradual area change

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the orifice.

**Version History**

Introduced in R2020a

# Ball Valve

(To be removed) Valve with a sliding ball control mechanism

---

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

---

## Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Valves / Flow Control Valves

## Description

The Ball Valve block models an orifice with a variable opening area controlled by a sliding ball mechanism. The opening area changes with the relative position of the ball—the *valve lift*. A displacement toward the orifice decreases flow while a displacement away increases flow. The interface between the orifice and the ball—the *valve seat*—can be **Sharp-edged**, shown left in the figure, or **Conical**, shown right.

## Ball Valve Seat Types

### Opening Area

The valve lift is a function of the displacement signal specified through port **S**. The two can, but generally do not, have the same value. The valve lift differs from the displacement whenever the **Ball displacement offset** parameter is nonzero:

$$h(x) = x_0 + s,$$

where:

- $h$  is the valve lift.
- $x_0$  is the ball displacement offset.
- $s$  is the ball displacement (relative to the specified offset).

The valve is fully closed when the valve lift is equal to zero or less. It is fully open when the valve lift reaches or exceeds a (geometry-dependent) value sufficient to completely clear the orifice. A fully closed valve has an opening area equal to the specified **Leakage area** parameter while a fully open valve has the maximum possible opening area. Adjusting for internal leakage:

$$A_{Max} = \pi r_O^2 + A_{Leak},$$

where:

- $A_{Max}$  is the maximum opening area.
- $r_O$  is the orifice radius.
- $A_{Leak}$  is the internal leakage area between the ports.

At intermediate values of the valve lift, the opening area depends on the valve seat geometry. If the **Valve seat specification** parameter is set to Sharp-Edged, the opening area as a function of valve lift is:

$$A(h) = \pi r_O \left( 1 - \left[ \frac{r_B}{d_{OB}(h)} \right]^2 \right) d_{OB}(h),$$

where:

- $A$  is the opening area at a given valve lift value.
- $r_B$  is the ball radius.
- $d_{OB}(h)$  is the distance from the center of the ball (point **O** in the figure) to the edge of the orifice (point **B**). This distance is a function of the valve lift ( $h$ ).

If the **Valve seat specification** parameter is set to Conical, the opening area becomes:

$$A(h) = \pi h \cos(\theta) \sin(\theta) \cdot (2r_B + h \sin(\theta)),$$

where  $\theta$  is the angle between the conical surface and the orifice centerline. The geometrical parameters and variables used in the equations are shown in the figure.

## Valve Geometries

### Flow Rate

The volumetric flow rate through the valve is a function of the opening area,  $A(h)$ , and of the pressure differential between the valve ports:

$$q = C_D A(h) \sqrt{\frac{2}{\rho}} \frac{\Delta p}{((\Delta p)^2 + p_{Cr}^2)^{1/4}},$$

where:

- $C_D$  is the flow discharge coefficient.
- $\rho$  is the hydraulic fluid density.
- $\Delta p$  is the pressure differential between the valve ports, defined as:

$$\Delta p = p_A - p_B,$$

where  $p_A$  is the pressure at port **A** and  $p_B$  is the pressure at port **B**.

- $p_{Cr}$  is the minimum pressure required for turbulent flow.

The critical pressure  $p_{Cr}$  is computed from the critical Reynolds number as:

$$p_{Cr} = \frac{\rho}{2} \left( \frac{Re_{Cr} \nu}{C_D D_H} \right)^2,$$

where:

- $Re_{Cr}$  is the critical Reynolds number.
- $\nu$  ( $nu$ ) is the hydraulic fluid dynamic viscosity.
- $D_H$  is the orifice hydraulic diameter:

$$D_H = \begin{cases} D_H^{Min}, & \text{if } h \leq 0 \\ D_H^{Max} + D_H^{Min}, & \text{if } h \geq h_{Max}, \\ \frac{4A}{l} + D_H^{Min}, & \text{otherwise} \end{cases}$$

in which:

- $D_H^{Min}$  is the minimum hydraulic diameter, corresponding to the smallest attainable flow area, the leakage flow area.
- $D_H^{Max}$  is the maximum hydraulic diameter, corresponding to the largest attainable flow area, that of the valve in the fully open position.
- $l$  is the wetted length of the valve perimeter—which can, but need not, be that of a circle.

## Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

## Assumptions

Fluid inertia is assumed to be negligible.

## Ports

### Input

**S** — Ball displacement, m  
physical signal

Physical signal input port for the ball displacement.

### Conserving

**A** — Valve inlet  
hydraulic (isothermal liquid)

Hydraulic (isothermal liquid) conserving port associated with the valve inlet.

**B** — Valve outlet  
hydraulic (isothermal liquid)

Hydraulic (isothermal liquid) conserving port associated with the valve outlet.

## Parameters

**Valve seat specification** — Valve seat geometry type  
Sharp-edged (default) | Conical

Geometry of the valve seat. The choice of geometry impacts the opening characteristics of the valve. See the block description for the valve opening calculations.

**Cone angle** — Angle between sloping edges of transverse seat cross section  
120 deg (default) | scalar in units of rotation

Angle between the sloping edges of the seat in a transverse cross-sectional view.

**Ball diameter** — Diameter of the ball control element  
0.01 m (default) | scalar in units of length

Diameter of the ball control element. This diameter must be greater than that specified for the orifice.

**Orifice diameter** — Diameter of the valve orifice  
0.005 m (default) | scalar in units of length

Diameter of the valve orifice. This diameter must be smaller than that specified for the ball control element.

**Ball displacement offset** — Neutral position of ball control element  
0 m (default) | scalar in units of length

Neutral position of the ball control element. The neutral position is that to which the ball returns when the displacement signal is zero. This parameter must be greater than or equal to zero.

**Discharge coefficient** — Semi-empirical parameter for valve capacity characterization

0.7 (default) | unitless scalar between 0 and 1

Ratio of the actual and theoretical flow rates through the valve. This parameter depends on the geometrical properties of the valve. Values are usually provided in textbooks and manufacturer data sheets.

**Leakage area** — Internal leakage area between valve inlets

1e-12 m<sup>2</sup> (default) | positive scalar in units of area

Total area of internal leaks in the completely closed state. The purpose of this parameter is to maintain the numerical integrity of the fluid network by preventing a portion of that network from becoming isolated when the valve is completely closed.

**Laminar transition specification** — Choice of parameter used to define the laminar-turbulent transition

Pressure ratio (default) | Reynolds number

Select the parameter to base the laminar-turbulent transition on. Options include:

- **Pressure ratio** — Flow transitions between laminar and turbulent at the pressure ratio specified in the **Laminar flow pressure ratio** parameter. Use this option for the smoothest and most numerically robust flow transitions.
- **Reynolds number** — The transition occurs at the Reynolds number specified in the **Critical Reynolds number** parameter. Flow transitions are more abrupt and can cause simulation issues at near-zero flow rates.

**Laminar flow pressure ratio** — Pressure ratio at the laminar-turbulent flow transition

0.999 (default) | unitless scalar between 0 and 1

Pressure ratio at which the flow transitions between the laminar and turbulent regimes. The pressure ratio is the fraction of the outlet pressure over the inlet pressure.

#### Dependencies

This parameter is active when the **Laminar transition specification** parameter is set to Pressure ratio.

**Critical Reynolds number** — Reynolds number at the laminar-turbulent flow transition

12 (default) | unitless positive scalar

Maximum Reynolds number for laminar flow. This parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value, 12, corresponds to a round orifice in thin material with sharp edges.

#### Dependencies

This parameter is active when the **Laminar transition specification** parameter is set to Reynolds number.

## Version History

Introduced in R2006a

## Ball Valve (IL)

Ball valve in an isothermal liquid network

### Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Flow Control Valves

### Description

The Ball Valve (IL) block represents a ball valve in an isothermal liquid network. A ball valve consists of a ball with a bore that can pivot inside of a valve body. When the valve is open, the bore fully overlaps with the valve body port. As the valve shuts, the ball rotates and reduces the amount of overlap, thereby reducing the effective area of the orifice. Ball valves are common for flow isolation purposes because they can securely shut off flow for many cycles. Ball valves are less common in applications where precise throttling is necessary.

You can parameterize the block analytically or by using tabulated data. When you set **Ball valve parameterization** to **Area of overlapping circles**, the block considers the area of the overlap between the valve port and the ball bore as the opening area such that

$$A_{open} = \sin(\varphi)R_{bore}^2[\cos^{-1}(\lambda_{bore}) - \lambda_{bore}\sqrt{1 - \lambda_{bore}^2}] + R_{port}^2[\cos^{-1}(\lambda_{port}) - \lambda_{port}\sqrt{1 - \lambda_{port}^2}]$$

$$\lambda_{bore} = \frac{R_{bore}^2 - R_{port}^2 + l^2}{2R_{bore}l}$$

$$\lambda_{port} = \frac{R_{port}^2 - R_{bore}^2 + l^2}{2R_{port}l}$$

where:

- $R_{port}$  and  $R_{bore}$  are the radii of the valve port and the ball bore, respectively.
- $l$  is the displacement of the bore center from the valve port center.
- $\varphi$  is the rotation of the ball valve given by the physical signal **S**. The valve is fully shut at 0 rad and fully open at  $\pi/2$  rad.

### Mass Flow Rate

The block calculates flow through the valve using the pressure-area relationship for orifices such that

$$\dot{m} = C_d A \sqrt{2\bar{\rho}} \frac{\Delta p}{(\Delta p^2 + \Delta p_{crit}^2)^{1/4}},$$

where:

- $C_d$  is the discharge coefficient.
- $\bar{\rho}$  is the average fluid density.
- $A$  is the area open to flow, where  $A = A_{open} + A_{leak}$ , and  $A_{leak}$  is the **Leakage area** parameter.

- $\Delta p_{crit}$  is the critical pressure differential associated with the critical Reynolds number,  $Re_{crit}$ .

The block calculates  $\Delta p_{crit}$  as

$$\Delta p_{crit} = \frac{\pi \bar{\rho}}{8A} \left( \frac{v Re_{crit}}{C_d} \right)^2.$$

When you set **Flow coefficient parameterization** to Cd coefficient and area, you can specify  $C_d$  using the **Discharge coefficient (Cd)** parameter. When you set **Flow coefficient parameterization** to Cv coefficient (USCS), the block calculates  $C_d$  as

$$C_d = \frac{C_v}{A} \sqrt{\frac{\rho_{water, 60^\circ F}}{2\Delta p_{C_v}}},$$

where  $C_v$  is the **Maximum valve flow coefficient (Cv)** parameter. When you set **Flow coefficient parameterization** to Kv coefficient (SI), the block uses

$$C_d = \frac{K_v}{A} \sqrt{\frac{\rho_{water, 15^\circ C}}{2\Delta p_{K_v}}},$$

where  $K_v$  is the **Maximum valve flow factor (Kv)** parameter. In either equation,  $\Delta p_{C_v}$  is 1 psi and  $\Delta p_{K_v}$  is 1 bar.

## Ports

### Input

**S** — Valve position, rad  
physical signal

Physical signal port associated with the position of the valve, in rad. A value of 0 represents a fully shut valve and a value of  $\pi/2$  represents a fully open valve.

### Conserving

**A** — Valve port A  
isothermal liquid

Isothermal liquid conserving port associated with valve port A.

**B** — Valve port B  
isothermal liquid

Isothermal liquid conserving port associated with valve port B.

## Parameters

**Ball valve parameterization** — Ball valve parameterization  
Area of overlapping circles (default) | Tabulated data

Option to parameterize the block using the method of area of overlapping circles or to use tabulated data.

**Flow coefficient parameterization** — Option to parameterize given flow coefficient  
Kv coefficient (SI) (default) | Cv coefficient (USCS) | Cd coefficient and area

Whether to parameterize the flow using  $K_v$ ,  $C_v$ , or  $C_d$ . The block uses these coefficient definitions:

- $K_v$  is the flow capacity of water through the fully open valve at 15°C with a pressure drop of 1 bar, in m<sup>3</sup>/h.
- $C_v$  is the flow capacity of water through the fully open valve at 60°F with a pressure drop of 1 psi, in gpm.
- $C_d$  is the unitless discharge coefficient that defines the efficiency of the valve.

**Maximum valve flow coefficient (Cv)** — Maximum valve flow coefficient  
32 gpm (default) | positive scalar

Maximum value of the valve flow coefficient. This value should correspond to the fully open position.

#### Dependencies

To enable this parameter, set **Ball valve parameterization** to Area of overlapping circles and **Flow coefficient parameterization** to Cv coefficient (USCS).

**Maximum valve flow factor (Kv)** — Maximum valve flow factor  
49 m<sup>3</sup>/hr (default) | positive scalar

Maximum value of the valve flow factor. This value should correspond to the fully open position.

#### Dependencies

To enable this parameter, set **Ball valve parameterization** to Area of overlapping circles and **Flow coefficient parameterization** to Kv coefficient (SI).

**Discharge coefficient (Cd)** — Discharge coefficient  
0.64 (default) | positive scalar

Discharge coefficient of the valve. This value is a correction factor that accounts for losses in the theoretical flow.

#### Dependencies

To enable this parameter, set **Flow coefficient parameterization** to Cd coefficient and area.

**Cross-sectional area at ports A and B** — Valve port cross-sectional area  
 $\pi * (25 \wedge 2) / 4$  mm<sup>2</sup> (default) | positive scalar

Cross-sectional area of the valve ports. The valve ports are the paths in the valve body where the flow meets the ball bore.

#### Dependencies

To enable this parameter, set **Ball valve parameterization** to Area of overlapping circles.

**Ball bore area** — Area of ball bore  
 $\pi * (20 \wedge 2) / 4$  mm<sup>2</sup> (default) | positive scalar

Cross-sectional area of the bore in the valve ball.

**Dependencies**

To enable this parameter, set **Ball valve parameterization** to Area of overlapping circles.

**Valve flow coefficient (Cv) vector** — Flow coefficient for given ball rotation

[1e-06, .58, 1.15, 1.9, 2.8, 4.3, 7, 10.5, 17, 26, 32] gpm (default) | vector

Valve flow coefficient for a given ball rotation. Each element corresponds one-to-one with the **Ball rotation vector** parameter. The first element corresponds to the valve leakage and must be nonzero.

**Dependencies**

To enable this parameter, set **Ball valve parameterization** to Tabulated data and **Flow coefficient parameterization** to Cv coefficient (USCS).

**Valve flow factor (Kv) vector** — Flow factor for given ball rotation

[1e-06, .34, .76, 1.6, 2.45, 4.1, 5.75, 9.4, 13, 28, 50] m<sup>3</sup>/hr (default) | vector

Valve flow factor for a given ball rotation. Each element corresponds one-to-one with the **Ball rotation vector** parameter. The first element corresponds to the valve leakage and must be nonzero.

**Dependencies**

To enable this parameter, set **Ball valve parameterization** to Tabulated data and **Flow coefficient parameterization** to Kv coefficient (SI).

**Area vector** — Area for given ball rotation

[1e-10, 62.5, 125, 187.5, 250, 312.5, 375, 437.5, 500, 562.5, 625] mm<sup>2</sup> (default) | vector

Flow area for a given ball rotation. Each element corresponds one-to-one with the **Ball rotation vector** parameter. The first element corresponds to the valve leakage and must be nonzero.

**Dependencies**

To enable this parameter, set **Ball valve parameterization** to Tabulated data and **Flow coefficient parameterization** to Cd coefficient and area.

**Ball rotation vector** — Ball rotation

$\pi / 2 .* [0, .1, .2, .3, .4, .5, .6, .7, .8, .9, 1]$  rad (default) | vector

Ball rotation for a given flow coefficient or area. The elements in this vector must align one-to-one with the elements in either the **Valve flow coefficient (Cv) vector** parameter, the **Valve flow factor (Kv) vector** parameter, or the **Area vector** parameter.

**Dependencies**

To enable this parameter, set **Ball valve parameterization** to Tabulated data.

**Leakage area** — Valve gap area when in fully shut position

1e-10 m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the valve is in the fully shut position. The block saturates any area smaller than this value to the specified leakage area. This value contributes to numerical stability by maintaining continuity in the flow.

**Dependencies**

To enable this parameter, set **Ball valve parameterization** to Area of overlapping circles.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

**Version History**

**Introduced in R2022b**

**Extended Capabilities****C/C++ Code Generation**

Generate C and C++ code using Simulink® Coder™.

## Poppet Valve (G)

Poppet valve in a gas network

### Libraries:

Simscape / Fluids / Gas / Valves & Orifices / Flow Control Valves

### Description

The Poppet Valve (G) block represents an orifice with a translating ball that moderates flow through the valve. In the fully closed position, the ball rests at the perforated seat, and fully blocks the fluid from passing between ports **A** and **B**. The area between the ball and seat is the opening area of the valve.

The flow can be laminar or turbulent, and it can reach up to sonic speeds. The maximum velocity happens at the throat of the valve where the flow is narrowest and fastest. The flow chokes and the velocity saturates when a drop in downstream pressure can no longer increase the velocity. Choking occurs when the back-pressure ratio reaches the critical value characteristic of the valve. The block does not capture supersonic flow.

### Ball Mechanics

The block models the displacement of the ball but not the valve opening or closing dynamics. The signal at port **L** provides the normalized ball position,  $L$ . Note that  $L$  is a normalized distance between 0 and 1, which indicate a fully closed valve and a fully open valve, respectively. If the calculation returns a number outside of this range, that number is set to the nearest bound.

### Numerical Smoothing

When the **Smoothing factor** parameter is nonzero, the block applies numerical smoothing to the normalized ball position,  $L$ . Enabling smoothing helps maintain numerical robustness in your simulation.

For more information, see “Numerical Smoothing”.

### Opening Area

The opening area of the valve depends on the **Valve seat geometry** parameter, which can be either **Sharp-edged** or **Conical**. The **Leakage flow fraction** parameter is the ratio of the flow rate of the valve when it is closed to when it is open. The **Leakage flow fraction** allows for small contact gaps between the ball and seat in the fully closed position. This parameter also maintains continuity in the flow for solver performance.

This figure shows the seat types for the poppet valve.

### Sharp-Edged Seat Geometry

The block calculates the opening area of the valve as

$$S_{open, sharp - edged} = \pi r_O \sqrt{(G_{sharp} + h)^2 + r_O^2} \left[ 1 - \frac{r_B^2}{(G_{sharp} + h)^2 + r_O^2} \right],$$

where:

- $h$  is the distance between the outer edge of the cylinder and the seat.
- $r_O$  is the seat orifice radius, which the block calculates from the **Orifice diameter** parameter.
- $r_B$  is the radius of the ball, which the block calculates from the **Ball diameter** parameter.
- $G_{sharp}$  is the geometric parameter:  $G_{sharp} = \sqrt{r_B^2 - r_O^2}$ .

The maximum displacement,  $h_{max}$ , bounds the opening area:

$$h_{max} = \sqrt{\frac{2r_B^2 - r_O^2 + r_O \sqrt{r_O^2 + 4r_B^2}}{2}} - G_{sharp}.$$

For any ball displacement larger than  $h_{max}$ ,  $S_{open}$  is the value of the maximum orifice area:

$$S_{open} = \frac{\pi}{4} d_O^2.$$

When the signal at port **L** is less than 0, the valve is closed and the **Leakage flow fraction** parameter determines the mass flow rate.

### Conical Seat Geometry

The block calculates the opening area of the valve as:

$$S_{open, conical} = G_{conical} h + \frac{\pi}{2} \sin(\theta) \sin\left(\frac{\theta}{2}\right) h^2,$$

where:

- $h$  is the vertical distance between the outer edge of the cylinder and the seat.
- $\theta$  is the value of the **Cone angle** parameter.
- $G_{conical}$  is the geometric parameter,  $G_{conical} = \pi r_B \sin(\theta)$ , where  $r_B$  is the ball radius.

The maximum displacement,  $h_{max}$ , bounds the opening area:

$$h_{\max} = \frac{\sqrt{r_B^2 + \frac{r_O^2}{\cos\left(\frac{\theta}{2}\right)} - r_B}}{\sin\left(\frac{\theta}{2}\right)}.$$

For any ball displacement larger than  $h_{\max}$ ,  $S_{open}$  is the value of the maximum orifice area:

$$S_{open} = \frac{\pi}{4}d_O^2.$$

When the signal at port **L** is less than 0, the valve is closed and the **Leakage flow fraction** parameter determines the mass flow rate.

### Valve Parameterizations

The block behavior depends on the **Valve parametrization** parameter:

- **Cv flow coefficient** — The flow coefficient  $C_v$  determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential.
- **Kv flow coefficient** — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential.
- **Sonic conductance** — The sonic conductance of the resistive element at steady state determines the block parameterization. The sonic conductance measures the ease with which a gas can flow when *choked*, which is a condition in which the flow velocity is at the local speed of sound. Choking occurs when the ratio between downstream and upstream pressures reaches a critical value known as the *critical pressure ratio*.
- **Orifice area based on geometry** — The size of the flow restriction determines the block parametrization.

The block scales the specified flow capacity by the fraction of valve opening. As the fraction of valve opening rises from 0 to 1, the measure of flow capacity scales from its specified minimum to its specified maximum.

### Mass Flow Rate

The block equations depend on the **Orifice parametrization** parameter. When you set **Orifice parametrization** to Cv flow coefficient parameterization, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C_v \frac{S_{open}}{S_{Max}} N_6 Y \sqrt{(p_{in} - p_{out}) \rho_{in}},$$

where:

- $C_v$  is the value of the **Maximum Cv flow coefficient** parameter.
- $S_{open}$  is the valve opening area.
- $S_{Max}$  is the maximum valve area where the valve is fully open.
- $N_6$  is a constant equal to 27.3 for mass flow rate in kg/hr, pressure in bar, and density in kg/m<sup>3</sup>.
- $Y$  is the expansion factor.

- $p_{in}$  is the inlet pressure.
- $p_{out}$  is the outlet pressure.
- $\rho_{in}$  is the inlet density.

The expansion factor is

$$Y = 1 - \frac{p_{in} - p_{out}}{3p_{in}F_{\gamma}x_T},$$

where:

- $F_{\gamma}$  is the ratio of the isentropic exponent to 1.4.
- $x_T$  is the value of the **xT pressure differential ratio factor at choked flow** parameter.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter,  $B_{lam}$ ,

$$\dot{m} = C_v \frac{S_{open}}{S_{Max}} N_6 Y_{lam} \sqrt{\frac{\rho_{avg}}{p_{avg}(1 - B_{lam})}} (p_{in} - p_{out}),$$

where:

$$Y_{lam} = 1 - \frac{1 - B_{lam}}{3F_{\gamma}x_T}.$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below  $1 - F_{\gamma}x_T$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = \frac{2}{3} C_v \frac{S_{open}}{S_{Max}} N_6 \sqrt{F_{\gamma}x_T p_{in} \rho_{in}}.$$

When you set **Orifice parametrization** to Kv flow coefficient parameterization, the block uses these same equations, but replaces  $C_v$  with  $K_v$  by using the relation  $K_v = 0.865C_v$ . For more information on the mass flow equations when the **Orifice parametrization** parameter is Kv flow coefficient parameterization or Cv flow coefficient parameterization, see [2][3].

When you set **Orifice parametrization** to Sonic conductance parameterization, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C \frac{S_{open}}{S_{Max}} \rho_{ref} p_{in} \sqrt{\frac{T_{ref}}{T_{in}}} \left[ 1 - \left( \frac{\frac{p_{out}}{p_{in}} - B_{crit}}{1 - B_{crit}} \right)^2 \right]^m,$$

where:

- $C$  is the value of the **Maximum sonic conductance** parameter.
- $B_{crit}$  is the critical pressure ratio.
- $m$  is the value of the **Subsonic index** parameter.
- $T_{ref}$  is the value of the **ISO reference temperature** parameter.

- $\rho_{ref}$  is the value of the **ISO reference density** parameter.
- $T_{in}$  is the inlet temperature.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter  $B_{lam}$ .

$$\dot{m} = C \frac{S_{open}}{S_{Max}} \rho_{ref} \sqrt{\frac{T_{ref}}{T_{avg}}} \left[ 1 - \left( \frac{B_{lam} - B_{crit}}{1 - B_{crit}} \right)^{2^m} \left( \frac{p_{in} - p_{out}}{1 - B_{lam}} \right) \right].$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below the critical pressure ratio,  $B_{crit}$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = C \frac{S_{open}}{S_{Max}} \rho_{ref} p_{in} \sqrt{\frac{T_{ref}}{T_{in}}}.$$

For more information on the mass flow equations when the **Orifice parametrization** parameter is Sonic conductance parameterization, see [1].

When you set **Orifice parametrization** to Orifice area based on geometry, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C_d S_{open} \sqrt{\frac{2\gamma}{\gamma-1} p_{in} \rho_{in} \left( \frac{p_{out}}{p_{in}} \right)^{\frac{2}{\gamma}} \frac{1 - \left( \frac{p_{out}}{p_{in}} \right)^{\frac{\gamma-1}{\gamma}}}{1 - \left( \frac{S_{open}}{S} \right)^2 \left( \frac{p_{out}}{p_{in}} \right)^{\frac{2}{\gamma}}}},$$

where:

- $S_{open}$  is the valve opening area.
- $S$  is the value of the **Cross-sectional area at ports A and B** parameter.
- $C_d$  is the value of the **Discharge coefficient** parameter.
- $\gamma$  is the isentropic exponent.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter,  $B_{lam}$ .

$$\dot{m} = C_d S_{open} \sqrt{\frac{2\gamma}{\gamma-1} p_{avg}^{\frac{2-\gamma}{\gamma}} \rho_{avg} B_{lam}^{\frac{2}{\gamma}} \frac{1 - B_{lam}^{\frac{\gamma-1}{\gamma}}}{1 - \left( \frac{S_{open}}{S} \right)^2 B_{lam}^{\frac{2}{\gamma}}} \left( \frac{p_{in}^{\frac{\gamma-1}{\gamma}} - p_{out}^{\frac{\gamma-1}{\gamma}}}{1 - B_{lam}^{\frac{\gamma-1}{\gamma}}} \right)}.$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below  $\left( \frac{2}{\gamma+1} \right)^{\frac{\gamma}{\gamma-1}}$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = C_d S_{open} \sqrt{\frac{2\gamma}{\gamma+1} p_{in} \rho_{in} \frac{1}{\left( \frac{\gamma+1}{2} \right)^{\frac{2}{\gamma-1}} - \left( \frac{S_{open}}{S} \right)^2}}.$$

For more information on the mass flow equations when the **Orifice parametrization** parameter is Orifice area based on geometry, see [4].

### Energy Balance

The resistive element of the block is an adiabatic component. No heat exchange can occur between the fluid and the wall that surrounds it. No work is done on or by the fluid as it traverses from inlet to outlet. Energy can flow only by advection, through ports **A** and **B**. By the principle of conservation of energy, the sum of the port energy flows is always equal to zero

$$\phi_A + \phi_B = 0,$$

where  $\phi$  is the energy flow rate into the valve through ports **A** or **B**.

### Mass Balance

The block assumes the volume and mass of fluid inside the valve is very small and ignores these values. As a result, no amount of fluid can accumulate in the valve. By the principle of conservation of mass, the mass flow rate into the valve through one port equals that out of the valve through the other port

$$\dot{m}_A + \dot{m}_B = 0,$$

where  $\dot{m}$  is defined as the mass flow rate into the valve through the port indicated by the **A** or **B** subscript.

### Assumptions and Limitations

- The Sonic conductance setting of the **Valve parameterization** parameter is for pneumatic applications. If you use this setting for gases other than air, you may need to scale the sonic conductance by the square root of the specific gravity.
- The equation for the Orifice area based on geometry parameterization is less accurate for gases that are far from ideal.
- This block does not model supersonic flow.

## Ports

### Conserving

**A** — Liquid port  
gas

Gas conserving port associated with the opening through which the flow enters or exits the valve.

**B** — Liquid port  
gas

Gas conserving port associated with the opening through which the flow enters or exits the valve.

### Input

**L** — Normalized ball displacement, in the range of [0,1]  
physical signal

Normalized ball displacement. The ball position is normalized by the maximum opening distance. A value of 0 indicates a fully closed valve and a value of 1 indicates a fully open valve.

## Parameters

**Valve seat specification** — Definition of valve seat geometry

Sharp-edged (default) | Conical

Geometry of the seat of the ball. This parameter determines the opening area of the valve.

**Cone angle** — Angle between the conical seat of the valve and its center lines

120 deg (default) | positive scalar

Angle formed by the slope of the conical seat against its center line.

### Dependencies

To enable this parameter, set **Valve seat specification** to Conical.

**Ball diameter** — Diameter of the ball used to regulate valve opening

0.01 m (default) | scalar

Diameter of the ball control element.

**Orifice diameter** — Diameter of the valve orifice

7e-3 m (default) | scalar

Diameter of the valve constant orifice. For a conical geometry, the diameter the root of the seat.

**Valve parameterization** — Parameterization used to specify flow characteristics of orifice

Orifice area based on geometry (default) | Cv flow coefficient | Kv flow coefficient | Sonic conductance

Method to calculate the mass flow rate.

- **Cv flow coefficient** — The flow coefficient  $C_v$  determines the block parameterization.
- **Kv flow coefficient** — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization.
- **Sonic conductance** — The sonic conductance of the resistive element at steady state determines the block parameterization.
- **Orifice area based on geometry** — The size of the flow restriction determines the block parameterization.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar in the range of [0,1]

Correction factor that accounts for discharge losses in theoretical flows.

### Dependencies

To enable this parameter, set **Valve parameterization** to Orifice area based on geometry.

**Maximum Cv flow coefficient** — Cv coefficient that corresponds to maximally open component

4 (default) | positive scalar

Value of the  $C_v$  flow coefficient when the restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

#### Dependencies

To enable this parameter, set **Valve parameterization** to  $C_v$  flow coefficient.

**xT pressure differential ratio factor at choked flow** — Ratio of pressure differentials  
0.7 (default) | positive scalar

Ratio between the inlet pressure,  $p_{in}$ , and the outlet pressure,  $p_{out}$ , defined as  $(p_{in} - p_{out})/p_{in}$  where choking first occurs. If you do not have this value, look it up in table 2 in ISA-75.01.01 [3]. Otherwise, the default value of 0.7 is reasonable for many valves.

#### Dependencies

To enable this parameter, set **Valve parameterization** to  $C_v$  flow coefficient or  $K_v$  flow coefficient.

**Maximum  $K_v$  flow coefficient** —  $K_v$  coefficient that corresponds to maximally open component  
3.6 (default) | positive scalar

Maximum value of the  $K_v$  flow coefficient when the restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

#### Dependencies

To enable this parameter, set **Valve parameterization** to  $K_v$  flow coefficient.

**Maximum sonic conductance** — Sonic conductance corresponding to maximally open component  
12  $l/(bar*s)$  (default) | positive scalar

Value of the sonic conductance when the cross-sectional area available for flow is at a maximum.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**Critical pressure ratio** — Ratio of downstream and upstream pressures at which the flow first chokes  
0.3 (default) | positive scalar

Pressure ratio at which flow first begins to choke and the flow velocity reaches its maximum, given by the local speed of sound. The pressure ratio is the outlet pressure divided by inlet pressure.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**Subsonic index** — Exponent used to characterize mass flow in subsonic flow regime  
0.5 (default) | positive scalar

Empirical value used to more accurately calculate the mass flow rate in the subsonic flow regime.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**ISO reference temperature** — ISO 8778 reference temperature  
293.15 K (default) | scalar

Temperature at standard reference atmosphere, defined as 293.15 K in ISO 8778.

**Dependencies**

To enable this parameter, set **Valve parameterization** to `Sonic conductance`.

**ISO reference density** — ISO 8778 reference density  
1.185 kg/m<sup>3</sup> (default) | positive scalar

Density at standard reference atmosphere, defined as 1.185 kg/m<sup>3</sup> in ISO 8778.

**Dependencies**

To enable this parameter, set **Valve parameterization** to `Sonic conductance`.

**Leakage flow fraction** — Ratio of flow rates  
1e-6 (default) | positive scalar

Ratio of the flow rate of the orifice when it is closed to when it is open.

**Smoothing factor** — Numerical smoothing factor  
0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the orifice is in near-open or near-closed positions. Set this parameter to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Laminar flow pressure ratio** — Pressure ratio at which flow transitions between laminar and turbulent regimes  
0.999 (default) | positive scalar

Pressure ratio at which flow transitions between laminar and turbulent flow regimes. The pressure ratio is the outlet pressure divided by inlet pressure. Typical values range from 0.995 to 0.999.

**Cross-sectional area at ports A and B** — Flow area at gas ports  
0.01 m<sup>2</sup> (default) | positive scalar

Area normal to the flow path at each port. The ports are equal in size. The value of this parameter should match the inlet area of the components to which the resistive element connects.

## Version History

### Introduced in R2018b

#### R2022b: Model gas systems using improved flow computations

In previous versions, the blocks in the gas library used a conversion factor to implement different orifice parameterizations in terms of sonic conductance. You can use the **Valve parameterization** parameter to specify the parameterization.

The new parameterizations also include new parameters:

- **xT pressure differential ratio factor at choked flow**
- **Discharge coefficient**
- **Leakage flow fraction.** This parameter replaces the **Cv coefficient (USCS) at leakage flow**, **Kv coefficient (SI) at leakage flow**, **Sonic conductance at leakage flow**, and **Restriction area at leakage flow** parameters.

To improve clarity:

- The **Opening parameterization** parameter has been renamed to **Opening characteristic**.
- The **Reference temperature** and **Reference density** parameters have been renamed to **ISO reference temperature** and **ISO reference density**, respectively.
- The **Cv coefficient (USCS) at maximum flow** and **Kv coefficient (USCS) at maximum flow** parameters have been renamed to **Maximum Cv coefficient** and **Maximum Kv coefficient**, respectively.
- The **Sonic conductance at maximum flow** parameter has been renamed to **Maximum sonic conductance**.

#### **R2022b: Updated block name**

The title of the Ball Valve (G) block changed to Poppet Valve (G).

#### **R2022b: Offset parameter removed**

The block no longer has a **Valve lift control offset** parameter and the block no longer offsets the input signal. This change does not impact compatibility.

# Cartridge Valve Insert

(To be removed) Hydraulic cartridge valve insert

---

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

---

## Library

Directional Valves

## Description

The Cartridge Valve Insert block represents an insert of a hydraulic cartridge valve consisting of a poppet interacting with the seat. The poppet position is determined by pressures at ports A, B, and X and force of the spring. A schematic diagram of the cartridge valve insert is shown in the following illustration.

The Cartridge Valve Insert block is a structural model consisting of a Hydraulic Cartridge Valve Actuator block and a Variable Orifice block, as shown in the next illustration.

Pressures at port A and port B tend to open the valve, while pressure at the control port X, together with the spring, acts to close it. The model does not account for flow rates caused by poppet displacement and any loading on the poppet, such as inertia and friction. The valve remains closed as long as the aggregate pressure force is lower than the spring preload force. The poppet is forced off its seat as the preload force is reached and moves up proportionally to pressure increase until it passes the full stroke. Hydraulic properties of the gap between the poppet and the seat are simulated with the Variable Orifice block.

Connections A, B, and X are hydraulic conserving ports associated with the valve inlet, valve outlet, and valve control terminal, respectively. The block positive direction is from port A to port B. Pressure at port X acts to close the valve, while pressures at port A and port B act to open the orifice.

## Basic Assumptions and Limitations

- Valve opening is linearly proportional to the pressure differential.
- No loading on the poppet, such as inertia or friction, is considered.
- The model does not account for flow rates caused by poppet displacement.
- For orifices specified by the passage area (the first two parameterization options), the transition between laminar and turbulent regimes is assumed to be sharp and taking place exactly at  $Re=Re_{cr}$ .
- For orifices specified by pressure-flow characteristics (the third parameterization option), the model does not explicitly account for the flow regime or leakage flow rate because the tabulated data is assumed to account for these characteristics.

## Parameters

### Port A poppet area

Effective poppet area at port A. The parameter value must be greater than zero. The default value is  $2e-4 \text{ m}^2$ .

### Port A to port X area ratio

Ratio between poppet areas at port A and port X. The parameter value must be greater than zero. The default value is 0.66.

**Preload force**

Spring preload force. The default value is 26 N.

**Spring rate**

Spring rate. The default value is 1.4e4 N/m.

**Poppet stroke**

Maximum poppet stroke. The parameter value must be greater than or equal to zero. The default value is 5e-3 m. This parameter is used if **Orifice specification** is set to **By maximum area and opening**.

**Initial opening**

The initial opening of the valve. Its value must be greater than or equal to zero. The default value is 0.

**Orifice specification**

Select one of the following methods for specifying the hydraulic properties of the gap between the poppet and the seat:

- **By maximum area and opening** — Provide values for the maximum orifice area and the maximum orifice opening. The passage area is linearly dependent on the control member displacement, that is, the orifice is closed at the initial position of the control member (zero displacement), and the maximum opening takes place at the maximum displacement. This is the default method.
- **By area vs. opening table** — Provide tabulated data of orifice openings and corresponding orifice areas. The passage area is determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.
- **By pressure-flow characteristic** — Provide tabulated data of orifice openings, pressure differentials, and corresponding flow rates. The flow rate is determined by two-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.

For more information on these options, see the Variable Orifice block reference page.

**Orifice maximum area**

Specify the area of a fully opened orifice. The parameter value must be greater than zero. The default value is 5e-5 m<sup>2</sup>. This parameter is used if **Orifice specification** is set to **By maximum area and opening**.

**Tabulated orifice openings**

Specify the vector of input values for orifice openings as a one-dimensional array. The input values vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in meters, are [-0.002 0 0.002 0.005 0.015]. If **Orifice specification** is set to **By area vs. opening table**, the **Tabulated orifice openings** values will be used together with **Tabulated orifice area** values for one-dimensional table lookup. If **Orifice specification** is set to **By pressure-flow characteristic**, the **Tabulated orifice openings** values will be used together with **Tabulated pressure differentials** and **Tabulated flow rates** for two-dimensional table lookup.

**Tabulated orifice area**

Specify the vector of orifice areas as a one-dimensional array. The vector must be of the same size as the orifice openings vector. All the values must be positive. The default values, in m<sup>2</sup>, are

[1e-09 2.0352e-07 4.0736e-05 0.00011438 0.00034356]. This parameter is used if **Orifice specification** is set to By area vs. opening table.

### Tabulated pressure differentials

Specify the pressure differential vector as a one-dimensional array. The vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in Pa, are [-1e+07 -5e+06 -2e+06 2e+06 5e+06 1e+07]. This parameter is used if **Orifice specification** is set to By pressure-flow characteristic.

### Tabulated flow rates

Specify the flow rates as an m-by-n matrix, where m is the number of orifice openings and n is the number of pressure differentials. Each value in the matrix specifies flow rate taking place at a specific combination of orifice opening and pressure differential. The matrix size must match the dimensions defined by the input vectors. The default values, in m<sup>3</sup>/s, are:

```
[-1e-07 -7.0711e-08 -4.4721e-08 4.4721e-08 7.0711e-08 1e-07;
-2.0352e-05 -1.4391e-05 -9.1017e-06 9.1017e-06 1.4391e-05 2.0352e-05;
-0.0040736 -0.0028805 -0.0018218 0.0018218 0.0028805 0.0040736;
-0.011438 -0.0080879 -0.0051152 0.0051152 0.0080879 0.011438;
-0.034356 -0.024293 -0.015364 0.015364 0.024293 0.034356;]
```

This parameter is used if **Orifice specification** is set to By pressure-flow characteristic.

### Interpolation method

Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- **Linear** — Select this option to get the best performance.
- **Smooth** — Select this option to produce a continuous curve (By area vs. opening table) or surface (By pressure-flow characteristic) with continuous first-order derivatives.

For more information on interpolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

### Extrapolation method

Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- **Linear** — Select this option to produce a curve or surface with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.
- **Nearest** — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

### Flow discharge coefficient

Semi-empirical parameter for valve capacity characterization. Its value depends on the geometrical properties of the orifice, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.7.

### Laminar transition specification

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

### **Laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

### **Critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12, which corresponds to a round orifice in thin material with sharp edges. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

### **Leakage area**

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is  $1e-12 \text{ m}^2$ .

### **Time constant**

Sets the time constant of the first-order lag, which is introduced between the required and the actual poppet positions to account for actuator dynamics. The parameter value must be greater than zero. The default value is 0.01 s.

### **Restricted Parameters**

When your model is in Restricted editing mode, you cannot modify the following parameters:

- **Orifice specification**
- **Interpolation method**
- **Extrapolation method**

All other block parameters are available for modification. The actual set of modifiable block parameters depends on the value of the **Orifice specification** parameter at the time the model entered Restricted mode.

### **Global Parameters**

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the valve inlet.

B

Hydraulic conserving port associated with the valve outlet.

X

Hydraulic conserving port associated with the valve control terminal.

## Version History

**Introduced in R2008a**

**R2023a: To be removed**

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Cartridge Valve Actuator (IL)

Actuator that maintains equilibrium between valve and pilot pressures in an isothermal liquid system

### Libraries:

Simscape / Fluids / Valve Actuators & Forces

### Description

The Cartridge Valve Actuator (IL) block models an actuator that maintains equilibrium between the valve and pilot-line pressures. The valve between ports **A** and **B** remains closed until the pilot spring **Spring preload force** is surpassed, at which point the piston begins to move. The piston position is output as a physical signal at port **S**. A schematic of a 4-port cartridge valve actuator is shown below.

### Actuator Force Balance

The actuator piston moves to adjust the pressure in the actuator chamber, which maintains equilibrium between the actuator port pressures and pilot line pressures:

$$p_A A_A + p_B A_B = F_{preload} + F_{pilot},$$

where:

- $p_A$  and  $p_B$  are the pressures at ports **A** and **B**.
- $A_X$  is calculated from the **Port A to port X area ratio**.
- $A_B$  is the port **B** area,  $A_X - A_A$ , when the **Number of pressure ports** is set to 3. When the **Number of pressure ports** is set to 4,  $A_B$  is  $A_X - A_A + A_Y$ .
- $F_{preload}$  is the initial spring force in the system.
- $F_{pilot}$  is  $p_X A_X$  if **Number of pressure ports** is set to 3 and  $p_X A_X + p_Y A_Y$  if **Number of pressure ports** is set to 4.

## Piston Position

The steady piston displacement is calculated as:

$$x_{steady} = \frac{F\varepsilon}{k} = \frac{F_A + F_B - F_{pilot} - F_{preload}}{k} \varepsilon,$$

where  $\varepsilon$  is the **Opening orientation**, which assigns movement in a positive direction (extension) or negative direction (retraction). The dynamic change in piston displacement is:

$$\dot{x}_{dyn} = \frac{x_{steady} - x_{dyn}}{\tau},$$

where  $\tau$  is the **Actuator time constant**. When  $\dot{x}_{dyn} = \frac{x_{dyn}}{\tau}$  is less than the **Spring preload force**,  $x_{steady} = 0$ .

If  $\dot{x}_{dyn} = \frac{x_{dyn}}{\tau}$  is greater than the sum of the preload force and  $kx_{stroke}$ ,  $x_{steady} = x_{stroke}$ .

## Opening Dynamics

If opening dynamics are modeled, a lag is introduced to the flow response to the modeled control pressure.  $p_{control}$  becomes the dynamic control pressure,  $p_{dyn}$ ; otherwise,  $p_{control}$  is the steady-state pressure. The instantaneous change in dynamic control pressure is calculated based on the **Opening time constant**,  $\tau$ :

$$\dot{p}_{dyn} = \frac{p_{control} - p_{dyn}}{\tau}.$$

By default, **Opening dynamics** is set to Off.

## Numerically-Smoothed Force

When the actuator is close to full extension or full retraction, you can maintain numerical robustness in your simulation by adjusting the block **Smoothing factor**. A smoothing function is applied to all calculated forces, but primarily influences the simulation at the extremes of the piston motion.

The normalized force is

$$\hat{F} = \frac{F_A + F_B - F_{Preload} - F_{Pilot}}{kx_{stroke}}.$$

where:

- $F_A$  is the force at port **A**.
- $F_B$  is the force at port **B**.
- $F_{Preload}$  is the **Spring preload force**.
- $F_{Pilot}$  is the force at port **X**.

If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the normalized force between 0 and 1.

For more information, see “Numerical Smoothing”.

## Assumptions and Limitations

Internal fluid volumes are not modeled in this block. There is no mass flow rate through ports **A**, **B**, **X**, and **Y**.

## Ports

### Conserving

**A** — Pressure port  
isothermal liquid

Pressure port associated with the valve inlet.

**B** — Pressure port  
isothermal liquid

Pressure port associated with the valve outlet.

**X** — Pressure port  
isothermal liquid

Pressure port at poppet end.

**Y** — Pressure port  
isothermal liquid

Pilot pressure port. To enable this port, set **Number of pressure ports** to 4.

### Output

**S** — Poppet position, m  
physical signal

Poppet position in m, specified as a physical signal.

## Parameters

**Number of pressure ports** — Number of pilot pressure ports  
3 (default) | 4

Number of pilot pressure ports. Port **X** measures the pressure at the end of the poppet. Setting this parameter to 4 enables the additional pilot-side port **Y**.

**Port A poppet area** — Cross-sectional area of port A  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of port **A**.

**Port A poppet to port X pilot area ratio** — Ratio of inlet to pilot port area  
0.5 (default) | positive scalar

Ratio of the inlet port, **A**, to the pilot pressure port, **X**. This value is used to calculate the force at port **X**.

**Port Y pilot area** — Cross-sectional area of port Y  
 $1.5e-4 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of port **Y**.

**Dependencies**

To enable this parameter, set **Number of pressure ports** to 4.

**Spring preload force** — Initial spring force  
 $25 \text{ N}$  (default) | positive scalar

Spring force in the valve due to spring preloading. This parameter is a threshold value which, when added to the pilot pressures at ports **X** and **Y**, counterbalances the valve opening due to the pressures at ports **A** and **B**.

**Spring stiffness** — Stiffness constant  
 $15e3 \text{ N/m}$  (default) | positive scalar

Spring stiffness constant.

**Poppet stroke** — Maximum poppet extension  
 $5e-3 \text{ m}$  (default) | positive scalar

Maximum poppet extension.

**Smoothing factor** — Numerical smoothing factor  
 $0.01$  (default) | positive scalar in the range  $[0,1]$

Continuous smoothing factor that introduces a layer of gradual change to the piston position when it is near full extension or full retraction. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Connected valve opening orientation** — Direction of poppet displacement  
 Positive displacement opens valve (default) | Negative displacement opens valve

Direction of the poppet displacement that opens a connected valve. Setting this parameter to `Positive displacement opens valve` indicates poppet extension. Setting the parameter to `Negative displacement opens valve` indicates poppet retraction.

**Actuator dynamics** — Whether to account for transients during actuation  
 Off (default) | On

Whether to account for transient effects in the spool position due to actuation. Setting **Actuator dynamics** to `On` approximates actuator motion by introducing a first-order lag in the spool position. The **Actuator time constant** also impacts the modeled dynamics.

**Actuator time constant** — Piston displacement time constant  
 $0.1 \text{ s}$  (default) | positive scalar

Constant that captures the time required for the piston to reach steady-state when moving from one position to another. This parameter impacts the modeled actuator dynamics.

**Dependencies**

To enable this parameter, set **Actuator dynamics** to `On`.

# Cartridge Valve Insert (IL)

Cartridge flow-control valve in an isothermal liquid network

## Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Flow Control Valves

## Description

The Cartridge Valve Insert (IL) block models a cartridge flow-control valve in an isothermal liquid network. The valve seat can be specified as conical or as a custom opening parameterized by analytical or tabular formulations. The valve opens when the combined pressures at ports **A** and **B** exceed the **Spring preload force** and pressure at port **X**.

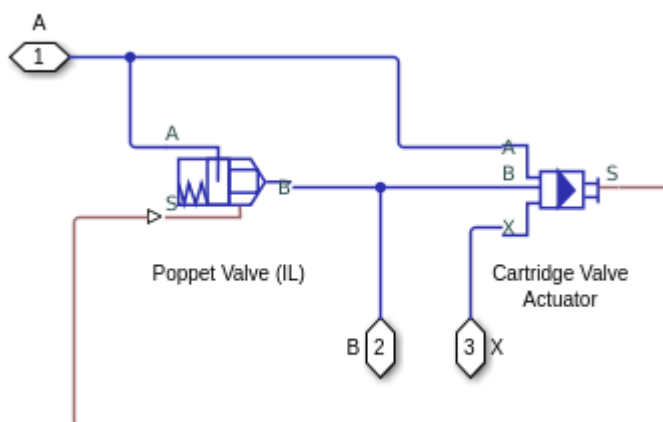

You can specify the block seat geometry as either conical or a custom. This seat setting determines the sub-components that make up the block. In both configurations, the **Port A poppet to port X pilot area ratio** parameter sets the force ratio in the underlying Cartridge Valve Actuator block.

Use the Cartridge Valve Insert (IL) block when you would like flow control set by a pilot pressure line. Use the Pressure-Compensated 3-Way Flow Control Valve (IL) or Pressure-Compensated Flow Control Valve (IL) block for flow control due to a pressure differential or the Poppet Valve (IL) block for valve opening controlled by an external physical signal.

### Conical Valve Seat

The conical cartridge valve insert is a composite of two Isothermal Liquid library blocks:

- Poppet Valve (IL)
- Cartridge Valve Actuator (IL)

**Conical Cartridge Valve Insert Schematic**

## Custom Valve Seat

The custom cartridge valve insert is a composite of two Isothermal Liquid library blocks:

- Orifice (IL)
- Cartridge Valve Actuator (IL)

In the custom configuration, you can parameterize the valve opening analytically or with a data set.

## Custom Cartridge Valve Insert Schematic

### Analytical Parameterization

By setting **Orifice parameterization** to Linear - area vs. control member position, the valve opening area is linearly proportional to the poppet position. Once the pressure at port **A** or **B** exceeds the **Spring preload force**, the valve opens until the **Maximum orifice area** is reached. When the valve is fully closed, a small **Leakage area** remains open to flow so that numerical continuity is maintained in the network.

### Tabulated Parameterization

By setting **Orifice parameterization** to Tabulated data - Area vs. control member position, you can supply the opening profile based on opening area and poppet position. The block queries between data points with linear interpolation and uses nearest extrapolation for points beyond the table boundaries.

By setting **Orifice parameterization** to Tabulated data - Volumetric flow rate vs. control member position and pressure drop, you can supply the volumetric flow rate through the valve as a parameterized table of poppet position and valve pressure drop. The block queries between data points with linear interpolation and uses linear extrapolation for points beyond the table boundaries. The volumetric flow rate is converted to a mass flow rate by multiplying by the fluid density.

### Opening Dynamics

If opening dynamics are modeled, a lag is introduced to the flow response to the modeled control pressure.  $p_{\text{control}}$  becomes the dynamic control pressure,  $p_{\text{dyn}}$ ; otherwise,  $p_{\text{control}}$  is the steady-state pressure. The instantaneous change in dynamic control pressure is calculated based on the **Opening time constant**,  $\tau$ :

$$\dot{p}_{dyn} = \frac{p_{control} - p_{dyn}}{\tau}.$$

By default, **Opening dynamics** is set to Off.

### Numerically-Smoothed Force and Opening

When the actuator is close to full extension or full retraction, and **Orifice parameterization** is set to **Linear - area vs. control member position**, you can maintain numerical robustness in your simulation by adjusting the block **Smoothing factor**. A smoothing function is applied to the actuator force and orifice opening or area, but primarily influences the simulation at the extremes of these ranges.

The normalized force that opens the valve is

$$\hat{F} = \frac{F_A + F_B - F_{Preload} - F_{Pilot}}{k \times stroke}.$$

where:

- $F_A$  is the force at port **A**.
- $F_B$  is the force at port **B**.
- $F_{Preload}$  is the **Spring preload force**.
- $F_{Pilot}$  is the force at port **X**.

When **Valve seat specification** is set to **Conical**, the block smoothly saturates the orifice opening distance between  $\theta$  and the maximum orifice opening distance. When **Valve seat specification** is set to **Custom**, the block smoothly saturates the valve opening area between the **Leakage area** parameter and the **Maximum orifice area** parameter.

For more information, see “Numerical Smoothing”.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Liquid entry or exit port.

**B** — Liquid port  
isothermal liquid

Liquid entry or exit port.

**X** — Pressure port  
isothermal liquid

Pilot pressure port. There is no mass flow rate through port **X**.

## Parameters

**Valve seat specification** — Geometry of valve seat

Conical (default) | Custom

Geometry of valve seat. This parameter is used for calculating the open area between the poppet and seat.

**Poppet diameter** — Diameter of the valve control member

0.01 m (default) | positive scalar

Diameter of the valve control member.

### Dependencies

To enable this parameter, set **Valve seat specification** to Conical.

**Seat cone angle** — Angle of the seat opening

120 deg (default) | positive scalar

Angle of the seat opening.

### Dependencies

To enable this parameter, set **Valve seat specification** to Conical.

**Orifice parameterization** — Method of calculating orifice area

Linear - area vs. control member position (default) | Tabulated data - Area vs. control member position | Tabulated data - Volumetric flow rate vs. control member position and pressure drop

The valve opening is calculated in one of three ways, linearly or by tabulated data:

- **Linear - area vs. control member position:** The orifice area is determined by a linear relationship to the poppet opening or closing distance.
- **Tabulated data - Area vs. control member position:** The opening area is interpolated from the **Poppet position vector** and the **Orifice area vector** based on the current poppet position.
- **Tabulated data - Volumetric flow rate vs. control member position and pressure drop.** The volumetric flow rate is directly interpolated from the provided **Poppet position vector,  $s$** ; **Pressure drop vector,  $dp$** ; and **Volumetric flow rate table,  $q(s,dp)$**  parameters, based on the current poppet position.

### Dependencies

To enable this parameter, set **Valve seat specification** to Custom.

**Poppet stroke** — Maximum poppet extension

5e-3 m (default) | positive scalar

Maximum poppet extension.

### Dependencies

To enable this parameter, set **Valve seat specification** to Custom and **Orifice parameterization** to Linear - area vs. control member position.

**Maximum orifice area** — Maximum orifice cross-sectional area  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the orifice in its fully open position. This parameter is used as an upper limit for area-pressure calculations during the simulation.

#### Dependencies

To enable this parameter, set **Valve seat specification** to Custom and **Orifice parameterization** to Linear - area vs. control member position.

**Poppet position vector** — Vector of opening positions  
 $[0, .002, .004, .007, .017] \text{ m}$  (default) | 1-by- $n$  vector

Vector of orifice opening positions for the tabular parameterization of the orifice opening area. The vector elements must correspond one-to-one with the elements in the **Orifice area vector** parameter. The elements are listed in ascending order and must be greater than 0.

#### Dependencies

To enable this parameter, set **Valve seat specification** to Custom and **Orifice parameterization** to Tabulated data - Area vs. control member position.

**Orifice area vector** — Vector of opening areas  
 $[1e-09, 2.0352e-07, 4.0736e-05, .00011438, .00034356] \text{ m}^2$  (default) | 1-by- $n$  vector

Vector of valve opening areas for the tabular parameterization of the valve opening area. The vector elements must correspond one-to-one with the elements in the **Poppet position vector** parameter. The elements are listed in ascending order and must be greater than 0.

#### Dependencies

To enable this parameter, set **Valve seat specification** to Custom and **Orifice parameterization** to Tabulated data - Area vs. control member position.

**Poppet position vector, s** — Vector of control member positions  
 $[0, .002, .004, .007, .017] \text{ m}$  (default) | 1-by- $n$  vector

Vector of control member positions for the tabular parameterization of the volumetric flow rate. The spool travel vector forms an independent axis with the **Pressure drop vector, dp** parameter for the 3-D dependent **Volumetric flow rate table, q(s,dp)** parameter. A positive displacement corresponds to valve opening. The values are listed in ascending order and the first element must be 0. Linear interpolation is employed between table data points.

#### Dependencies

To enable this parameter, set **Valve seat specification** to Custom and **Orifice parameterization** to Volumetric flow rate vs. control member position and pressure drop.

**Pressure drop vector, dp** — Vector of pressure differential values  
 $[.3, .5, .7] \text{ MPa}$  (default) | 1-by- $n$  vector

Vector of pressure drop values for tabular parametrization of volumetric flow rate. The pressure drop vector forms an independent axis with the **Poppet position vector, s** parameter for the 3-D dependent **Volumetric flow rate table, q(s,dp)** parameter. The values are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Valve seat specification** to Custom and **Orifice parameterization** to Volumetric flow rate vs. control member position and pressure drop.

**Volumetric flow rate table,  $q(s,dp)$**  — Array of volumetric flow rate values  
 $[1.7e-05, 2e-05, 2.6e-05; .0035, .0045, .0053; .7, .9, 1.06; 1.96, 2.5, 3; 6, 7.7, 9.13]$  .\*  $1e-3$  m<sup>3</sup>/s (default) |  $M$ -by- $N$  array

Matrix of volumetric flow rates based on independent values of pressure drop and spool travel distance.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of elements in the **Poppet position vector,  $s$**  parameter.
- $N$  is the number of elements in the **Pressure drop vector,  $dp$**  parameter.

**Dependencies**

To enable this parameter, set **Valve seat specification** to Custom and **Orifice parameterization** to Volumetric flow rate vs. control member position and pressure drop.

**Port A poppet area** — Cross-sectional area of port A  
 $1e-4$  m<sup>2</sup> (default) | positive scalar

Cross-sectional area of port **A**.

**Port A poppet to port X pilot area ratio** — Ratio of inlet to pilot port area  
 $0.5$  (default) | positive scalar

Ratio of the inlet port, **A**, to the pilot pressure port, **X**. This value is used to calculate the force at port **X**. The ratio must be less than or equal to 1.

**Spring preload force** — Spring force in neutral poppet position  
 $25$  N (default) | positive scalar

Spring force on the poppet when the poppet is in the neutral position. This parameter is a threshold value which, when added to the pilot pressure at port **X**, counterbalances the valve opening due to the pressures at ports **A** and **B**.

**Spring stiffness** — Stiffness constant  
 $15e3$  N/m (default) | positive scalar

Spring stiffness constant.

**Leakage area** — Gap area when in fully closed position  
 $1e-10$  m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the valve is in the fully closed position. Any area smaller than this value is saturated to the specified leakage area. This contributes to numerical stability by maintaining continuity in the flow.

**Dependencies**

To enable this parameter, set either:

- **Valve seat specification** to Conical.

- **Valve seat specification** to Custom and **Orifice parameterization** to Linear - Area vs. control member position.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Correction factor that accounts for discharge losses in theoretical flows.

#### Dependencies

To enable this parameter, set either:

- **Valve seat specification** to Conical.
- **Valve seat specification** to Custom and **Orifice parameterization** to Linear - Area vs. control member position or Tabulated data - Area vs. control member position.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

#### Dependencies

To enable this parameter, set either:

- **Valve seat specification** to Conical.
- **Valve seat specification** to Custom and **Orifice parameterization** to Linear - Area vs. control member position or Tabulated data - Area vs. control member position.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

#### Dependencies

To enable this parameter, set either:

- **Valve seat specification** to Conical.
- **Valve seat specification** to Custom and **Orifice parameterization** to Linear - Area vs. control member position.

**Valve opening time constant** — Valve time constant

0.1 s (default) | positive scalar

Constant that captures the time required for the fluid to reach steady-state conditions when opening or closing the valve from one position to another. This parameter impacts the modeled opening dynamics.

## Library

Directional Valves

## Description

The Cartridge Valve Insert with Conical Seat block represents an insert of a hydraulic cartridge valve consisting of a poppet interacting with the conical seat. The poppet position is determined by pressures at ports A, B, and X and force of the spring. A schematic diagram of the cartridge valve insert with conical seat is shown in the following illustration.

The Cartridge Valve Insert with Conical Seat block is a structural model consisting of a Hydraulic Cartridge Valve Actuator block and a Poppet Valve block, as shown in the next illustration.

Pressures at port A and port B tend to open the valve, while pressure at the control port X, together with the spring, acts to close it. The model does not account for flow rates caused by poppet displacement and any loading on the poppet, such as inertia and friction. The valve remains closed as long as the aggregate pressure force is lower than the spring preload force. The poppet is forced off its seat as the preload force is reached and moves up proportionally to pressure increase until it passes the full stroke. Hydraulic properties of the gap between the poppet and the seat are simulated with the Poppet Valve block.

Connections A, B, and X are hydraulic conserving ports associated with the valve inlet, valve outlet, and valve control terminal, respectively. The block positive direction is from port A to port B. Pressure at port X acts to close the valve, while pressures at port A and port B act to open the orifice.

## Basic Assumptions and Limitations

- Valve opening is linearly proportional to the pressure differential.
- No loading on the poppet, such as inertia or friction, is considered.
- The model does not account for flow consumption caused by poppet displacement.

## Parameters

### Port A poppet area

Effective poppet area at port A. The parameter value must be greater than zero. The default value is  $2e-4 \text{ m}^2$ .

### Port A to port X area ratio

Ratio between poppet areas at port A and port X. The parameter value must be greater than zero. The default value is 0.66.

### Preload force

Spring preload force. The default value is 26 N.

### Spring rate

Spring rate. The default value is  $1.4e4 \text{ N/m}$ .

### Poppet stroke

Maximum poppet stroke. The parameter value must be greater than zero. The default value is 0.005 m.

### Poppet diameter

Maximum poppet diameter. The parameter value must be greater than or equal to zero. The default value is 0.01 m.

**Seat cone angle**

The cone angle of the valve seat. The default value is 120 degrees.

**Initial opening**

The initial opening of the valve. Its value must be greater than or equal to zero. The default value is 0.

**Flow discharge coefficient**

Semi-empirical parameter for valve capacity characterization. Its value depends on the geometrical properties of the orifice, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.7.

**Laminar transition specification**

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

**Laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

**Critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12, which corresponds to a round orifice in thin material with sharp edges. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

**Leakage area**

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is  $1e-12 \text{ m}^2$ .

**Time constant**

Sets the time constant of the first-order lag, which is introduced between the required and the actual poppet positions to account for actuator dynamics. The parameter value must be greater than zero. The default value is 0.01 s.

**Global Parameters**

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the valve inlet.

B

Hydraulic conserving port associated with the valve outlet.

X

Hydraulic conserving port associated with the valve control terminal.

## Examples

For an example of using this block, see the “Injection Molding Actuation System” example.

## Library

Valve Actuators

## Description

The Hydraulic 4-Port Cartridge Valve Actuator block represents a double-acting hydraulic valve actuator driven by four pressures. Use it as a pilot actuator for cartridge valves, pilot-operated pressure and control valves, and similar devices. A schematic diagram of the 4-port cartridge valve actuator is shown in the following illustration.

The actuator drives a valve (spool, poppet, and so on) whose position depends on pressures at ports A, B, X, and Y and the spring force. Pressures at ports A and B tend to open the valve, while pressures

at control ports X and Y, together with the spring force, act to close it. The model does not account for flow consumption and loading forces, except spring and pressure forces.

Inertial properties of the actuator are accounted for by adding a first order lag between the steady-state and actual valve displacements. The lag is simulated with the combination of the PS Gain and PS Integrator blocks, enveloped by the unity feedback.

The valve remains closed as long as the aggregate pressure force is lower than the spring preload force. The poppet is forced off its seat as the preload force is reached and moves up proportionally to pressure increase until it passes the full stroke.

The force acting on the poppet and the poppet displacement are computed with the following equations:

$$F_P = p_A \cdot A_A + p_B \cdot A_B - p_X \cdot A_X - p_Y \cdot A_Y$$

$$x_s = \begin{cases} 0 & \text{for } F_P \leq F_{PR} \\ (F_P - F_{PR})/k_{spr} & \text{for } F_{PR} < F_P < F_{PR} + k_{spr} \cdot x_{max} \\ x_{max} & \text{for } F_P \geq F_{PR} + k_{spr} \cdot x_{max} \end{cases}$$

$$x = x_s \frac{1}{T_S + 1}$$

where

$F_P$	Pressure force acting on the poppet
$p_A, p_B, p_X, p_Y$	Pressures at ports A, B, X, and Y, respectively
$A_A, A_B, A_X, A_Y$	Areas at ports A, B, X, and Y, respectively. Areas at ports A and Y are block parameters. Area at port X is specified by its ratio to that at port A, $A_A / A_X$ . Area at port B is determined as $A_B = A_X - A_A$ .
$x$	Actual poppet displacement
$x_s$	Steady-state poppet displacement
$x_{max}$	Full stroke
$F_{PR}$	Spring preload force
$k_{spr}$	Spring rate

Connections A, B, X, and Y are hydraulic conserving ports associated with the actuator ports. Connection P is a physical signal port whose output corresponds to poppet displacement. Pressures applied at ports A and B move the poppet in the positive or negative direction, depending on the value of the **Actuator orientation** parameter. Pressures at ports X and Y act in the opposite direction to pressures at ports A and B.

## Basic Assumptions and Limitations

- The flow consumption associated with the valve motion is assumed to be negligible.
- The inertia, friction, and hydraulic axial forces are assumed to be small and are not taken into account.

## Parameters

### Port A poppet area

Effective poppet area at port A. The parameter value must be greater than zero. The default value is  $3.3e-4 \text{ m}^2$ .

### Port A to port X area ratio

Ratio between poppet areas at port A and port X. The parameter value must be greater than zero. The default value is 0.66.

### Port Y piston area

Effective piston area at port Y. The parameter value must be greater than zero. The default value is  $1.65e-4 \text{ m}^2$ .

### Preload force

Spring preload force. The default value is 26 N.

### Spring rate

Spring rate. The default value is  $1.4e4 \text{ N/m}$ .

### Poppet stroke

Maximum poppet stroke. The parameter value must be greater than zero. The default value is  $5e-3 \text{ m}$ .

### Poppet-seat initial gap

Initial gap between the poppet and the seat. The parameter value must be greater than or equal to zero. The default value is 0.

### Time constant

Time constant of the first-order lag. The default value is 0.01 s.

### Actuator orientation

Specifies actuator orientation with respect to the globally assigned positive direction. The actuator can be installed in two different ways, depending upon whether it moves the poppet in the positive or in the negative direction when pressure is applied at its inlet. If pressures applied at ports A and B move the poppet in the negative direction, set the parameter to `Acts in negative direction`. The default value is `Acts in positive direction`.

### Restricted Parameters

When your model is in Restricted editing mode, you cannot modify the following parameter:

- **Actuator orientation**

All other block parameters are available for modification.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the valve inlet.

B

Hydraulic conserving port associated with the valve outlet.

X

Hydraulic conserving port associated with the valve control terminal.

Y

Hydraulic conserving port associated with the valve control terminal.

P

Physical signal port that outputs poppet displacement.

## Examples

For an example of using this block, see the “Injection Molding Actuation System” example.

## Library

Valve Actuators

## Description

Use the Hydraulic Cartridge Valve Actuator block as a pilot actuator for cartridge valves, as well as pilot-operated pressure and control valves in applications where all the forces, except spring and pressure forces, and flow consumption can be neglected. This block represents a double-acting hydraulic valve actuator driven by three pressures. The actuator drives a valve (spool, poppet, etc.) whose position depends on pressures at ports A, B, and X and the force of the spring. Pressures at ports A and B tend to open the valve, while pressure at control port X together with the spring force act to close it.

Inertial properties of the actuator are accounted for by adding a first order lag between the steady-state and actual valve displacements. The lag is simulated with the combination of the PS Gain and PS Integrator blocks, enveloped by the unity feedback.

The valve remains closed as long as the aggregate pressure force is lower than the spring preload force. The poppet is forced off its seat as the preload force is reached and moves up proportionally to pressure increase until it passes the full stroke.

Connections A, B, and X are hydraulic conserving ports associated with the actuator ports. Connection P is a physical signal port whose output corresponds to poppet displacement. Pressures applied at ports A and B move the poppet in the positive or negative direction, depending on the value of the **Actuator orientation** parameter, with pressure at port X acting in the opposite direction.

## Basic Assumptions and Limitations

- The flow consumption associated with the valve motion is assumed to be negligible.
- The inertia, friction, and hydraulic axial forces are assumed to be small and are not taken into account.

- The clearances between the valve and the washers are not taken into account.

## Parameters

### Port A poppet area

Effective poppet area at port A. The parameter value must be greater than zero. The default value is  $3.3e-4 \text{ m}^2$ .

### Port A to port X area ratio

Ratio between poppet areas at port A and port X. The parameter value must be greater than zero. The default value is 0.66.

### Preload force

Spring preload force. The default value is 26 N.

### Spring rate

Spring rate. The default value is  $1.4e4 \text{ N/m}$ .

### Poppet stroke

Maximum poppet stroke. The parameter value must be greater than or equal to zero. The default value is  $5e-3 \text{ m}$ .

### Poppet-seat initial gap

Initial gap between the poppet and the seat. The parameter value must be greater than or equal to zero. The default value is 0.

### Time constant

Time constant of the first-order lag. The default value is 0.01 s.

### Actuator orientation

Specifies actuator orientation with respect to the globally assigned positive direction. The actuator can be installed in two different ways, depending upon whether it moves the poppet in the positive or in the negative direction when pressure is applied at its inlet. If pressures applied at ports A and B move the poppet in the negative direction, set the parameter to `Acts in negative direction`. The default value is `Acts in positive direction`.

## Restricted Parameters

When your model is in Restricted editing mode, you cannot modify the following parameter:

- **Actuator orientation**

All other block parameters are available for modification.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the valve inlet.

B

Hydraulic conserving port associated with the valve outlet.

X

Hydraulic conserving port associated with the valve control terminal.

P

Physical signal port that outputs poppet displacement.

## Library

Hydraulic Cylinders

## Description

The Centrifugal Force in Rotating Cylinder block is a building block to be used in hydraulic cylinder models, to account for centrifugal forces exerted by fluid on a piston, if the cylinder rotates about its symmetry axis. Such cylinders are used in control mechanisms of various friction clutches, brakes, square-jaw positive clutches, dog clutches, and so on. No inertial effects are considered in the model. In other words, the angular velocity is assumed to be constant or changing at very low speed.

The centrifugal force is computed with the following equation:

$$F = \frac{\pi\rho\omega^2}{4}(r_o^4 - r_i^4 - 2r_p^2(r_o^2 - r_i^2))$$

where

$F$	Centrifugal force
$r_o$	Piston outer radius
$r_i$	Piston inner radius
$r_p$	Fluid entry radius. For design purposes, $r_p < \sqrt{(r_o^2 + r_i^2)}/2$
$\rho$	Fluid density
$\omega$	Shaft angular velocity

Connections R and C are mechanical translational conserving ports corresponding to the cylinder rod and case, respectively. Connection W is a physical signal port through which shaft angular velocity is imported. The block directionality is adjustable and can be controlled with the **Cylinder orientation** parameter.

## Basic Assumptions and Limitations

- No inertial effects are considered in the model; that is, the angular velocity of the cylinder is assumed to be constant or changing at very low speed.
- Fluid inertia is not taken into account.
- Fluid compressibility is not taken into account.

## Parameters

### Piston outer radius

The default value is 0.1 m.

### Piston inner radius

The default value is 0.05 m.

### Fluid entry radius

The default value is 0.06 m.

### Fluid density

The default value is 880 kg/m<sup>3</sup>.

### Cylinder orientation

Specifies block orientation with respect to the globally assigned positive direction. The block can be installed in two different ways, depending upon whether it exerts force in the positive or in the negative direction. If positive velocity applied at port W exerts force in negative direction, set the parameter to `Acts in negative direction`. The default value is `Acts in positive direction`.

## Restricted Parameters

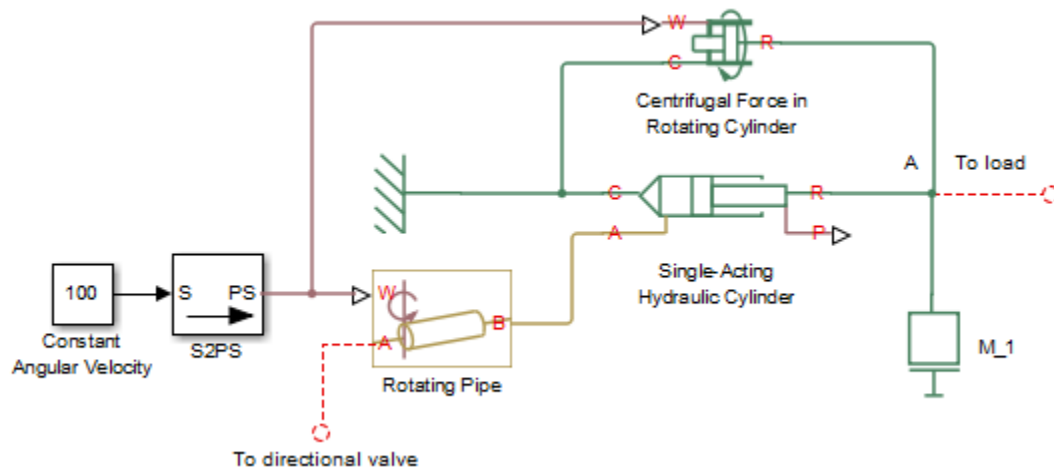

When your model is in Restricted editing mode, you cannot modify the following parameter:

- **Cylinder orientation**

All other block parameters are available for modification.

## Examples

The following schematic diagram shows a model of a custom single-acting hydraulic cylinder built of the Single-Acting Hydraulic Cylinder, Rotating Pipe, and Centrifugal Force in Rotating Cylinder blocks.

The centrifugal force generated by the Centrifugal Force in Rotating Cylinder block sums up with that of the cylinder at node A. The Rotating Pipe block simulates the pipeline between the cylinder chamber and the channel in the center of a rotating shaft where the cylinder is installed.

## Ports

The block has the following ports:

R

Mechanical translational conserving port associated with the cylinder rod.

C

Mechanical translational conserving port associated with the cylinder clamping structure.

W

Physical signal port providing the angular velocity value.

## Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Pumps and Motors

## Description

The Centrifugal Pump block represents a centrifugal pump of any type as a data-sheet-based model. Depending on data listed in the manufacturer's catalog or data sheet for your particular pump, you can choose one of the following model parameterization options:

- By approximating polynomial — Provide values for the polynomial coefficients. These values can be determined analytically or experimentally, depending on the data available. This is the default method.
- By two 1D characteristics: P-Q and N-Q — Provide tabulated data of pressure differential P and brake power N versus pump delivery Q characteristics. The pressure differential and brake power are determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.
- By two 2D characteristics: P-Q-W and N-Q-W — Provide tabulated data of pressure differential P and brake power N versus pump delivery Q characteristics at different angular velocities W. The pressure differential and brake power are determined by two-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.

These parameterization options are further described in greater detail:

Connections P and T are hydraulic conserving ports associated with the pump outlet and inlet, respectively. Connection S is a mechanical rotational conserving port associated with the pump driving shaft. The block positive direction is from port T to port P. This means that the pump transfers fluid from T to P as its driving shaft S rotates in the globally assigned positive direction.

### Parameterizing the Pump by Approximating Polynomial

If you set the **Model parameterization** parameter to By approximating polynomial, the pump is parameterized with the polynomial whose coefficients are determined, analytically or experimentally, for a specific angular velocity depending on the data available. The pump characteristics at other angular velocities are determined using the affinity laws.

The approximating polynomial is derived from the Euler pulse moment equation, Equations 1 and 2, which for a given pump, angular velocity, and fluid can be represented as the following:

$$p_{ref} = k \cdot p_E - p_{HL} - p_D \quad (1-1)$$

where

$p_{ref}$	Pressure differential across the pump for the reference regime, characterized by the reference angular velocity and density
$k$	Correction factor. The factor is introduced to account for dimensional fluctuations, blade incongruity, blade volumes, fluid internal friction, and so on. The factor should be set to 1 if the approximating coefficients are determined experimentally.
$p_E$	Euler pressure
$p_{HL}$	Pressure loss due to hydraulic losses in the pump passages
$p_D$	Pressure loss caused by deviations of the pump delivery from its nominal (rated) value

The Euler pressure,  $p_E$ , is determined with the Euler equation for centrifugal machines in Equations 1 and 2 based on known pump dimensions. For an existing pump, operating at constant angular velocity and specific fluid, the Euler pressure can be approximated with the equation

$$p_E = \rho_{ref}(c_0 - c_1 \cdot q_{ref})$$

where

$\rho_{ref}$	Fluid density
$c_0, c_1$	Approximating coefficients. They can be determined either analytically from the Euler equation (Equations 1 and 2) or experimentally.
$q_{ref}$	Pump volumetric delivery at reference regime

The pressure loss due to hydraulic losses in the pump passages,  $p_{HL}$ , is approximated with the equation

$$p_{HL} = \rho_{ref} \cdot c_2 \cdot q_{ref}^2$$

where

$\rho_{ref}$	Fluid density
$c_2$	Approximating coefficient
$q_{ref}$	Pump volumetric delivery at reference regime

The blade profile is determined for a specific fluid velocity, and deviation from this velocity results in pressure loss due to inconsistency between the fluid velocity and blade profile velocity. This pressure loss,  $p_D$ , is estimated with the equation

$$p_D = \rho_{ref} \cdot c_3 (q_D - q_{ref})^2$$

where

$\rho_{ref}$	Fluid density
--------------	---------------

$c_3$	Approximating coefficient
$q_{ref}$	Pump volumetric delivery at reference regime
$q_D$	Pump design delivery (nominal delivery)

The resulting approximating polynomial takes the form:

$$p_{ref} = \rho_{ref} \left( k(c_0 - c_1 q_{ref}) - c_2 q_{ref}^2 - c_3 (q_D - q_{ref})^2 \right) \quad (1-2)$$

The pump characteristics, approximated with four coefficients  $c_0$ ,  $c_1$ ,  $c_2$ , and  $c_3$ , are determined for a specific fluid and a specific angular velocity of the pump's driving shaft. These two parameters correspond, respectively, to the **Reference density** and **Reference angular velocity** parameters in the block dialog box. To apply the characteristics for another velocity  $\omega$  or density  $\rho$ , the affinity laws are used. With these laws, the delivery at reference regime, which corresponds to given pump delivery and angular velocity, is computed with the expression

$$q_{ref} = q \frac{\omega_{ref}}{\omega} \quad (1-3)$$

where  $q$  and  $\omega$  are the instantaneous values of the pump delivery and angular velocity. Then the pressure differential  $p_{ref}$  at reference regime computed with Equation 2 and converted into pressure differential  $p$  at current angular velocity and density

$$p = p_{ref} \cdot \left( \frac{\omega}{\omega_{ref}} \right)^2 \cdot \frac{\rho}{\rho_{ref}}$$

Equation 2 describes pump characteristic for  $\omega > 0$  and  $q \geq 0$ . Outside this range, the characteristic is approximated with the following relationships:

$$p = \begin{cases} -k_{leak} \cdot q & \text{for } \omega < 0 \\ p_{max} - k_{leak} \cdot q & \text{for } \omega > 0, q < 0 \\ -k_{leak} \cdot (q - q_{max}) & \text{for } \omega > 0, q > q_{max} \end{cases} \quad (1-4)$$

$$q_{max} = \frac{-b + \sqrt{b^2 + 4ac}}{2a}$$

$$a = (c_2 + c_3) \cdot \alpha^2$$

$$b = (k \cdot c_1 - 2c_3 \cdot q_D) \cdot \alpha$$

$$c = k \cdot c_0 - c_3 \cdot q_D^2$$

$$\alpha = \frac{\omega}{\omega_{ref}}$$

$$q_{max} = \rho \frac{1}{\alpha^2} (k \cdot c_0 - c_3 \cdot q_D^2)$$

where

$k_{leak}$	Leakage resistance coefficient
------------	--------------------------------

$q_{\max}$	Maximum pump delivery at given angular velocity. The delivery is determined from Equation 2 at $p = 0$ .
$p_{\max}$	Maximum pump pressure at given angular velocity. The pressure is determined from Equation 2 at $q = 0$ .
$k$	Correction factor, as described in Equation 1.

The hydraulic power at the pump outlet at reference conditions is

$$N_{hyd} = p_{ref} \cdot q_{ref}$$

The output hydraulic power at arbitrary angular velocity and density is determined with the affinity laws

$$N = N_{ref} \left( \frac{\omega}{\omega_{ref}} \right) \cdot \frac{\rho}{\rho_{ref}}$$

The power at the pump driving shaft consists of the theoretical hydraulic power (power before losses associated with hydraulic loss and deviation from the design delivery) and friction loss at the driving shaft. The theoretical hydraulic power is approximated using the Euler pressure

$$N_{hyd0} = p_{Eref} \cdot q_{ref} \cdot \left( \frac{\omega}{\omega_{ref}} \right)^3$$

where

$N_{hyd0}$	Pump theoretical hydraulic power
$p_{Eref}$	Euler pressure. The theoretical pressure developed by the pump before losses associated with hydraulic loss and deviation from the design delivery.

The friction losses are approximated with the relationship:

$$N_{fr} = (T_0 + k_p \cdot p) \cdot \omega$$

where

$N_{fr}$	Friction loss power
$T_0$	Constant torque at driving shaft associated with shaft bearings, seal friction, and so on
$k_p$	Torque-pressure relationship, which characterizes the influence of pressure on the driving shaft torque

The power and torque at the pump driving shaft (brake power  $N_{mech}$  and brake torque  $T$ ) are

$$N_{mech} = N_{hyd0} + N_{fr}$$

$$T = \frac{N_{mech}}{\omega}$$

The pump total efficiency  $\eta$  is computed as

$$\eta = \frac{N_{hyd}}{N_{mech}}$$

### Parameterizing the Pump by Pressure Differential and Brake Power Versus Pump Delivery

If you set the **Model parameterization** parameter to By two 1D characteristics: P-Q and N-Q, the pump characteristics are computed by using two one-dimensional table lookups: for the pressure differential based on the pump delivery and for the pump brake power based on the pump delivery. Both characteristics are specified at the same angular velocity  $\omega_{ref}$  (**Reference angular velocity**) and the same fluid density  $\rho_{ref}$  (**Reference density**).

To compute pressure differential at another angular velocity, affinity laws are used, similar to the first parameterization option. First, the new reference delivery  $q_{ref}$  is computed with the expression

$$q_{ref} = q \frac{\omega_{ref}}{\omega}$$

where  $q$  is the current pump delivery. Then the pressure differential across the pump at current angular velocity  $\omega$  and density  $\rho$  is computed as

$$p = p_{ref} \cdot \left( \frac{\omega}{\omega_{ref}} \right)^2 \cdot \frac{\rho}{\rho_{ref}}$$

where  $p_{ref}$  is the pressure differential determined from the P-Q characteristic at pump delivery  $q_{ref}$ .

Brake power is determined with the equation

$$N = N_{ref} \cdot \left( \frac{\omega}{\omega_{ref}} \right)^3 \cdot \frac{\rho}{\rho_{ref}}$$

where  $N_{ref}$  is the reference brake power obtained from the N-Q characteristic at pump delivery  $q_{ref}$ .

The torque at the pump driving shaft is computed with the equation  $T = N / \omega$ .

### Parameterizing the Pump by Pressure Differential and Brake Power Versus Pump Delivery at Different Angular Velocities

If you set the **Model parameterization** parameter to By two 2D characteristics: P-Q-W and N-Q-W, the pump characteristics are read out from two two-dimensional table lookups: for the pressure differential based on the pump delivery and angular velocity and for the pump brake power based on the pump delivery and angular velocity.

Both the pressure differential and brake power are scaled if fluid density  $\rho$  is different from the reference density  $\rho_{ref}$ , at which characteristics have been obtained

$$p = p_{ref} \cdot \frac{\rho}{\rho_{ref}}$$

$$N = N_{ref} \cdot \frac{\rho}{\rho_{ref}}$$

where  $p_{ref}$  and  $N_{ref}$  are the pressure differential and brake power obtained from the plots.

### Basic Assumptions and Limitations

- Fluid compressibility is neglected.
- The pump rotates in positive direction, with speed that is greater or equal to zero.

- The reverse flow through the pump is allowed only at still shaft.

## Ports

### Conserving

**T** — Suction port  
isothermal liquid

Hydraulic conserving port associated with the pump suction, or inlet.

**P** — Outlet port  
isothermal liquid

Hydraulic conserving port associated with the pump outlet.

**S** — Shaft port  
isothermal liquid

Mechanical rotational conserving port associated with the pump driving shaft.

## Parameters

**Model parameterization** — Model configurations by pressure differential, brake power, and pump capacity

By approximating polynomial (default) | By two 1D characteristics: P-Q and N-Q | By two 2D characteristics: P-Q-W and N-Q-W

Select one of the following methods for specifying the pump parameters:

- **By approximating polynomial** — Provide values for the polynomial coefficients. These values can be determined analytically or experimentally, depending on the data available. The relationship between pump characteristics and angular velocity is determined from the affinity laws.
- **By two 1D characteristics: P-Q and N-Q** — Provide tabulated data of pressure differential and brake power versus pump delivery characteristics. The pressure differential and brake power are determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods. The relationship between pump characteristics and angular velocity is determined from the affinity laws.
- **By two 2D characteristics: P-Q-W and N-Q-W** — Provide tabulated data of pressure differential and brake power versus pump delivery characteristics at different angular velocities. The pressure differential and brake power are determined by two-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.

**First approximating coefficient** — Coefficient  $c_0$  of the Euler pulse moment equation for pressure  $326.8 \text{ Pa}/(\text{kg}/\text{m}^3)$  (default)

Approximating coefficient  $c_0$  in the block description preceding. This parameter is used if **Model parameterization** is set to **By approximating polynomial**.

**Second approximating coefficient** — Coefficient  $c_1$  of the Euler pulse moment equation for pressure  $3.104\text{e}4 \text{ Pa}\cdot\text{s}/\text{kg}$  (default)

Approximating coefficient  $c_1$  in the block description preceding. This parameter is used if **Model parameterization** is set to By approximating polynomial.

**Third approximating coefficient** — Coefficient  $c_2$  of the hydraulic losses calculation  
 $1.097e7 \text{ Pa}\cdot\text{s}^2/(\text{kg}\cdot\text{m}^3)$  (default)

Approximating coefficient  $c_2$  in the block description preceding. This coefficient accounts for hydraulic losses in the pump. This parameter is used if **Model parameterization** is set to By approximating polynomial.

**Fourth approximating coefficient** — Coefficient  $c_3$  that accounts for the difference in losses between nominal flow and flow through pump geometry  
 $2.136e5 \text{ Pa}\cdot\text{s}^2/(\text{kg}\cdot\text{m}^3)$  (default)

Approximating coefficient  $c_3$  in the block description preceding. This coefficient accounts for additional hydraulic losses caused by deviation from the nominal delivery. This parameter is used if **Model parameterization** is set to By approximating polynomial.

**Correction factor** — Correction of Euler pressure calculation for reference pressure calculation  
 $0.8$  (default)

The factor, denoted as  $k$  in the block description preceding, accounts for dimensional fluctuations, blade incongruity, blade volumes, fluid internal friction, and other factors that decrease Euler theoretical pressure. This parameter is used if **Model parameterization** is set to By approximating polynomial.

**Pump design delivery** — Nominal pump capacity  
 $130 \text{ lpm}$  (default)

The pump nominal delivery. The blades profile, pump inlet, and pump outlet are shaped for this particular delivery. Deviation from this delivery causes an increase in hydraulic losses. This parameter is used if **Model parameterization** is set to By approximating polynomial.

**Reference angular velocity** — Shaft speed  
 $1770 \text{ rpm}$  (default)

Angular velocity of the driving shaft, at which the pump characteristics are determined. This parameter is used if **Model parameterization** is set to By approximating polynomial or By two 1D characteristics: P-Q and N-Q.

**Reference density** — Reference density  
 $920 \text{ kg/m}^3$  (default)

Fluid density at which the pump characteristics are determined.

**Leak resistance** — Coefficient for pressure outside of pump normal operating range  
 $1e8 \text{ Pa}/(\text{m}^3/\text{s})$  (default)

Leakage resistance coefficient (see Equation 4). This parameter is used if **Model parameterization** is set to By approximating polynomial.

**Drive shaft torque** — Shaft friction torque  
 $0.1 \text{ N}\cdot\text{m}$  (default)

The friction torque on the shaft at zero velocity. This parameter is used if **Model parameterization** is set to By approximating polynomial.

**Torque-pressure coefficient** — Relationship between pump pressure and shaft torque  
 $0.1e-5 \text{ N}\cdot\text{m}/\text{Pa}$  (default)

The coefficient that provides relationship between torque and pump pressure. The default value is  $1e-6 \text{ N}\cdot\text{m}/\text{Pa}$ . This parameter is used if **Model parameterization** is set to By approximating polynomial.

**Pump delivery vector for Pressure differential** — Capacity vector for tabular parameterization of pump pressure  
 $[0, 28, 90, 130, 154, 182] \text{ lpm}$  (default)

Specify the vector of pump deliveries, as a one-dimensional array, to be used together with the vector of pressure differentials to specify the P-Q pump characteristic. The vector values must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. This parameter is used if **Model parameterization** is set to By two 1D characteristics: P-Q and N-Q.

**Pressure differential across pump vector** — Pressure vector for tabular parameterization of pump pressure  
 $[2.6, 2.4, 2, 1.6, 1.2, .8] \text{ bar}$  (default)

Specify the vector of pressure differentials across the pump as a one-dimensional array. The vector will be used together with the pump delivery vector to specify the P-Q pump characteristic. The vector must be of the same size as the pump delivery vector for the P-Q table. This parameter is used if **Model parameterization** is set to By two 1D characteristics: P-Q and N-Q.

**Pump delivery vector for Brake power** — Capacity vector for tabular parameterization of brake power  
 $[0, 20, 40, 60, 80, 100, 120, 140, 160] \text{ lpm}$  (default)

Specify the vector of pump deliveries, as a one-dimensional array, to be used together with the vector of the pump brake power to specify the N-Q pump characteristic. The vector values must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. This parameter is used if **Model parameterization** is set to By two 1D characteristics: P-Q and N-Q.

**Brake power vector** — Brake power vector for tabular parameterization of brake power  
 $[220, 280, 310, 360, 390, 420, 480, 500, 550] \text{ W}$  (default)

Specify the vector of pump brake power as a one-dimensional array. The vector will be used together with the pump delivery vector to specify the N-Q pump characteristic. The vector must be of the same size as the pump delivery vector for the N-Q table. This parameter is used if **Model parameterization** is set to By two 1D characteristics: P-Q and N-Q.

**Angular velocity vector,  $w$**  — Shaft speed vector for tabular parameterization of pump pressure  
 $[3200, 3300, 3400, 3500] \text{ rpm}$  (default)

Specify the vector of angular velocities, as a one-dimensional array, to be used for calculating both the pump P-Q-W and N-Q-W characteristics. The vector values must be strictly increasing. The values

can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. This parameter is used if **Model parameterization** is set to By two 2D characteristics: P-Q-W and N-Q-W.

**Pump delivery vector for Pressure differential,  $Q_p$**  — Capacity vector for tabular parameterization of pump pressure  
[0, 50, 100, 150, 200, 250, 300, 350] lpm (default)

Specify the vector of pump deliveries, as a one-dimensional array, to be used together with the vector of angular velocities and the pressure differential matrix to specify the pump P-Q-W characteristic. The vector values must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. This parameter is used if **Model parameterization** is set to By two 2D characteristics: P-Q-W and N-Q-W.

**Pressure differential table,  $p(Q_p, w)$**  — Pressure matrix for tabular parameterization of pump pressure  
[8.3, 8.8, 9.3, 9.9; 7.8, 8.3, 8.8, 9.4; 7.2, 7.6, 8.2, 8.7; 6.5, 7, 7.5, 8; 5.6, 6.1, 6.6, 7.1; 4.7, 5.2, 5.7, 6.2; 3.4, 4, 4.4, 4.9; 2.3, 2.7, 3.4, 3.6] bar (default)

Specify the pressure differentials across pump as an m-by-n matrix, where m is the number of the P-Q-W pump delivery values and n is the number of angular velocities. This matrix will define the pump P-Q-W characteristic together with the pump delivery and angular velocity vectors. Each value in the matrix specifies pressure differential for a specific combination of pump delivery and angular velocity. The matrix size must match the dimensions defined by the pump delivery and angular velocity vectors. This parameter is used if **Model parameterization** is set to By two 2D characteristics: P-Q-W and N-Q-W.

**Pump delivery vector for Brake power,  $Q_b$**  — Capacity vector for tabular parameterization of brake power  
[0, 50, 100, 150, 200, 250, 300, 350] lpm (default)

Specify the vector of pump deliveries, as a one-dimensional array, to be used together with the vector of angular velocities and the brake power matrix to specify the pump N-Q-W characteristic. The vector values must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. This parameter is used if **Model parameterization** is set to By two 2D characteristics: P-Q-W and N-Q-W.

**Brake power table,  $W_b(Q_b, w)$**  — Brake power matrix for tabular parameterization of brake power  
[1223, 1341, 1467, 1600; 1414, 1551, 1696, 1850; 1636, 1794, 1962, 2140; 1941, 2129, 2326, 2540; 2224, 2439, 2660, 2910; 2453, 2691, 2947, 3210; 2757, 3024, 3307, 3608; 2945, 3230, 3533, 3854] W (default)

Specify the pump brake power as an m-by-n matrix, where m is the number of the N-Q-W pump delivery values and n is the number of angular velocities. This matrix will define the pump N-Q-W characteristic together with the pump delivery and angular velocity vectors. Each value in the matrix specifies brake power for a specific combination of pump delivery and angular velocity. The matrix size must match the dimensions defined by the pump delivery and angular velocity vectors. This parameter is used if **Model parameterization** is set to By two 2D characteristics: P-Q-W and N-Q-W.

**Angular speed threshold for flow reversal** — Shaft speed threshold region for flow reversal  
1e-9 (default)

Shaft angular velocity that indicates the transition threshold between forward and reverse flow. A transition region is defined around 0 rad/s between the positive and negative values of the angular velocity threshold. Within this transition region, the computed leakage flow rate and friction torque are adjusted according to the transition term  $\alpha$  to ensure smooth transition from one mode to the other.

**Interpolation method** — Tabular interpolation  
Linear (default) | Smooth

Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- **Linear** — Select this option to get the best performance.
- **Smooth** — Select this option to produce a continuous curve or surface with continuous first-order derivatives.

This parameter is used if **Model parameterization** is set to By two 1D characteristics: P-Q and N-Q or By two 2D characteristics: P-Q-W and N-Q-W. For more information on interpolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

**Extrapolation method** — Tabular extrapolation  
Linear (default) | Nearest

Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- **Linear** — Select this option to produce a curve or surface with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.
- **Nearest** — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

This parameter is used if **Model parameterization** is set to By two 1D characteristics: P-Q and N-Q or By two 2D characteristics: P-Q-W and N-Q-W. For more information on extrapolation algorithms, see the PS Lookup Table (1D) and PS Lookup Table (2D) block reference pages.

## Version History

**Introduced in R2007a**

**R2023a: To be removed**

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

# Centrifugal Pump (IL)

Centrifugal pump in isothermal liquid network

## Libraries:

Simscape / Fluids / Isothermal Liquid / Pumps & Motors

## Description

The Centrifugal Pump (IL) block represents a centrifugal pump that transfers energy from the shaft to a fluid in an isothermal liquid network. The pressure differential and mechanical torque are functions of the pump head and brake power, which depend on pump capacity. You can parameterize the pump analytically or by linear interpolation of tabulated data. The pump affinity laws define the core physics of the block, which scale the pump performance to the ratio of the current to the reference values of the pump angular velocity and impeller diameter.

By default, the flow and pressure gain are from port **A** to port **B**. Port **C** represents the pump casing, and port **R** represents the pump shaft. You can specify the normal operating shaft direction in the **Mechanical orientation** parameter. If the shaft begins to spin in the opposite direction, the pressure difference across the block drops to zero.

The figure shows the location of the block ports on a typical centrifugal pump.

## Port Configuration

### Analytical Parameterization: Capacity, Head, and Brake Power

When you set, **Pump parameterization** to Capacity, head, and brake power at reference shaft speed, the block calculates the pressure gain over the pump as a function of the pump affinity laws and the reference pressure differential:

$$p_B - p_A = \Delta H_{ref} \rho g \left( \frac{\omega}{\omega_{ref}} \right)^2 \left( \frac{D}{D_{ref}} \right)^2,$$

where:

- $g$  is the gravitational acceleration.
- $\Delta H$  is the reference pump head, which the block derives from a quadratic fit of the pump pressure differential between the values of the **Maximum head at zero capacity**, **Nominal head**, and **Maximum capacity at zero head** parameters.
- $\omega$  is the shaft angular velocity,  $\omega_R - \omega_C$ .
- $\omega_{ref}$  is the value of the **Reference shaft speed** parameter.
- $\frac{D}{D_{ref}}$  is the value of the **Impeller diameter scale factor** parameter. This block does not reflect changes in pump efficiency due to pump size.
- $\rho$  is the network fluid density.

The shaft torque is:

$$\tau = W_{brake,ref} \frac{\omega^2}{\omega_{ref}^3} \left( \frac{D}{D_{ref}} \right)^5.$$

The reference brake power,  $W_{brake,ref}$ , is calculated as capacity·head/efficiency. The pump efficiency curve is quadratic with its peak corresponding to the **Nominal brake power** parameter, and it falls to zero when capacity is zero or maximum as the pump curve figure demonstrates.

The block calculates the reference capacity as:

$$q_{ref} = \frac{\dot{m}}{\rho} \frac{\omega_{ref}}{\omega} \left( \frac{D_{ref}}{D} \right)^3.$$

You can choose to be warned when the block flow rate becomes negative or exceeds the maximum pump capacity by setting **Check if operating beyond normal pump operation** to 0n.

### 1-D Tabulated Data Parameterization: Head and Brake Power as a Function of Capacity

When you set **Pump parameterization** to 1D tabulated data - head and brake power vs. capacity at reference shaft speed, the pressure gain over the pump functions with the **Reference head vector** parameter,  $\Delta H_{ref}$ , which is a function of the reference capacity,  $q_{ref}$ :

$$\Delta p = \rho g \Delta H_{ref}(q_{ref}) \left( \frac{\omega}{\omega_{ref}} \right)^2 \left( \frac{D}{D_{ref}} \right)^2,$$

where  $g$  is the gravitational acceleration.

The block bases the shaft torque on the **Reference brake power vector** parameter,  $W_{ref}$ , which is a function of the reference capacity:

$$\tau = W_{ref}(q_{ref}) \frac{\omega^2}{\omega_{ref}^3} \left( \frac{\rho}{\rho_{ref}} \right) \left( \frac{D}{D_{ref}} \right)^5,$$

where  $\rho_{ref}$  is the **Reference density** parameter. The reference capacity is:

$$q_{ref} = \frac{\dot{m}}{\rho} \left( \frac{\omega_{ref}}{\omega} \right) \left( \frac{D_{ref}}{D} \right)^3,$$

which the block uses to interpolate the values of the **Reference capacity vector**, **Reference head vector**, and **Reference brake power vector** parameters as a function of  $q_{ref}$ .

When the simulation is outside the range of the provided tables, the block extrapolates head based on the average slope of the pump curves and brake power to the nearest point.

## 2-D Tabulated Data Parameterization: Head and Brake Power as a Function of Capacity and Shaft Speed

When you set **Pump parameterization** to 2D tabulated data - head and brake power vs. capacity and shaft speed, the pressure gain over the pump is a function of the **Head table**, **H(q,w)** parameter,  $\Delta H_{ref}$ , which is a function of the reference capacity,  $q_{ref}$ , and the shaft speed,  $\omega$ :

$$\Delta p = \rho g \Delta H_{ref}(q_{ref}, \omega) \left( \frac{D}{D_{ref}} \right)^2.$$

The shaft torque is a function of the **Brake power table**, **Wb(q,w)** parameter,  $W_{ref}$ , which is a function of the reference capacity,  $q_{ref}$ , and the shaft speed,  $\omega$ :

$$\tau = \frac{W_{ref}(q_{ref}, \omega)}{\omega} \left( \frac{\rho}{\rho_{ref}} \right) \left( \frac{D}{D_{ref}} \right)^5.$$

The reference capacity is:

$$q_{ref} = \frac{\dot{m}}{\rho} \left( \frac{D_{ref}}{D} \right)^3.$$

When the simulation is outside the range of the provided tables, the block extrapolates head based on the average slope of the pump curves and brake power to the nearest point.

### Missing Data

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the pump curves. Do not use artificial numerical values because these values distort pump behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Head table**, **H(q,w)** and **Brake power table**, **Wb(q,w)** parameters must match each other.
- NaN elements must be located in the lower-left portion of the table, which corresponds to the highest capacity and lowest shaft speed.

## Visualizing the Pump Curve

You can check the parameterized pump performance by plotting the head, power, efficiency, and torque as a function of the flow. To generate a plot of the current pump settings, right-click on the block and select **Fluids > Plot Pump Characteristics**. If you change settings or data, click **Apply** on the block parameters and click **Reload Data** on the pump curve figure.

The default block parameterization results in these plots:

## Predefined Parameterization

You can populate the block with pre-parameterized manufacturing data, which allows you to model a specific supplier component.

To load a predefined parameterization:

- 1 In the block dialog box, next to **Selected part**, click the "<click to select>" hyperlink next to **Selected part** in the block dialogue box settings.
- 2 The Block Parameterization Manager window opens. Select a part from the menu and click **Apply all**. You can narrow the choices using the **Manufacturer** drop down menu.
- 3 You can close the **Block Parameterization Manager** menu. The block now has the parameterization that you specified.

- 4 You can compare current parameter settings with a specific supplier component in the Block Parameterization Manager window by selecting a part and viewing the data in the **Compare selected part with block** section.

---

**Note** Predefined block parameterizations use available data sources to supply parameter values. The block substitutes engineering judgement and simplifying assumptions for missing data. As a result, expect some deviation between simulated and actual physical behavior. To ensure accuracy, validate the simulated behavior against experimental data and refine your component models as necessary.

---

To learn more, see “List of Pre-Parameterized Components”.

### Assumptions and Limitations

- If the shaft rotates opposite to the specified mechanical orientation, pressure difference across the block drops to zero and the results may not be accurate.
- The block does not account for dynamic pressure in the pump. The block only considers pump head due to static pressure.
- Pre-defined parameterizations use available data and the block fills in missing data where necessary. Validate your model against expected results.

## Ports

### Conserving

**A** — Pump inlet  
isothermal liquid

Isothermal liquid conserving port associated with the fluid inlet.

**B** — Pump outlet  
isothermal liquid

Thermal liquid conserving port associated with the fluid outlet.

**R** — Impeller shaft  
mechanical rotational

Mechanical rotational conserving port associated with the shaft.

**C** — Pump casing  
mechanical rotational

Mechanical rotational conserving port associated with the case.

## Parameters

**Pump parameterization** — Head and brake power parameterization

Capacity, head, and brake power at reference shaft speed (default) | 1D tabulated data - head and brake power vs. capacity at reference shaft speed | 2D tabulated data - head and brake power vs. capacity and shaft speed

Parameterization of the pump head and brake power, specified as:

- Capacity, head, and brake power at reference shaft speed: Parameterize pump pressure gain and shaft torque with an analytical formula.
- 1D tabulated data - head and brake power vs. capacity at reference shaft speed: Parameterize head and brake power from tabulated data of the head and brake power at a given capacity.
- 2D tabulated data - head and brake power vs. capacity and shaft speed: Parameterize head and brake power from tabulated data of the head and brake power at a given capacity and shaft speed.

**Nominal capacity** — Pump volumetric flow rate

45 lpm (default) | positive scalar

Nominal pump volumetric flow rate at a reference shaft angular velocity.

**Dependencies**

To enable this parameter, set **Pump parameterization** to Capacity, head, and brake power at reference shaft speed.

**Nominal head** — Pump head

40 m (default) | positive scalar

Nominal pump pressure differential, normalized by gravity and the fluid density, at a reference shaft angular velocity.

**Dependencies**

To enable this parameter, set **Pump parameterization** to Capacity, head, and brake power at reference shaft speed.

**Nominal brake power** — Pump power

0.85 kW (default) | positive scalar

Nominal mechanical shaft power at a reference angular velocity.

**Dependencies**

To enable this parameter, set **Pump parameterization** to Capacity, head, and brake power at reference shaft speed.

**Maximum head at zero capacity** — Maximum pump head with no flow

60 m (default) | positive scalar

Maximum pump head with no flow at a reference angular velocity. This parameter determines the reference pressure differential over the pump, which the block uses to fit a quadratic equation for pressure in addition to the **Nominal capacity**, **Nominal head**, and **Maximum capacity at zero head** parameters.

**Dependencies**

To enable this parameter, set **Pump parameterization** to Capacity, head, and brake power at reference shaft speed.

**Maximum capacity at zero head** — Maximum flow rate with zero head

80 lpm (default) | positive scalar

Maximum fluid load with zero head at a reference angular velocity. This parameter determines the reference pressure differential over the pump, which the block uses to fit a quadratic equation for pressure in addition to the **Nominal capacity**, **Nominal head**, and **Maximum head at zero capacity** parameters.

#### Dependencies

To enable this parameter, set **Pump parameterization** to Capacity, head, and brake power at reference shaft speed.

**Reference shaft speed** — Reference shaft angular velocity for affinity law calculations  
1770 rpm | 3500 rpm | positive scalar

Reference angular velocity for affinity law calculations. The default value depends on the **Pump parameterization** setting.

#### Dependencies

To enable this parameter, set **Pump parameterization** to either:

- Capacity, head, and brake power at reference shaft speed.
- 1D tabulated data - head and brake power vs. capacity at reference shaft speed.

**Minimum shaft speed threshold as fraction of reference** — Threshold for minimum shaft speed  
1e-2 (default) | positive scalar

Threshold for the minimum shaft speed as a fraction of the reference shaft speed. The block uses this value to prevent the shaft speed from becoming zero and causing a division by zero error in the expression for  $q_{ref}$ .

#### Dependencies

To enable this parameter, set **Pump parameterization** to Capacity, head, and break power at reference shaft speed or 1D tabulated data – head and break power vs. capacity at reference shaft speed.

**Reference capacity vector** — Volumetric flow rate  
[16.67, 30, 40, 53.33, 66.67, 83.33] lpm (default) | vector

Vector of volumetric flow rates for the tabular parameterization of the pump head or brake power. The elements in this vector correspond one-to-one with the elements in the **Reference head vector** and **Reference brake power vector** parameters. In normal operating conditions the elements in this parameter are nonnegative, but the block does accept negative values. Negative capacity is a non-normal operating condition that may arise from certain situations.

#### Dependencies

To enable this parameter, set **Pump parameterization** to 1D tabulated data - head and brake power vs. capacity at reference shaft speed.

**Reference head vector** — Pump head vector  
[50, 47.5, 45, 40, 35, 25] m (default) | vector

Vector of the pump head values for the 1-D tabular parameterization of the pump head and brake power. This parameter corresponds one-to-one with the **Reference capacity vector** parameter. In

normal operating conditions the elements in this parameter are nonnegative, but the block does accept negative values. Negative head, or pressure drop, is possible in non-normal operating conditions at the end of the vector.

#### Dependencies

To enable this parameter, set **Pump parameterization** to 1D tabulated data - head and brake power vs. capacity at reference shaft speed.

**Reference brake power vector** — Pump brake power vector

[.6, .75, .85, .93, .98, .99] kW (default) | vector

Vector of pump brake power values for the 1-D tabular parameterization of the pump head and brake power. This parameter corresponds one-to-one with the **Reference capacity vector** parameter. In normal operating conditions, the elements in this parameter are nonnegative, but the block does accept negative values. Negative brake power is possible in non-normal operating conditions at the end of the vector.

#### Dependencies

To enable this parameter, set **Pump parameterization** to 1D tabulated data - head and brake power vs. capacity at reference shaft speed.

**Capacity vector,  $q$**  — Volumetric displacement vector

[16.67, 23.33, 30, 40, 53.33, 60] lpm (default) | vector

Vector of volumetric flow rates for the tabular parameterization of the pump head. This vector forms an independent axis with the **Shaft speed vector,  $w$**  parameter for the 2-D **Head table,  $H(q,w)$**  and **Brake power table,  $W_b(q,w)$**  parameters. The vector elements must be listed in ascending order. In normal operating conditions, the elements in this parameter are nonnegative, but the block does accept negative values. Negative capacity is a non-normal operating condition that may arise from certain situations.

#### Dependencies

To enable this parameter, set **Pump parameterization** to 2D tabulated data - head and brake power vs. capacity and shaft speed.

**Shaft speed vector,  $w$**  — Angular velocity vector

[2450, 2800, 3150, 3500] rpm (default) | vector

Vector of shaft angular velocity values for the tabular parameterization of the pump head. This vector forms an independent axis with the **Capacity vector,  $q$**  parameter for the 2-D **Head table,  $H(q,w)$**  and **Brake power table,  $W_b(q,w)$**  parameters. The vector elements must be listed in ascending order and must be greater than 0.

#### Dependencies

To enable this parameter, set **Pump parameterization** to 2D tabulated data - head and brake power vs. capacity and shaft speed.

**Head table,  $H(q,w)$**  — Pump head matrix

[25, 32.7, 42.5, 50; 24, 31.7, 41, 49; 22.7, 30.5, 39, 47.5; 20, 28, 36, 45; 15.7, 24, 32, 40; 12.5, 21, 29.5, 37.5] m (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of pump head values at the specified volumetric flow rate and angular velocity. In normal operating conditions, the elements in this parameter are nonnegative, but the block does

accept negative values. Negative head, or pressure drop, is possible in non-normal operating conditions at the bottom of the table. The block employs linear interpolation between the table elements.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of elements in the **Capacity vector,  $q$**  parameter.
- $N$  is the number of elements in the **Shaft speed vector,  $w$**  parameter. All rows must be in strictly ascending order.

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the pump curves. Do not use artificial numerical values because these values distort pump behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Head table,  $H(q,w)$**  and **Brake power table,  $Wb(q,w)$**  parameters must match each other.
- NaN elements must be located in the lower-left portion of the table, which corresponds to the highest capacity and lowest shaft speed.

#### Dependencies

To enable this parameter, set **Pump parameterization** to 2D tabulated data - head and brake power vs. capacity and shaft speed.

**Brake power table,  $Wb(q,w)$**  — Pump brake power matrix

[.28, .38, .5, .6; .31, .41, .55, .68; .33, .44, .6, .75; .36, .48, .65, .83; .38, .53, .72, .93; .39, .55, .75, .97] kW (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of pump brake power values at the specified volumetric flow rate and angular velocity. In normal operating conditions these values are nonnegative, but the block does accept negative values. The block employs linear interpolation between the table elements.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of vector elements in the **Capacity vector,  $q$**  parameter.
- $N$  is the number of vector elements in the **Shaft speed vector,  $w$**  parameter. All rows must be in strictly ascending order.

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the pump curves. Do not use artificial numerical values because these values distort pump behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Head table,  $H(q,w)$**  and **Brake power table,  $Wb(q,w)$**  parameters must match each other.
- NaN elements must be located in the lower-left portion of the table, which corresponds to the highest capacity and lowest shaft speed.

#### Dependencies

To enable this parameter, set **Pump parameterization** to 2D tabulated data - head and brake power vs. capacity and shaft speed.

**Reference density** — Fluid density for given pump performance data  
998 kg/m<sup>3</sup> (default) | positive scalar

Reference fluid density. The reference or data sheet typically specifies this value. This parameter scales the pump performance between different fluids.

#### **Dependencies**

To enable this parameter, set **Pump parameterization** to 1D tabulated data - head and brake power vs. capacity at reference shaft speed or 2D tabulated data - head and brake power vs. capacity and shaft speed.

**Impeller diameter scale factor** — Ratio of model diameter to reference diameter for affinity law calculations

1 (default) | positive scalar

Ratio of the model-to-reference diameter for affinity law calculations. Modify this value if there is a difference between your reference and the system impeller diameters, such as when testing pump scaling. For system pumps smaller than the reference pump, use a value less than one. For system pumps larger than the reference pump, use a value greater than one. The block does not reflect changes in pump efficiency due to pump size.

**Mechanical orientation** — Shaft normal rotational direction

Positive angular velocity of port R relative to port C corresponds to normal pump operation (default) | Negative angular velocity of port R relative to port C corresponds to normal pump operation

Shaft rotational direction for flow from port **A** to **B**.

**Check if operating beyond normal pump operation** — Option to notify when block is beyond operating bounds

Warning (default) | None | Error

Option to notify if the block operates outside of the normal pump boundary. This situation occurs when the flow rate through the pump is negative or beyond the maximum capacity of the pump.

#### **Dependencies**

To enable this parameter, set **Pump parameterization** to Capacity, head, and brake power at reference shaft speed.

## **Version History**

**Introduced in R2020a**

### **R2023a: Expose threshold for low shaft speed**

Use the **Minimum shaft speed threshold as fraction of reference** parameter to control the minimum shaft speed threshold as a fraction of the reference shaft speed. The **Minimum shaft speed threshold as fraction of reference** parameter is available in the block when the **Pump parameterization** parameter is Capacity, head, and brake power at reference shaft speed or 1D tabulated data – head and brake power vs. capacity at reference shaft speed.

## R2022b: Extend performance beyond normal operating conditions

Both the 1-D and 2-D parameterizations now allow negative values. When simulation is outside the range of the provided table, the block extrapolates the pump head based on the average slope of the pump curves.

You can now use NaN elements where pump data is unavailable. These 2-D tabulated parameters support contiguous NaN elements in the lower-left portion of the table:

- **Head table  $H(q,w)$**
- **Brake power table,  $W_b(q,w)$**

For each block, if the shaft rotates opposite to the specified mechanical orientation, the pressure difference across the block drops to zero and the results may not be accurate.

## Centrifugal Pump (TL)

Centrifugal pump in a thermal liquid network

### Libraries:

Simscape / Fluids / Thermal Liquid / Pumps & Motors

### Description

The Centrifugal Pump (TL) block represents a centrifugal pump that transfers energy from the shaft to a fluid in a thermal liquid network. The pressure differential and mechanical torque are functions of the pump head and brake power, which depend on pump capacity. You can parameterize the pump analytically or by linear interpolation of tabulated data. The pump affinity laws define the core physics of the block, which scales the pump performance by the ratio of the current to the reference values of the pump angular velocity and impeller diameter.

By default, the flow and pressure gain are from port **A** to port **B**. Port **C** represents the pump casing, and port **R** represents the pump shaft. You can specify the normal operating shaft direction in the **Mechanical orientation** parameter. If the shaft begins to spin in the opposite direction, the pressure difference across the pump drops to zero.

### Analytical Parameterization: Capacity, Head, and Brake Power

The block calculates the pressure gain over the pump as a function of the pump affinity laws and the reference pressure differential

$$p_B - p_A = \Delta H_{ref} \rho g \left( \frac{\omega}{\omega_{ref}} \right)^2 \left( \frac{D}{D_{ref}} \right)^2,$$

where:

- $\Delta p_{ref}$  is the reference pressure gain, which the block determines from a quadratic fit of the pump pressure differential between the **Maximum head at zero capacity**, **Nominal head**, and **Maximum capacity at zero head** parameters.
- $\omega$  is the shaft angular velocity, where  $\omega = \omega_R - \omega_C$ .
- $\omega_{ref}$  is the value of the **Reference shaft speed** parameter.
- $\frac{D}{D_{ref}}$  is the value of the **Impeller diameter scale factor** parameter. This block does not reflect changes in pump efficiency due to pump size.
- $\rho$  is the network fluid density.

The shaft torque is

$$\tau = W_{brake,ref} \frac{\omega^2}{\omega_{ref}^3} \left( \frac{D}{D_{ref}} \right)^5.$$

The block calculates the reference brake power,  $W_{brake,ref}$ , as capacity·head/efficiency. The pump efficiency curve is quadratic with its peak corresponding to the **Nominal brake power** parameter, and it falls to zero when capacity is zero or maximum as the pump curve demonstrates.

The block calculates the reference capacity as

$$q_{ref} = \frac{\dot{m}}{\rho} \frac{\omega_{ref}}{\omega} \left( \frac{D_{ref}}{D} \right)^3.$$

### 1-D Tabulated Data Parameterization: Head and Brake Power as a Function of Capacity

When you set **Pump parameterization** to 1D tabulated data - head and brake power vs. capacity at reference shaft speed, the pressure gain over the pump is a function of the **Reference head vector** parameter,  $\Delta H_{ref}$ , which is a function of the reference capacity,  $q_{ref}$

$$\Delta p = \rho g \Delta H_{ref}(q_{ref}) \left( \frac{\omega}{\omega_{ref}} \right)^2 \left( \frac{D}{D_{ref}} \right)^2,$$

where  $g$  is the gravitational acceleration.

The block bases the shaft torque on the **Reference brake power vector** parameter,  $W_{ref}$ , which is a function of the reference capacity

$$\tau = W_{ref}(q_{ref}) \frac{\omega^2}{\omega_{ref}^3} \left( \frac{\rho}{\rho_{ref}} \right) \left( \frac{D}{D_{ref}} \right)^5,$$

where  $\rho_{ref}$  is the value of the **Reference density** parameter. The reference capacity is

$$q_{ref} = \frac{\dot{m}}{\rho} \left( \frac{\omega_{ref}}{\omega} \right) \left( \frac{D_{ref}}{D} \right)^3,$$

which the block uses to interpolate the values of the **Reference capacity vector**, **Reference head vector**, and **Reference brake power vector** parameters as a function of  $q_{ref}$ .

When the simulation is outside the range of the provided tables, the block extrapolates head based on the average slope of the pump curves and brake power to the nearest point.

## 2-D Tabulated Data Parameterization: Head and Brake Power as a Function of Capacity and Shaft Speed

When you set **Pump parameterization** to 2D tabulated data - head and brake power vs. capacity and shaft speed, the pressure gain over the pump is a function of the **Head table, H(q,w)** parameter,  $\Delta H_{ref}$ , which is a function of the reference capacity,  $q_{ref}$ , and the shaft speed,  $\omega$

$$\Delta p = \rho g \Delta H_{ref}(q_{ref}, \omega) \left( \frac{D}{D_{ref}} \right)^2.$$

The shaft torque is a function of the **Brake power table, Wb(q,w)** parameter,  $W_{ref}$ , which is a function of the reference capacity,  $q_{ref}$ , and the shaft speed,  $\omega$

$$\tau = \frac{W_{ref}(q_{ref}, \omega)}{\omega} \left( \frac{\rho}{\rho_{ref}} \right) \left( \frac{D}{D_{ref}} \right)^5.$$

The reference capacity is

$$q_{ref} = \frac{\dot{m}}{\rho} \left( \frac{D_{ref}}{D} \right)^3.$$

When the simulation is outside the range of the provided tables, the block extrapolates head based on the average slope of the pump curves and brake power to the nearest point.

### Missing Data

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the pump curves. Do not use artificial numerical values because these values distort pump behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Head table, H(q,w)** and **Brake power table, Wb(q,w)** parameters must match each other.
- NaN elements must be located in the lower-left portion of the table, which corresponds to the highest capacity and lowest shaft speed.

### Visualizing the Pump Curve

You can check the parameterized pump performance by plotting the head, power, efficiency, and torque as a function of the flow. To generate a plot of the current pump settings, right-click on the block and select **Fluids > Plot Pump Characteristics**. If you change settings or data, click **Apply** on the block parameters and click **Reload Data** on the pump curve figure.

The default block parameterization results in these plots:

### Energy Balance

Mechanical work is a result of the energy exchange from the shaft to the fluid. The governing energy balance equation is

$$\phi_A + \phi_B + P_{hydro} = 0,$$

where:

- $\phi_A$  is the energy flow rate at port **A**.
- $\phi_B$  is the energy flow rate at port **B**.

The pump hydraulic power is a function of the pressure difference between pump ports

$$P_{hydro} = \Delta p \frac{\dot{m}}{\rho}.$$

### Assumptions and Limitations

- If the shaft rotates opposite to the specified mechanical orientation, the pressure difference across the block drops to zero and the results may not be accurate.
- The block does not account for dynamic pressure in the pump. The block only considers pump head due to static pressure.

## Ports

### Conserving

**A** — Pump inlet  
thermal liquid

Thermal liquid conserving port associated with the fluid.

**B** — Pump outlet  
thermal liquid

Thermal liquid conserving port associated with the fluid.

**R** — Impeller shaft  
mechanical rotational

Mechanical rotational conserving port associated with the shaft.

**C** — Pump casing  
mechanical rotational

Mechanical rotational conserving port associated with the case.

## Parameters

**Pump parameterization** — Head and brake power parameterization

Capacity, head, and brake power at reference shaft speed (default) | 1D tabulated data - head and brake power vs. capacity at reference shaft speed | 2D tabulated data - head and brake power vs. capacity and shaft speed

Parameterization of the pump head and brake power, specified as:

- Capacity, head, and brake power at reference shaft speed — Parameterize pump pressure gain and shaft torque with an analytical formula.
- 1D tabulated data - head and brake power vs. capacity at reference shaft speed — Parameterize head and brake power from tabulated data of the head and brake power at a given capacity.
- 2D tabulated data - head and brake power vs. capacity and shaft speed — Parameterize head and brake power from tabulated data of the head and brake power at a given capacity and shaft speed.

**Nominal capacity** — Pump volumetric flow rate  
45 lpm (default) | positive scalar

Nominal pump volumetric flow rate at a reference shaft angular velocity.

### Dependencies

To enable this parameter, set **Pump parameterization** to Capacity, head, and brake power at reference shaft speed.

**Nominal head** — Pump head  
40 m (default) | positive scalar

Nominal pump pressure differential, normalized by gravity and the fluid density, at a reference shaft angular velocity.

#### Dependencies

To enable this parameter, set **Pump parameterization** to Capacity, head, and brake power at reference shaft speed.

**Nominal brake power** — Pump power  
0.85 kW (default) | positive scalar

Nominal mechanical shaft power at a reference angular velocity.

#### Dependencies

To enable this parameter, set **Pump parameterization** to Capacity, head, and brake power at reference shaft speed.

**Maximum head at zero capacity** — Maximum pump head with no flow  
60 m (default) | positive scalar

Maximum pump head with no flow at a reference angular velocity. This parameter determines the reference pressure differential over the pump, which the block uses to fit a quadratic equation for pressure in addition to the **Nominal capacity**, **Nominal head**, and **Maximum capacity at zero head** parameters.

#### Dependencies

To enable this parameter, set **Pump parameterization** to Capacity, head, and brake power at reference shaft speed.

**Maximum capacity at zero head** — Maximum flow rate with zero head  
80 lpm (default) | positive scalar

Maximum fluid load with zero head at a reference angular velocity. This parameter determines the reference pressure differential over the pump, which the block uses to fit a quadratic equation for pressure in addition to the **Nominal capacity**, **Nominal head**, and **Maximum head at zero capacity** parameters.

#### Dependencies

To enable this parameter, set **Pump parameterization** to Capacity, head, and brake power at reference shaft speed.

**Reference shaft speed** — Reference shaft angular velocity for affinity law calculations  
1770 rpm | 3500 rpm | positive scalar

Reference angular velocity for affinity law calculations. The default value depends on the **Pump parameterization** setting.

#### Dependencies

To enable this parameter, set **Pump parameterization** to Capacity, head, and break power at reference shaft speed or 1D tabulated data – head and break power vs. capacity at reference shaft speed.

**Minimum shaft speed threshold as fraction of reference** — Threshold for minimum shaft speed  
1e-2 (default) | positive scalar

Threshold for the minimum shaft speed as a fraction of the reference shaft speed. The block uses this value to prevent the shaft speed from becoming zero and causing a division by zero error in the expression for  $q_{ref}$ .

#### Dependencies

To enable this parameter, set **Pump parameterization** to Capacity, head, and brake power at reference shaft speed or 1D tabulated data – head and brake power vs. capacity at reference shaft speed.

**Reference capacity vector** — Volumetric flow rate

[16.67, 30, 40, 53.33, 66.67, 83.33] lpm (default) | vector

Vector of volumetric flow rates for the tabular parameterization of the pump head or brake power. The elements in this vector correspond one-to-one with the elements in the **Reference head vector** and **Reference brake power vector** parameters. In normal operating conditions, the elements in this parameter are nonnegative, but the block does accept negative values. Negative capacity is a non-normal operating condition that may arise from certain situations.

#### Dependencies

To enable this parameter, set **Pump parameterization** to 1D tabulated data - head and brake power vs. capacity at reference shaft speed.

**Reference head vector** — Pump head vector

[50, 47.5, 45, 40, 35, 25] m (default) | vector

Vector of pump head values for the 1-D tabular parameterization of the pump head and brake power. This parameter corresponds one-to-one with the **Reference capacity vector** parameter. In normal operating conditions, the elements in this parameter are nonnegative, but the block does accept negative values. Negative head, or pressure drop, is possible in non-normal operating conditions at the end of the vector.

#### Dependencies

To enable this parameter, set **Pump parameterization** to 1D tabulated data - head and brake power vs. capacity at reference shaft speed.

**Reference brake power vector** — Pump brake power vector

[.6, .75, .85, .93, .98, .99] kW (default) | vector

Vector of pump brake power values for the 1-D tabular parameterization of the pump head and brake power. This parameter corresponds one-to-one with the **Reference capacity vector** parameter. In normal operating conditions, the elements in this parameter are nonnegative, but the block does accept negative values. Negative brake power is possible in non-normal operating conditions at the end of the vector.

#### Dependencies

To enable this parameter, set **Pump parameterization** to 1D tabulated data - head and brake power vs. capacity at reference shaft speed.

**Capacity vector, q** — Volumetric displacement vector

[16.67, 23.33, 30, 40, 53.33, 60] lpm (default) | vector

Vector of volumetric flow rates for the tabular parameterization of the pump head. This vector forms an independent axis with the **Shaft speed vector, w** parameter for the 2-D **Head table, H (q,w)** and

**Brake power table,  $W_b(\mathbf{q}, \mathbf{w})$**  parameters. The vector elements must be listed in ascending order. In normal operating conditions, the elements in this parameter are nonnegative, but the block does accept negative values. Negative capacity is a non-normal operating condition that may arise from certain situations.

#### Dependencies

To enable this parameter, set **Pump parameterization** to 2D tabulated data - head and brake power vs. capacity and shaft speed.

**Shaft speed vector,  $\mathbf{w}$**  — Angular velocity vector

[2450, 2800, 3150, 3500] rpm (default) | vector

Vector of shaft angular velocity values for the tabular parameterization of the pump head. This vector forms an independent axis with the **Capacity vector,  $\mathbf{q}$**  parameter for the 2-D **Head table,  $\mathbf{H}(\mathbf{q}, \mathbf{w})$**  and **Brake power table,  $W_b(\mathbf{q}, \mathbf{w})$**  parameters. The vector elements must be listed in ascending order and must be greater than 0.

#### Dependencies

To enable this parameter, set **Pump parameterization** to 2D tabulated data - head and brake power vs. capacity and shaft speed.

**Head table,  $\mathbf{H}(\mathbf{q}, \mathbf{w})$**  — Pump head matrix

[25, 32.7, 42.5, 50; 24, 31.7, 41, 49; 22.7, 30.5, 39, 47.5; 20, 28, 36, 45; 15.7, 24, 32, 40; 12.5, 21, 29.5, 37.5] m (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of pump head values at the specified volumetric flow rate and angular velocity. In normal operating conditions, the elements in this parameter are nonnegative, but the block does accept negative values. Negative head, or pressure drop, is possible in non-normal operating conditions at the bottom of the table. The block employs linear interpolation between table elements.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of elements in the **Capacity vector,  $\mathbf{q}$**  parameter.
- $N$  is the number of elements in the **Shaft speed vector,  $\mathbf{w}$**  parameter. All rows must be in strictly ascending order.

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the pump curves. Do not use artificial numerical values because these values distort pump behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Head table,  $\mathbf{H}(\mathbf{q}, \mathbf{w})$**  and **Brake power table,  $W_b(\mathbf{q}, \mathbf{w})$**  parameters must match each other.
- NaN elements must be located in the lower-left portion of the table, which corresponds to the highest capacity and lowest shaft speed.

#### Dependencies

To enable this parameter, set **Pump parameterization** to 2D tabulated data - head and brake power vs. capacity and shaft speed.

**Brake power table,  $W_b(q,w)$**  — Pump brake power matrix

[.28, .38, .5, .6; .31, .41, .55, .68; .33, .44, .6, .75; .36, .48, .65, .83; .38, .53, .72, .93; .39, .55, .75, .97] kW (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of pump brake power values at the specified volumetric flow rate and angular velocity. In normal operating conditions these values are nonnegative, but the block does accept negative values. Linear interpolation is employed between table elements.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of vector elements in the **Capacity vector,  $q$**  parameter.
- $N$  is the number of vector elements in the **Shaft speed vector,  $w$**  parameter. All rows must be in strictly ascending order.

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the pump curves. Do not use artificial numerical values because these values distort pump behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Head table,  $H(q,w)$**  and **Brake power table,  $W_b(q,w)$**  parameters must match each other.
- NaN elements must be located in the lower-left portion of the table, which corresponds to the highest capacity and lowest shaft speed.

**Dependencies**

To enable this parameter, set **Pump parameterization** to 2D tabulated data - head and brake power vs. capacity and shaft speed.

**Reference density** — Fluid density for given pump performance data

998 kg/m<sup>3</sup> (default) | positive scalar

Reference fluid density. The reference or data sheet typically specifies this value. This parameter scales the pump performance between different fluids.

**Dependencies**

To enable this parameter, set **Pump parameterization** to 1D tabulated data - head and brake power vs. capacity at reference shaft speed or 2D tabulated data - head and brake power vs. capacity and shaft speed.

**Impeller diameter scale factor** — Ratio of model diameter to reference diameter for affinity law calculations

1 (default) | positive scalar

Ratio of the model-to-reference diameter for affinity law calculations. Modify this value if there is a difference between your reference and the system impeller diameters, such as when testing pump scaling. For system pumps smaller than the reference pump, use a value less than one. For system pumps larger than the reference pump, use a value greater than one. The block does not reflect changes in pump efficiency due to pump size.

**Mechanical orientation** — Shaft normal rotational direction

Positive angular velocity of port R relative to port C corresponds to normal pump operation (default) | Negative angular velocity of port R relative to port C corresponds to normal pump operation

Shaft rotational direction for flow from port **A** to **B**.

**Cross-sectional area at ports A and B** — Flow area at pump inlet and outlet  
 $0.01 \text{ m}^2$  (default) | positive scalar

Flow area at the pump inlet and outlet. The block assumes that the areas are equal.

## Version History

Introduced in R2018a

### R2023a: Expose threshold for low shaft speed

Use the **Minimum shaft speed threshold as fraction of reference** parameter to control the minimum shaft speed threshold as a fraction of the reference shaft speed. The **Minimum shaft speed threshold as fraction of reference** parameter is available in the block when the **Pump parameterization** parameter is Capacity, head, and break power at reference shaft speed or 1D tabulated data – head and break power vs. capacity at reference shaft speed.

### R2022b: Extend performance beyond normal operating conditions

Both the 1-D and 2-D parameterizations now allow negative values. When simulation is outside the range of the provided table, the block extrapolates the pump head based on the average slope of the pump curves.

You can now use NaN elements where pump data is unavailable. These 2-D tabulated parameters support contiguous NaN elements in the lower-left portion of the table:

- **Head table  $H(q,w)$**
- **Brake power table,  $W_b(q,w)$**

For each block, if the shaft rotates opposite to the specified mechanical orientation, the pressure difference across the block drops to zero and the results may not be accurate.

# Check Valve

(To be removed) Hydraulic valve that allows flow in one direction only

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Valves / Directional Valves

## Description

The Check Valve block represents a hydraulic check valve as a data-sheet-based model. The check valve permits flow in one direction and blocks it in the opposite direction. This figure shows the typical dependency between the valve passage area  $A$  and the pressure differential across the valve  $\Delta p = p_A - p_B$ .

The valve remains closed when the pressure differential across the valve is lower than the valve cracking pressure. When cracking pressure is reached, the valve control member, such as a spool or poppet, is forced off its seat, thus creating a passage between the inlet and outlet. If the flow rate is high enough and pressure continues to rise, the area increases until the control member reaches its maximum displacement. At this moment, the valve passage area is at its maximum. The catalogs and manufacturer data sheets generally provide the valve maximum area and the cracking and maximum pressures.

The leakage area is also required to characterize the valve. The **Leakage area** parameter accounts for possible leakage and maintains the numerical integrity of the circuit, by preventing a portion of the system from getting isolated after the valve is completely closed. Because isolated parts of the system could affect computational efficiency or cause failure of computation, the parameter value must be greater than zero.

By default, the block does not include the valve opening dynamics, and the valve sets its opening area directly as a function of pressure:

$$A = A(p).$$

Adding valve opening dynamics provides continuous behavior that is more physically realistic, and is helpful in situations with rapid valve opening and closing. The pressure-dependent orifice passage area  $A(p)$  in the block equations then becomes the steady-state area, and the instantaneous orifice passage area in the flow equation is:

$$A(t = 0) = A_{init}$$

$$\frac{dA}{dt} = \frac{A(p) - A}{\tau}$$

For both settings of **Opening dynamics**, the flow rate through the valve is:

$$q = C_D \cdot A \sqrt{\frac{2}{\rho}} \cdot \frac{p}{(p^2 + p_{cr}^2)^{1/4}}$$

$$A(p) = \begin{cases} A_{leak} & \text{for } p \leq p_{crack} \\ A_{leak} + k \cdot (p - p_{crack}) & \text{for } p_{crack} < p < p_{max} \\ A_{max} & \text{for } p \geq p_{max} \end{cases}$$

$$k = \frac{A_{max} - A_{leak}}{p_{max} - p_{crack}}$$

$$\Delta p = p_A - p_B,$$

$$p_{cr} = \frac{\rho}{2} \left( \frac{Re_{cr} \cdot v}{C_D \cdot D_H} \right)^2$$

$$D_H = \sqrt{\frac{4A}{\pi}}$$

where:

$q$	Flow rate
$p$	Pressure differential
$p_A, p_B$	Gauge pressures at the block terminals
$C_D$	Flow discharge coefficient
$A$	Instantaneous orifice passage area
$A(p)$	Pressure-dependent orifice passage area
$A_{init}$	Initial open area of the valve

$A_{\max}$	Fully open valve passage area
$A_{\text{leak}}$	Closed valve leakage area
$p_{\text{crack}}$	Valve cracking pressure
$p_{\max}$	Pressure needed to fully open the valve
$p_{\text{cr}}$	Minimum pressure for turbulent flow
$Re_{\text{cr}}$	Critical Reynolds number
$D_{\text{H}}$	Instantaneous orifice hydraulic diameter
$\rho$	Fluid density
$\nu$	Fluid kinematic viscosity
$\tau$	Time constant for the first order response of the valve opening
$t$	Time

The block positive direction is from port **A** to port **B**. This means that the flow rate is positive if it flows from **A** to **B**, and the pressure differential is  $\Delta p = p_{\text{A}} - p_{\text{B}}$ .

### Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

### Assumptions and Limitations

- The valve opening is linearly proportional to the pressure differential.
- The block does not consider loading on the valve, such as inertia, friction, spring, and so on.

### Ports

#### Conserving

**A** — Valve inlet  
hydraulic

Hydraulic conserving port associated with the valve inlet.

**B** — Valve outlet  
hydraulic

Hydraulic conserving port associated with the valve outlet.

### Parameters

**Maximum passage area** — Valve passage maximum cross-sectional area  
1e-4 m<sup>2</sup> (default) | positive scalar

Maximum cross-sectional area of the valve passage.

**Cracking pressure** — Pressure level at which orifice of valve starts to open  
 $0.3e5$  Pa (default) | positive scalar

Pressure level at which the orifice of the valve starts to open.

**Maximum opening pressure** — Pressure differential across valve needed to fully open valve  
 $1.2e5$  Pa (default) | positive scalar

Pressure differential across the valve needed to fully open the valve. This value must be higher than the cracking pressure.

**Flow discharge coefficient** — Valve capacity characterization  
 $0.7$  (default) | positive scalar

Semi-empirical parameter for the valve capacity characterization. This value depends on the geometrical properties of the orifice. Manufacturer data sheets and textbooks typically provide this value.

**Leakage area** — Total area of possible leaks in the completely closed valve  
 $1e-12$  m<sup>2</sup> (default) | positive scalar

Total area of possible leaks in the completely closed valve. This parameter maintains the numerical integrity of the circuit by preventing a portion of the system from being isolated when the valve is completely closed.

**Laminar transition specification** — How block transitions between laminar and turbulent regimes  
 Pressure ratio (default) | Reynolds number

How the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime takes place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

**Laminar flow pressure ratio** — Pressure ratio at which flow transitions between laminar and turbulent regimes  
 $0.999$  (default) | scalar between 0 and 1

Pressure ratio at which the flow transitions between laminar and turbulent regimes.

#### Dependencies

To enable this parameter, set **Laminar transition specification** to **Pressure ratio**.

**Critical Reynolds number** — Maximum Reynolds number for laminar flow  
 $12$  (default) | positive scalar

Maximum Reynolds number for laminar flow. This value depends on the orifice geometrical profile. You can find recommendations for this value in hydraulics textbooks. The default value, 12, corresponds to a round orifice in thin material with sharp edges.

**Dependencies**

To enable this parameter, set **Laminar transition specification** to Reynolds number.

**Opening dynamics** — Whether to include valve opening dynamics

Do not include valve opening dynamics (default) | Include valve opening dynamics

Whether to include the valve opening dynamics. Select one of the following options:

- **Do not include valve opening dynamics** — The valve sets its orifice passage area directly as a function of pressure. If the area changes instantaneously, so does the flow equation.
- **Include valve opening dynamics** — This setting provides continuous behavior that is more physically realistic by adding a first-order lag when the valve opens and closes. Use this option in hydraulic simulations with the local solver for real-time simulation. This option is also helpful if you are interested in valve opening dynamics in variable step simulations.

**Opening time constant** — Time constant for first-order response of valve opening

0.1 s (default) | positive scalar

Time constant for the first-order response of the valve opening.

**Dependencies**

To enable this parameter, set **Opening dynamics** to Include valve opening dynamics.

**Initial area** — Initial opening area of valve

1e-12 m<sup>2</sup> (default) | positive scalar

Initial opening area of the valve. This value must be greater than the **Leakage area** parameter and less than the **Maximum passage area** parameter.

**Dependencies**

To enable this parameter, set **Opening dynamics** to Include valve opening dynamics.

## Version History

**Introduced in R2006a**

**R2023a: To be removed**

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Extended Capabilities

**C/C++ Code Generation**

Generate C and C++ code using Simulink® Coder™.

**See Also**

Pilot-Operated Check Valve

## Check Valve (IL)

Check valve in an isothermal liquid system

### Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Directional Control Valves

### Description

The Check Valve (IL) block represents a check valve with free flow from port **A** to port **B** and restricted flow from port **B** to port **A**. When the pressure at port **A** or the pressure differential meets or exceeds the set pressure threshold, the valve begins to open.

You can model valve opening either linearly or by tabulated data, and you can include faults by setting **Enable faults** to On.

### Opening Parameterization

When **Opening parameterization** is set to Linear - Area vs. pressure, the valve open area is linearly related to the opening pressure differential.

### Opening Pressure

There are two options for valve control:

- When **Opening pressure differential** is set to Pressure differential, the control pressure is the pressure differential between ports **A** and **B**. The valve begins to open when  $P_{\text{control}}$  meets or exceeds the **Cracking pressure differential**.
- When **Opening pressure differential** is set to Pressure at port A, the control pressure is the pressure difference between port **A** and atmospheric pressure. When  $P_{\text{control}}$  meets or exceeds the **Cracking pressure (gauge)**, the valve begins to open.

### Opening Area and Pressure

The linear parameterization of the valve area is

$$A_{\text{valve}} = \hat{p}(A_{\text{max}} - A_{\text{leak}}) + A_{\text{leak}},$$

where the normalized pressure,  $\hat{p}$ , is

$$\hat{p} = \frac{p_{\text{control}} - p_{\text{cracking}}}{p_{\text{max}} - p_{\text{cracking}}}.$$

When the valve is in a near-open or near-closed position in the linear parameterization, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the control pressure between  $p_{\text{cracking}}$  and  $p_{\text{max}}$ . For more information, see “Numerical Smoothing”.

When you set **Opening parameterization** to Tabulated data - Volumetric flow rate vs. pressure,  $A_{\text{valve}}$  is the linearly interpolated value of the **Opening area vector** parameter versus **Pressure differential vector** parameter curve for a simulated pressure differential.

### Mass Flow Rate Equation

Mass is conserved through the valve:

$$\dot{m}_A + \dot{m}_B = 0.$$

The mass flow rate through the valve is calculated as:

$$\dot{m} = \frac{C_d A_{\text{valve}} \sqrt{2\bar{\rho}}}{\sqrt{PR_{\text{loss}} \left(1 - \left(\frac{A_{\text{valve}}}{A_{\text{port}}}\right)^2\right)}} \frac{\Delta p}{[\Delta p^2 + \Delta p_{\text{crit}}^2]^{1/4}},$$

where:

- $C_d$  is the **Discharge coefficient**.
- $A_{\text{valve}}$  is the instantaneous valve open area.
- $A_{\text{port}}$  is the **Cross-sectional area at ports A and B**.
- $\bar{\rho}$  is the average fluid density.
- $\Delta p$  is the valve pressure difference  $p_A - p_B$ .

The critical pressure difference,  $\Delta p_{\text{crit}}$ , is the pressure differential associated with the **Critical Reynolds number**,  $Re_{\text{crit}}$ , the flow regime transition point between laminar and turbulent flow:

$$\Delta p_{\text{crit}} = \frac{\pi \bar{\rho}}{8 A_{\text{valve}}} \left( \frac{\nu Re_{\text{crit}}}{C_d} \right)^2.$$

*Pressure loss* describes the reduction of pressure in the valve due to a decrease in area.  $PR_{\text{loss}}$  is calculated as:

$$PR_{\text{loss}} = \frac{\sqrt{1 - \left(\frac{A_{\text{valve}}}{A_{\text{port}}}\right)^2 (1 - C_d^2)} - C_d \frac{A_{\text{valve}}}{A_{\text{port}}}}{\sqrt{1 - \left(\frac{A_{\text{valve}}}{A_{\text{port}}}\right)^2 (1 - C_d^2)} + C_d \frac{A_{\text{valve}}}{A_{\text{port}}}}.$$

*Pressure recovery* describes the positive pressure change in the valve due to an increase in area. If you do not wish to capture this increase in pressure, clear the **Pressure recovery** check box. In this case,  $PR_{\text{loss}}$  is 1.

### Tabulated Volumetric Flow Rate Parameterization

When **Opening parameterization** is set to Tabulated data - Volumetric flow rate vs. pressure, the valve opens according to the user-provided tabulated data of volumetric flow rate and pressure differential between ports **A** and **B**.

Within the limits of the tabulated data, the mass flow rate is calculated as:

$$\dot{m} = \bar{\rho} \dot{V},$$

where:

- $\dot{V}$  is the volumetric flow rate.
- $\bar{\rho}$  is the average fluid density.

When the simulation pressure falls below the first element of the **Pressure drop vector**,  $\Delta p_{TLU}(1)$ , the mass flow rate is calculated as:

$$\dot{m} = K_{Leak} \bar{\rho} \sqrt{\Delta p}.$$

$$K_{Leak} = \frac{V_{TLU}(1)}{\sqrt{|\Delta p_{TLU}(1)|}},$$

where  $V_{TLU}(1)$  is the first element of the **Volumetric flow rate vector**.

When the simulation pressure rises above the last element of the **Pressure drop vector**,  $\Delta p_{TLU}(end)$ , the mass flow rate is calculated as:

$$\dot{m} = K_{Max} \bar{\rho} \sqrt{\Delta p}$$

$$K_{Max} = \frac{V_{TLU}(end)}{\sqrt{|\Delta p_{TLU}(end)|}}$$

where  $V_{TLU}(end)$  is the last element of the **Volumetric flow rate vector**.

### Opening Dynamics

The linear parameterization supports valve opening and closing dynamics. If opening dynamics are modeled, a lag is introduced to the flow response to the modeled control pressure.  $p_{control}$  becomes the dynamic control pressure,  $p_{dyn}$ ; otherwise,  $p_{control}$  is the steady-state pressure. The instantaneous change in dynamic control pressure is calculated based on the **Opening time constant**,  $\tau$ :

$$\dot{p}_{dyn} = \frac{p_{control} - p_{dyn}}{\tau}.$$

By default, the block clears the **Opening dynamics** check box.

### Faults

When faults are enabled, the valve open area becomes stuck at a specified value in response to one or both of these triggers:

- Simulation time — Faulting occurs at a specified time.
- Simulation behavior — Faulting occurs in response to an external trigger. This exposes port **T**.

Three fault options are available in the **Opening area when faulted** parameter:

- Closed
- Open
- Maintain at last value

Once triggered, the valve remains at the faulted area for the rest of the simulation. You can set the block to issue a fault report as a warning or error message in the Simulink Diagnostic Viewer with the **Reporting when fault occurs** parameter.

### Faulting in the Linear Parameterization

In the linear parameterization, the fault options are defined by the valve area:

- Closed — The valve area freezes at the **Leakage area**.
- Open — The valve area freezes at the **Maximum opening area**.
- Maintain at last value — The valve freezes at the open area when the trigger occurs.

#### Faulting in the Tabulated Data Parameterization

In the tabulated parameterization, the fault options are defined by the mass flow rate through the valve:

- Closed — The valve freezes at the mass flow rate associated with the first elements of the **Volumetric flow rate vector** and the **Pressure drop vector**:

$$\dot{m} = K_{Leak} \bar{\rho} \sqrt{\Delta p}$$

- Open — The valve freezes at the mass flow rate associated with the last elements of the **Volumetric flow rate vector** and the **Pressure drop vector**:

$$\dot{m} = K_{Max} \bar{\rho} \sqrt{\Delta p}$$

- Maintain at last value — The valve freezes at the mass flow rate and pressure differential when the trigger occurs:

$$\dot{m} = K_{Last} \bar{\rho} \sqrt{\Delta p},$$

where

$$K_{Last} = \frac{|\dot{m}|}{\bar{\rho} \sqrt{|\Delta p|}}$$

#### Predefined Parameterization

You can populate the block with pre-parameterized manufacturing data, which allows you to model a specific supplier component.

To load a predefined parameterization:

- 1 In the block dialog box, next to **Selected part**, click the "<click to select>" hyperlink next to **Selected part** in the block dialogue box settings.
- 2 The Block Parameterization Manager window opens. Select a part from the menu and click **Apply all**. You can narrow the choices using the **Manufacturer** drop down menu.
- 3 You can close the **Block Parameterization Manager** menu. The block now has the parameterization that you specified.
- 4 You can compare current parameter settings with a specific supplier component in the Block Parameterization Manager window by selecting a part and viewing the data in the **Compare selected part with block** section.

---

**Note** Predefined block parameterizations use available data sources to supply parameter values. The block substitutes engineering judgement and simplifying assumptions for missing data. As a result, expect some deviation between simulated and actual physical behavior. To ensure accuracy, validate the simulated behavior against experimental data and refine your component models as necessary.

---

To learn more, see "List of Pre-Parameterized Components".

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Entry point to the valve.

**B** — Liquid port  
isothermal liquid

Exit point to the valve.

### Input

**T** — External fault trigger  
physical signal

Physical signal port for an external fault trigger. Triggering occurs when the value is greater than 0.5. There is no unit associated with the trigger value.

### Dependencies

This port is visible when **Enable faults** is set to On and **Enable external fault trigger** is set to Fault when  $T \geq 0.5$ .

## Parameters

### Parameters

**Opening parameterization** — Method of calculating valve opening  
Linear - Area vs. pressure (default) | Tabulated data - Area vs. pressure |  
Tabulated data - Volumetric flow rate vs. pressure

Method of calculating valve opening.

- **Linear - Area vs. pressure:** The valve opening area corresponds linearly to the valve pressure.
- **Tabulated data - Area vs. pressure:** The valve mass flow rate is determined from a table of area values with respect to pressure differential.
- **Tabulated data - Volumetric flow rate vs. pressure:** The valve mass flow rate is determined from a table of volumetric flow rate values with respect to pressure differential.

**Opening pressure specification** — Pressure differential used for valve control  
Pressure differential (default) | Pressure at port A

Specifies the control pressure differential. The **Pressure differential** option refers to the pressure difference between ports **A** and **B**. The **Pressure at port A** option refers to the pressure difference between port **A** and atmospheric pressure.

### Dependencies

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure.

**Cracking pressure differential** — Threshold pressure

0.01 MPa (default) | positive scalar

Pressure beyond which the valve operation is triggered. This is the set pressure when the control pressure is the pressure differential between ports **A** and **B**.

**Dependencies**

To enable this parameter, set **Opening pressure specification** to Pressure differential and **Opening parameterization** to Linear - Area vs. pressure.

**Cracking pressure (gauge)** — Threshold pressure

0.1 MPa (default) | positive scalar

Gauge pressure beyond which valve operation is triggered when the control pressure is the pressure differential between port **A** and atmospheric pressure.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure and **Opening pressure specification** to Pressure at port A.

**Maximum opening pressure differential** — Valve differential pressure maximum

0.1 MPa (default) | positive scalar

Maximum valve differential pressure. This parameter provides an upper limit to the pressure so that system pressures remain realistic.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure and **Opening pressure specification** to Pressure differential.

**Maximum opening pressure (gauge)** — Valve pressure maximum

0.2 MPa (default) | positive scalar

Maximum valve gauge pressure. This parameter provides an upper limit to the pressure so that system pressures remain realistic.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure and **Opening pressure specification** to Pressure at port A.

**Maximum opening area** — Area of fully opened valve1e-4 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the valve in its fully open position.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure.

**Leakage area** — Valve gap area when in fully closed position1e-12 m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the valve is in its fully closed position. Any area smaller than this value is saturated to the specified leakage area. This contributes to numerical stability by maintaining continuity in the flow.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure.

**Pressure differential vector** — Differential pressure values for tabular parameterization  
[0.01 : 0.01 : 0.1] MPa (default) | 1-by-*n* vector

Vector of pressure differential values for the tabular parameterization of the valve opening area. The vector elements must correspond one-to-one with the elements in the **Opening area vector** parameter. The elements are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set:

- **Set pressure control** to Constant.
- **Opening parameterization** to Linear - Area vs. pressure or Tabulated data - Area vs. pressure.
- **Opening pressure specification** to Pressure differential.

**Opening area vector** — Valve opening areas for tabular parameterization  
[1e-10, 1e-05, 2e-05, 3e-05, 4e-05, 5e-05, 6e-05, 7.5e-05, 8.5e-05, .0001]  
m<sup>2</sup> (default) | 1-by-*n* vector

Vector of valve opening areas for the tabular parameterization of the valve opening area. The vector elements must correspond one-to-one with the elements in the **Pressure differential vector** parameter. The elements are listed in ascending order and must be greater than 0. Linear interpolation is employed between table data points.

**Dependencies**

To enable this parameter, set **Set pressure control** to Constant and **Opening parameterization** to Tabulated data - Area vs. pressure.

**Cross-sectional area at ports A and B** — Area at valve entry or exit  
inf m<sup>2</sup> (default) | positive scalar

Cross-sectional area at the entry and exit ports **A** and **B**. These areas are used in the pressure-flow rate equation that determines the mass flow rate through the valve.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure or Tabulated data - Area vs. pressure.

**Discharge coefficient** — Discharge coefficient  
0.64 (default) | positive scalar

Correction factor that accounts for discharge losses in theoretical flows.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure or Tabulated data - Area vs. pressure.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure or Tabulated data - Area vs. pressure.

**Smoothing factor** — Numerical smoothing factor  
0.01 (default) | positive scalar

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure.

**Pressure recovery** — Whether to account for pressure increase in area expansions  
off (default) | on

Whether to account for pressure increase when fluid flows from a region of smaller cross-sectional area to a region of larger cross-sectional area.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure.

**Opening dynamics** — Whether to account for flow response to valve opening  
off (default) | on

Whether to account for transient effects to the fluid system due to opening the valve. Selecting **Opening dynamics** approximates the opening conditions by introducing a first-order lag in the flow response. The **Opening time constant** also impacts the modeled opening dynamics.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure.

**Opening time constant** — Valve opening time constant  
0.1 s (default) | positive scalar

Constant that captures the time required for the fluid to reach steady-state when opening or closing the valve from one position to another. This parameter impacts the modeled opening dynamics.

**Dependencies**

To enable this parameter, set **Opening parameterization** to Linear - Area vs. pressure and select **Opening dynamics**.

**Volumetric flow rate vector** — Vector of volumetric flow rate for tabulated data parameterization  
[.000358, .045, .11, .191, .284, .39, .505, .63, .764, .905] .\* 1e-3 m<sup>3</sup>/s  
(default) | 1-by-*n* vector

Vector of volumetric flow rate values for the tabular parameterization of valve opening. This vector must have the same number of elements as the **Pressure drop vector** parameter. The vector elements must be listed in ascending order.

#### **Dependencies**

To enable this parameter, set **Opening parameterization** to Tabulated data - Volumetric flow rate vs. pressure.

#### **Faults**

**Enable faults** — Fault option  
Off (default) | On

Enable externally or temporally triggered faults. When faulting occurs, the valve area normally set by the opening parameterization will be set to the value specified in the **Opening area when faulted** parameter.

**Opening area when faulted** — Set faulted characteristics  
Closed (default) | Open | Maintain at last value

Sets the faulted valve area or mass flow rate. You can choose for the valve to seize at the fully closed or fully open position, or at the conditions when faulting is triggered. This parameter sets the area when **Opening parameterization** is set to Linear - Area vs. pressure and the mass flow rate when **Opening parameterization** is set to Tabulated data.

#### **Dependencies**

To enable this parameter, set **Enable faults** to On.

**Enable external fault trigger** — External trigger option  
Off (default) | Fault when T >= 0.5

Enables port **T**. A physical signal at port **T** that is greater than 0.5 triggers faulting.

#### **Dependencies**

To enable this parameter, set **Enable faults** to On.

**Enable temporal fault trigger** — Temporal trigger option  
Off (default) | On

Enables fault triggering at a specified time. When the **Simulation time for fault event** is reached, the valve area will be set to the value specified in the **Opening area when faulted** parameter.

#### **Dependencies**

To enable this parameter, set **Enable faults** to On.

**Simulation time for fault event** — Time at which faulting is triggered  
5 s (default) | positive scalar

When the **Simulation time for fault event** is reached, the valve area is set to the value specified in the **Opening area when faulted** parameter.

#### **Dependencies**

To enable this parameter, set **Enable faults** to On and **Enable temporal fault trigger** to On.

#### **Reporting when fault occurs** — Fault condition report

None (default) | Warning | Error

Reporting preference for the fault condition. When reporting is set to Warning or Error, a message is displayed in the Simulink Diagnostic Viewer. When Error is selected, the simulation will stop if faulting occurs.

#### **Dependencies**

To enable this parameter, set **Enable faults** to On.

## Check Valve (G)

Check valve in a gas network

### Libraries:

Simscape / Fluids / Gas / Valves & Orifices / Directional Control Valves

### Description

The Check Valve (G) block represents an orifice with a unidirectional opening mechanism that prevents unwanted backflow. The opening mechanism responds to pressure, and opens the orifice when the pressure gradient falls from the inlet at port **A** to the outlet at port **B**. Check valves protect components upstream against pressure surges, temperature spikes, and chemical contamination stemming from points downstream.

The valve begins opening at the cracking pressure and continues opening until the end of the pressure regulation range. The cracking pressure is the initial resistance, due to friction or spring forces, that the valve must overcome to crack open. Below this threshold, the valve is closed and only leakage flow can pass. Past the end of the pressure regulation range, the valve is fully open and the flow at the maximum value is determined by the instantaneous pressure conditions.

The flow can be laminar or turbulent, and it can reach up to sonic speeds. The maximum velocity happens at the throat of the valve where the flow is narrowest and fastest. The flow chokes and the velocity saturates when a drop in downstream pressure can no longer increase the velocity. Choking occurs when the back-pressure ratio reaches the critical value characteristic of the valve. The block does not capture supersonic flow.

### Control and Other Pressures

The pressure to which the valve responds is the control pressure. By default, the control pressure is the drop from inlet to outlet. This setting ensures that the valve closes if the direction of flow should reverse.

You can also specify the control pressure as the gauge pressure at the inlet. Use this setting if you know that the inlet will always be at a higher pressure than the outlet. For example, when the inlet connects to a pressure source, such as a pump.

You can select the control pressure by setting the **Opening pressure specification** parameter to Pressure difference of port A relative to port B or Gauge pressure at port A.

#### Pressure difference of port A relative to port B

When the **Opening pressure specification** parameter is Pressure difference of port A relative to port B:

- The control pressure is:

$$P_{Ctl} = P_A - P_B,$$

where  $P_A$  is the absolute pressure at port **A** and  $P_B$  is the absolute pressure at port **B**.

- The cracking pressure,  $P_{Crk}$ , is the value of the **Cracking pressure differential** parameter.
- The maximum pressure of the valve,  $P_{Max}$ , where the valve is fully open, is the value of the **Maximum opening pressure differential** parameter.

### Gauge pressure at port A

When the **Opening pressure specification** parameter is Gauge pressure at port A:

- The control pressure is

$$P_{Ctrl} = P_A - P_{Atm},$$

where  $P_{Atm}$  is the atmospheric pressure specified in the Gas Properties (G) block of the model.

- The cracking pressure,  $P_{Crk}$ , is the value of the **Cracking pressure (gauge)** parameter.
- The maximum pressure of the valve,  $P_{Max}$ , where the valve is fully open, is the value of the **Maximum opening pressure (gauge)** parameter.

### Fraction of Valve Opening

The degree to which the control pressure exceeds the cracking pressure determines how much the valve opens. The fraction of valve opening is

$$\hat{P} = \frac{P_{Ctrl} - P_{Crk}}{P_{Max} - P_{Crk}},$$

where:

- $P_{Ctrl}$  is the control pressure.
- $P_{Crk}$  is the cracking pressure.
- $P_{Max}$  is the maximum opening pressure.

The fraction is normalized so that it is 0 in the fully closed valve and 1 in the fully open valve. If the calculation returns a value outside of these bounds, the block saturates the value to the nearest of the two limits.

### Numerical Smoothing

When the **Smoothing factor** parameter is nonzero, the block applies numerical smoothing to the normalized control pressure,  $\hat{P}$ . Enabling smoothing helps maintain numerical robustness in your simulation.

For more information, see “Numerical Smoothing”.

### Valve Parameterizations

The block behavior depends on the **Valve parametrization** parameter:

- **Cv flow coefficient** — The flow coefficient  $C_v$  determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential.
- **Kv flow coefficient** — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential.

- **Sonic conductance** — The sonic conductance of the resistive element at steady state determines the block parameterization. The sonic conductance measures the ease with which a gas can flow when *choked*, which is a condition in which the flow velocity is at the local speed of sound. Choking occurs when the ratio between downstream and upstream pressures reaches a critical value known as the *critical pressure ratio*.
- **Orifice area** — The size of the flow restriction determines the block parametrization.

The block scales the specified flow capacity by the fraction of valve opening. As the fraction of valve opening rises from 0 to 1, the measure of flow capacity scales from its specified minimum to its specified maximum.

### Momentum Balance

The block equations depend on the **Orifice parametrization** parameter. When you set **Orifice parametrization** to Cv flow coefficient parameterization, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C_v N_6 Y \sqrt{(p_{in} - p_{out}) \rho_{in}},$$

where:

- $C_v$  is the flow coefficient.
- $N_6$  is a constant equal to 27.3 for mass flow rate in kg/hr, pressure in bar, and density in kg/m<sup>3</sup>.
- $Y$  is the expansion factor.
- $p_{in}$  is the inlet pressure.
- $p_{out}$  is the outlet pressure.
- $\rho_{in}$  is the inlet density.

The expansion factor is

$$Y = 1 - \frac{p_{in} - p_{out}}{3 p_{in} F_\gamma x_T},$$

where:

- $F_\gamma$  is the ratio of the isentropic exponent to 1.4.
- $x_T$  is the value of the **xT pressure differential ratio factor at choked flow** parameter.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter,  $B_{lam}$ ,

$$\dot{m} = C_v N_6 Y_{lam} \sqrt{\frac{\rho_{avg}}{\rho_{avg}(1 - B_{lam})}} (p_{in} - p_{out}),$$

where:

$$Y_{lam} = 1 - \frac{1 - B_{lam}}{3 F_\gamma x_T}.$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below  $1 - F_\gamma x_T$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = \frac{2}{3} C_v N_6 \sqrt{F_y x_T p_{in} \rho_{in}}.$$

When you set **Orifice parametrization** to Kv flow coefficient parameterization, the block uses these same equations, but replaces  $C_v$  with  $K_v$  by using the relation  $K_v = 0.865 C_v$ . For more information on the mass flow equations when the **Orifice parametrization** parameter is Kv flow coefficient parameterization or Cv flow coefficient parameterization, see [2][3].

When you set **Orifice parametrization** to Sonic conductance parameterization, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C \rho_{ref} p_{in} \sqrt{\frac{T_{ref}}{T_{in}}} \left[ 1 - \left( \frac{p_{out} - B_{crit}}{p_{in} - B_{crit}} \right)^2 \right]^m,$$

where:

- $C$  is the sonic conductance.
- $B_{crit}$  is the critical pressure ratio.
- $m$  is the value of the **Subsonic index** parameter.
- $T_{ref}$  is the value of the **ISO reference temperature** parameter.
- $\rho_{ref}$  is the value of the **ISO reference density** parameter.
- $T_{in}$  is the inlet temperature.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter  $B_{lam}$ ,

$$\dot{m} = C \rho_{ref} \sqrt{\frac{T_{ref}}{T_{avg}}} \left[ 1 - \left( \frac{B_{lam} - B_{crit}}{1 - B_{crit}} \right)^2 \right]^m \left( \frac{p_{in} - p_{out}}{1 - B_{lam}} \right).$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below the critical pressure ratio,  $B_{crit}$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = C \rho_{ref} p_{in} \sqrt{\frac{T_{ref}}{T_{in}}}.$$

For more information on the mass flow equations when the **Orifice parametrization** parameter is Sonic conductance parameterization, see [1].

When you set **Orifice parametrization** to Orifice area parameterization, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C_d S_r \sqrt{\frac{2\gamma}{\gamma-1} p_{in} \rho_{in} \left( \frac{p_{out}}{p_{in}} \right)^{\frac{2}{\gamma}} \frac{1 - \left( \frac{p_{out}}{p_{in}} \right)^{\frac{\gamma-1}{\gamma}}}{1 - \left( \frac{S_R}{S} \right)^2 \left( \frac{p_{out}}{p_{in}} \right)^{\frac{2}{\gamma}}}},$$

where:

- $S_r$  is the orifice or valve area.
- $S$  is the value of the **Cross-sectional area at ports A and B** parameter.
- $C_d$  is the value of the **Discharge coefficient** parameter.
- $\gamma$  is the isentropic exponent.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter,  $B_{lam}$ ,

$$\dot{m} = C_d S_r \sqrt{\frac{2\gamma}{\gamma-1} p_{avg}^{\frac{2-\gamma}{\gamma}} \rho_{avg} B_{lam}^{\frac{2}{\gamma}} \left[ \frac{1 - B_{lam}^{\frac{\gamma-1}{\gamma}}}{1 - \left(\frac{S_R}{S}\right)^2 B_{lam}^{\frac{2}{\gamma}}} \right] \left( \frac{p_{in}^{\frac{\gamma-1}{\gamma}} - p_{out}^{\frac{\gamma-1}{\gamma}}}{1 - B_{lam}^{\frac{\gamma-1}{\gamma}}} \right)}.$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below  $\left(\frac{2}{\gamma+1}\right)^{\frac{\gamma}{\gamma-1}}$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = C_d S_r \sqrt{\frac{2\gamma}{\gamma+1} p_{in} \rho_{in} \frac{1}{\left(\frac{\gamma+1}{2}\right)^{\frac{2}{\gamma-1}} - \left(\frac{S_R}{S}\right)^2}}.$$

For more information on the mass flow equations when the **Orifice parametrization** parameter is Orifice area parameterization, see [4].

### Mass Balance

The block assumes the volume and mass of fluid inside the valve is very small and ignores these values. As a result, no amount of fluid can accumulate in the valve. By the principle of conservation of mass, the mass flow rate into the valve through one port equals that out of the valve through the other port

$$\dot{m}_A + \dot{m}_B = 0,$$

where  $\dot{m}$  is defined as the mass flow rate into the valve through the port indicated by the **A** or **B** subscript.

### Energy Balance

The resistive element of the block is an adiabatic component. No heat exchange can occur between the fluid and the wall that surrounds it. No work is done on or by the fluid as it traverses from inlet to outlet. Energy can flow only by advection, through ports **A** and **B**. By the principle of conservation of energy, the sum of the port energy flows is always equal to zero

$$\phi_A + \phi_B = 0,$$

where  $\phi$  is the energy flow rate into the valve through ports **A** or **B**.

### Assumptions and Limitations

- The Sonic conductance setting of the **Valve parameterization** parameter is for pneumatic applications. If you use this setting for gases other than air, you may need to scale the sonic conductance by the square root of the specific gravity.

- The equation for the `Orifice area` parameterization is less accurate for gases that are far from ideal.
- This block does not model supersonic flow.

## Ports

### Conserving

**A** — Valve entrance  
gas

Gas conserving port associated with the opening through which the flow must enter the valve.

**B** — Valve entrance  
gas

Gas conserving port associated with the opening through which the flow must exit the valve.

## Parameters

**Opening pressure specification** — Choice of pressure measurement to use as valve control signal  
Pressure difference of port A relative to port B (default) | Gauge pressure at port A

Choice of pressure measurement to use as valve control signal. The block uses this setting to determine when the valve should begin to open. In the default setting, `Pressure difference of port A relative to port B`, the opening pressure of the valve is expressed as a pressure drop from inlet to outlet. In the alternative setting, `Gauge pressure at port A`, it is expressed as a gauge pressure.

**Cracking pressure differential** — Pressure drop required to open valve  
0.01 MPa (default) | positive scalar

Minimum pressure drop, from inlet to outlet, required to open the valve. This value marks the beginning of the pressure differential range of the valve, over which it progressively opens to allow for increased flow.

### Dependencies

To enable this parameter, set **Opening pressure specification** to `Pressure difference of port A relative to port B`.

**Maximum opening pressure differential** — Pressure drop at which valve is fully open  
0.02 MPa (default) | positive scalar

Pressure drop, from inlet to outlet, at which the valve is fully open. This value marks the end of the pressure differential range of the valve, over which the same progressively opens to allow for increased flow.

### Dependencies

To enable this parameter, set **Opening pressure specification** to `Pressure difference of port A relative to port B`.

**Cracking pressure (gauge)** — Minimum pressure at inlet required to open valve  
 0.01 MPa (default) | positive scalar

Minimum gauge pressure at the inlet (port **A**) required to open the valve. This value marks the beginning of the pressure range of the valve, over which the same progressively opens to allow for increased flow.

#### Dependencies

To enable this parameter, set **Opening pressure specification** to Gauge pressure at port **A**.

**Maximum opening pressure (gauge)** — Maximum pressure at inlet  
 0.02 MPa (default) | positive scalar

Maximum pressure at inlet port **A**, at which the valve is fully open. This value marks the end of the pressure differential range of the valve, over which the same progressively opens to allow for increased flow.

#### Dependencies

To enable this parameter, set **Opening pressure specification** to Gauge pressure at port **A**.

**Valve parameterization** — Parameterization used to specify flow characteristics of orifice  
 Cv flow coefficient (default) | Kv flow coefficient | Sonic conductance | Orifice area

Method to calculate the mass flow rate.

- **Cv flow coefficient** — The flow coefficient  $C_v$  determines the block parameterization.
- **Kv flow coefficient** — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization.
- **Sonic conductance** — The sonic conductance of the resistive element at steady state determines the block parameterization.
- **Orifice area** — The size of the flow restriction determines the block parametrization.

**Maximum Cv flow coefficient** — Cv coefficient that corresponds to maximally open component  
 4 (default) | positive scalar

Value of the  $C_v$  flow coefficient when the restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Cv flow coefficient.

**xT pressure differential ratio factor at choked flow** — Ratio of pressure differentials  
 0.7 (default) | positive scalar

Ratio between the inlet pressure,  $p_{in}$ , and the outlet pressure,  $p_{out}$ , defined as  $(p_{in} - p_{out})/p_{in}$  where choking first occurs. If you do not have this value, look it up in table 2 in ISA-75.01.01 [3]. Otherwise, the default value of 0.7 is reasonable for many valves.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Cv flow coefficient or Kv flow coefficient.

**Maximum Kv flow coefficient** — Kv coefficient that corresponds to maximally open component  
3.6 (default) | positive scalar

Maximum value of the  $K_v$  flow coefficient when the restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Kv flow coefficient.

**Maximum sonic conductance** — Sonic conductance corresponding to maximally open component  
12 l/(bar\*s) (default) | positive scalar

Value of the sonic conductance when the cross-sectional area available for flow is at a maximum.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**Critical pressure ratio** — Ratio of downstream and upstream pressures at which the flow first chokes  
0.3 (default) | positive scalar

Pressure ratio at which flow first begins to choke and the flow velocity reaches its maximum, given by the local speed of sound. The pressure ratio is the outlet pressure divided by inlet pressure.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**Subsonic index** — Exponent used to characterize mass flow in subsonic flow regime  
0.5 (default) | positive scalar

Empirical value used to more accurately calculate the mass flow rate in the subsonic flow regime.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**ISO reference temperature** — ISO 8778 reference temperature  
293.15 K (default) | scalar

Temperature at standard reference atmosphere, defined as 293.15 K in ISO 8778.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**ISO reference density** — ISO 8778 reference density  
1.185 kg/m<sup>3</sup> (default) | positive scalar

Density at standard reference atmosphere, defined as 1.185 kg/m<sup>3</sup> in ISO 8778.

**Dependencies**

To enable this parameter, set **Valve parameterization** to `Sonic conductance`.

**Maximum orifice area** — Flow area corresponding to maximally open component  
`1e-4 m2 (default) | positive scalar`

Cross-sectional area of the orifice opening when the cross-sectional area available for flow is at a maximum.

**Dependencies**

To enable this parameter, set **Valve parameterization** to `Orifice area`.

**Discharge coefficient** — Discharge coefficient  
`0.64 (default) | positive scalar in the range of [0,1]`

Correction factor that accounts for discharge losses in theoretical flows.

**Dependencies**

To enable this parameter, set **Valve parameterization** to `Orifice area`.

**Leakage flow fraction** — Ratio of flow rates  
`1e-6 (default) | positive scalar`

Ratio of the flow rate of the orifice when it is closed to when it is open.

**Smoothing factor** — Numerical smoothing factor  
`0.01 (default) | positive scalar in the range [0,1]`

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the orifice is in near-open or near-closed positions. Set this parameter to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Laminar flow pressure ratio** — Pressure ratio at which flow transitions between laminar and turbulent regimes  
`0.999 (default) | positive scalar`

Pressure ratio at which flow transitions between laminar and turbulent flow regimes. The pressure ratio is the outlet pressure divided by inlet pressure. Typical values range from `0.995` to `0.999`.

**Cross-sectional area at ports A and B** — Flow area at gas ports  
`0.01 m2 (default) | positive scalar`

Area normal to the flow path at each port. The ports are equal in size. The value of this parameter should match the inlet area of the components to which the resistive element connects.

## Version History

**Introduced in R2018b****R2022b: Model gas systems using improved flow computations**

In previous versions, the blocks in the gas library used a conversion factor to implement different orifice parameterizations in terms of sonic conductance. You can use the **Valve parameterization** parameter to specify the parameterization.

The new parameterizations also include new parameters:

- **xT pressure differential ratio factor at choked flow**
- **Discharge coefficient**
- **Leakage flow fraction.** This parameter replaces the **Cv coefficient (USCS) at leakage flow**, **Kv coefficient (SI) at leakage flow**, **Sonic conductance at leakage flow**, and **Restriction area at leakage flow** parameters.

To improve clarity:

- The **Opening parameterization** parameter has been renamed to **Opening characteristic**.
- The **Reference temperature** and **Reference density** parameters have been renamed to **ISO reference temperature** and **ISO reference density**, respectively.
- The **Cv coefficient (USCS) at maximum flow** and **Kv coefficient (USCS) at maximum flow** parameters have been renamed to **Maximum Cv coefficient** and **Maximum Kv coefficient**, respectively.
- The **Sonic conductance at maximum flow** parameter has been renamed to **Maximum sonic conductance**.
- The **Pressure control specification** parameter has been renamed to **Opening pressure specification**. The options for this parameter have been renamed to **Pressure difference of port A relative to port B** and **Gauge pressure at port A**.

Orifice (G) | Pilot-Operated Check Valve (G)

## Check Valve (TL)

Valve for the prevention of flow aimed counter to its intended direction

### Libraries:

Simscape / Fluids / Thermal Liquid / Valves & Orifices / Directional Control Valves

### Description

The Check Valve (TL) block models the opening characteristics of a proportional valve that is forced shut when the pressure difference between its ports is reversed (or, more precisely, dropped below a threshold known as the *cracking pressure*). Check valves are common in backflow prevention devices, such as those used in public water supply networks, where contaminated water downstream of a water main must not be allowed to return upstream. No specific valve shutoff mechanism—whether ball, disc, diaphragm, or other—is assumed in the block. The allowed direction of flow is always from port **A** to port **B**.

### Y-Shaped Check Valve with Piston-Type Control Member Partially Retracted

The valve cracks open when the pressure drop across it rises above the cracking pressure specified in the block. The opening area increases linearly with pressure, save for two small pressure intervals near the fully open and fully closed positions (over which nonlinear smoothing is applied in order to remove numerical discontinuities). When the pressure drop reaches the maximum value specified in the block, the valve is fully open and its opening area no longer increases with pressure. The flow rate through the valve is never truly zero as a small leakage area remains when the pressure falls below the cracking pressure.

### Valve Opening Area

The (smoothed) valve opening area is first computed as a linear function of pressure, either that at the valve entrance (port **A**) or the drop between those at the entrance and at the outlet (port **B**). Which of these pressures—termed control pressures—features in the area calculations depends on the setting of the **Pressure specification method** block parameter:

$$p_{\text{Control}} = \begin{cases} p_A, & \text{Pressure at port A method} \\ p_A - p_B, & \text{Pressure differential method} \end{cases}$$

where  $p$  is pressure; the subscript **Control** indicates the value to be used in determining the opening area of the valve. Subscripts **A** and **B** denote the thermal liquid ports at which the pressures are obtained. The pressures at the ports are always defined as absolute pressures. The cracking pressure, at which the opening area is at a minimum, is similarly defined:

$$p_{\text{Crack}} = \begin{cases} p_{\text{Crack,G}} + p_{\text{Atm}}, & \text{Pressure at port A method} \\ \Delta p_{\text{Crack}}, & \text{Pressure differential method} \end{cases}$$

where the subscript **Crack** indicates a valve just cracking open, subscript **G** a gauge value, and subscript **Atm** the standard atmospheric value. The value of  $p_{\text{Crack,G}}$  is obtained from the **Cracking pressure (gauge)** block parameter; that of  $\Delta p_{\text{Crack}}$  is obtained from the **Cracking pressure differential** block parameter. The maximum pressure, at which the opening area is at its largest, is:

$$p_{\text{Max}} = \begin{cases} p_{\text{Max,G}} + p_{\text{Atm}}, & \text{Pressure at port A method} \\ \Delta p_{\text{Max}}, & \text{Pressure differential method} \end{cases}$$

where subscript **Max** denotes a maximum pressure (obtained as gauge). The value of  $p_{\text{Max,G}}$  is obtained from the **Maximum opening pressure (gauge)** block parameter; that of  $\Delta p_{\text{Max}}$  is obtained from the **Maximum opening pressure differential** block parameter. The control, cracking, and maximum pressures give for the linear form of the valve opening area:

$$S_{\text{Lin}} = \frac{S_{\text{Max}} - S_{\text{Crack}}}{p_{\text{Max}} - p_{\text{Crack}}} (p_{\text{Ctl}} - p_{\text{Crack}}) + S_{\text{Crack}}$$

where  $S$  denotes the (linear) opening area. The opening area at cracking is equal to the small value specified in the **Leakage area** block parameter. The primary purpose of this parameter is to ensure the numerical robustness of the model by ensuring that no portion of a thermal liquid network becomes completely isolated during simulation.

### Valve opening area as a linear function of pressure

When the valve is in a near-open or near-closed position in the linear parameterization, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the control pressure between  $p_{\text{Crack}}$  and  $p_{\text{Max}}$ . For more information, see “Numerical Smoothing”.

### Leakage Area

The primary purpose of the leakage area of a closed valve is to ensure that at no time does a portion of the hydraulic network become isolated from the remainder of the model. Such isolated portions reduce the numerical robustness of the model and can slow down simulation or cause it to fail. Leakage is generally present in minuscule amounts in real valves but in a model its exact value is less

important than it being a small number greater than zero. The leakage area is obtained from the block parameter of the same name.

### Mass Balance

The volume of fluid inside the valve, and therefore the mass of the same, is assumed to be very small and it is, for modeling purposes, ignored. As a result, no amount of fluid can accumulate there. By the principle of conservation of mass, the mass flow rate into the valve through one port must therefore equal that out of the valve through the other port:

$$\dot{m}_A + \dot{m}_B = 0,$$

where  $\dot{m}$  is defined as the mass flow rate *into* the valve through one of the ports (**A** or **B**).

### Momentum Balance

The causes of those pressure losses incurred in the passages of the valve are ignored in the block. Whatever their natures—sudden area changes, flow passage contortions—only their cumulative effect is considered during simulation. This effect is captured in the block by the discharge coefficient, a measure of the mass flow rate through the valve relative to the theoretical value that it would have in an ideal valve. Expressing the momentum balance in the valve in terms of the pressure drop induced in the flow:

$$p_A - p_B = \frac{\dot{m}_{\text{Avg}} \sqrt{\dot{m}_{\text{Avg}}^2 + \dot{m}_{\text{Crit}}^2}}{2\rho_{\text{Avg}} C_D S_{\text{Smooth}}^2} \left[ 1 - \left( \frac{S_{\text{Smooth}}}{S_{\text{Lin}}} \right)^2 \right] \xi_p,$$

where  $C_D$  is the discharge coefficient, and  $\xi_p$  is the pressure drop ratio—a measure of the extent to which the pressure recovery at the outlet contributes to the total pressure drop of the valve. The subscript Avg denotes an average of the values at the thermal liquid ports. The critical mass flow rate  $\dot{m}_{\text{Crit}}$  is calculated from the critical Reynolds number—that at which the flow in the orifice is assumed to transition from laminar to turbulent:

$$\dot{m}_{\text{Crit}} = \text{Re}_{\text{Crit}} \mu_{\text{Avg}} \sqrt{\frac{\pi}{4} S_{\text{Lin}}},$$

where  $\mu$  denotes dynamic viscosity. The pressure drop ratio is calculated as:

$$\xi_p = \frac{\sqrt{1 - \left( \frac{S_{\text{Smooth}}}{S_{\text{Lin}}} \right)^2} (1 - C_D^2) - C_D \frac{S_{\text{Smooth}}}{S_{\text{Lin}}}}{\sqrt{1 - \left( \frac{S_{\text{Smooth}}}{S_{\text{Lin}}} \right)^2} (1 - C_D^2) + C_D \frac{S_{\text{Smooth}}}{S_{\text{Lin}}}}.$$

### Energy Balance

The valve is modeled as an adiabatic component. No heat exchange can occur between the fluid and the wall of the valve. No work is done on or by the fluid as it traverses the valve. With these assumptions, energy can enter and exit the valve by advection only, through ports **A** and **B**. By the principle of conservation of energy then, the sum of the energy flows through the ports must always equal zero:

$$\phi_A + \phi_B = 0,$$

where  $\phi$  is defined as the energy flow rate *into* the valve through one of the ports (**A** or **B**).

## Ports

### Conserving

**A** — Valve inlet  
thermal liquid

Opening through which the flow can enter the valve.

**B** — Valve outlet  
thermal liquid

Opening through which the flow can exit the valve.

## Parameters

**Pressure control specification** — Choice of pressure to use in the block calculations  
Pressure at port A (default) | Pressure differential

Choice of pressure to use in the block calculations. The default setting corresponds to the gauge pressure at the valve inlet (port **A**). The alternative setting corresponds to the pressure differential from inlet (**A**) to outlet (**B**).

**Cracking pressure (gauge)** — Gauge pressure at which the valve begins to open  
0.1 MPa (default) | positive scalar in units of pressure

Gauge pressure at port **A** at which the valve begins to open. The valve opening area is saturated at the value of the **Leakage area** block parameter when the pressure at port **A** is at or below the value specified here.

### Dependencies

This parameter is active when the **Pressure control specification** block parameter is set to Pressure at port A.

**Maximum opening pressure (gauge)** — Gauge pressure at which the valve is fully open  
0.2 MPa (default) | positive scalar in units of pressure

Gauge pressure at port **A** at which the valve is fully open. The valve opening area is saturated at the value specified in the **Maximum opening area** block parameter when the pressure at port **A** is at or above the value specified here.

### Dependencies

This parameter is active when the **Pressure control specification** block parameter is set to Pressure at port A.

**Cracking pressure differential** — Pressure differential from port A to port B at which the valve begins to open  
0.1 MPa (default) | positive scalar in units of pressure

Pressure differential from port A to port B at which the valve begins to open. The valve opening area is saturated at the value of the **Leakage area** block parameter when the pressure differential is at or below the value specified here.

**Dependencies**

This parameter is active when the **Pressure control specification** block parameter is set to **Pressure differential**.

**Maximum opening pressure differential** — Pressure differential from port A to port B at which the valve is fully open

0.2 MPa (default) | positive scalar in units of pressure

Pressure differential from port A to port B at which the valve is fully open. The valve opening area is saturated at the value specified in the **Maximum opening area** block parameter when the pressure differential is at or above the value specified here.

**Dependencies**

This parameter is active when the **Pressure control specification** block parameter is set to **Pressure differential**.

**Maximum opening area** — Opening area of the valve in the fully open position

1e-4 m<sup>2</sup> (default) | positive scalar in units of area

Opening area of the valve in the fully open position. The valve is fully open if the pressure drop from port **A** to port **B** is equal to or greater than that given by the **Maximum opening pressure** block parameter.

**Leakage area** — Opening area of the valve in the maximally closed position

1e-10 m<sup>2</sup> (default) | positive scalar in units of area

Opening area of the valve in the fully closed position, when only internal leakage between its ports remains. This parameter serves primarily to ensure that closure of the valve does not cause portions of the thermal liquid network to become isolated. The exact value specified here is less important than its being a small number greater than zero.

**Smoothing factor** — Measure of the amount of smoothing to apply to the opening area function

0.01 (default) | positive unitless scalar

Measure of the amount of smoothing to apply to the opening area function. This parameter determines the widths of the regions to be smoothed, one being at the fully open position, the other at the fully closed position. The smoothing superposes on the linear opening area function two nonlinear segments, one for each region of smoothing. The greater the value specified, the greater the smoothing and the broader the nonlinear segments.

**Cross-sectional area at ports A and B** — Flow area at the thermal liquid ports

0.01 m<sup>2</sup> (default) | positive scalar in units of area

Area normal to the flow path at each port. The ports are assumed to be equal in size. The flow area specified here should match those of the inlets of those components to which the orifice connects.

**Discharge coefficient** — Empirical factor defined as the ratio of actual to ideal mass flow rates

0.64 (default) | positive unitless scalar

Ratio of the actual flow rate through the valve to the theoretical value that it would have in an ideal valve. This semi-empirical parameter measures the flow allowed through the valve: the greater its value, the greater the flow rate. Refer to the valve data sheet, if available, for this parameter.

**Critical Reynolds number** — Reynolds number at the boundary between laminar and turbulent flow regimes

150 (default) | positive unitless scalar

Reynolds number at which the flow is assumed to transition between laminar and turbulent regimes.

#### **Variables**

**Mass flow rate into port A** — Initial state target for the mass flow rate of the valve

cleared (default) | checked

Desired mass flow rate into the valve through port **A** at the start of simulation. This parameter serves as an initial state target, a guide used by Simscape in assembling the initial configuration of the model. How closely the target is met depends on the constraints imposed by the remainder of the model and on the priority level specified.

## Check Valve (2P)

Check valve in a two-phase fluid network

### Libraries:

Simscape / Fluids / Two-Phase Fluid / Valves & Orifices / Directional Control Valves

### Description

The Check Valve (2P) block models a directional control check valve in a two-phase fluid network. The valve maintains the fluid pressure by opening above a specified pressure and allowing flow from port **A** to port **B**, but not in the reverse direction. The pressure differential that opens the valve is specified in the **Opening pressure specification** parameter. This value can be either the pressure difference between ports **A** and **B** or the gauge pressure at port **A**.

Fluid properties inside the valve are calculated from inlet conditions. There is no heat exchange between the fluid and the environment, and therefore phase change inside the valve only occurs due to a pressure drop or a change propagated from another part of the model.

A number of block parameters are based on nominal operating conditions, which correspond to the valve rated performance, such as a specification on a manufacturer datasheet.

### Directional Control

The valve opens when the pressure in the valve,  $p_{control}$ , exceeds the cracking pressure,  $p_{crack}$ . The valve is fully open when the control pressure reaches the valve maximum pressure,  $p_{max}$ . The opening fraction of the valve,  $\lambda$ , is expressed as:

$$\lambda = (1 - f_{leak}) \frac{(p_{control} - p_{crack})}{(p_{max} - p_{crack})} + f_{leak}$$

where:

- $f_{leak}$  is the **Closed valve leakage as a fraction of nominal flow**.
- $p_{control}$  is the control pressure, which depends on the **Opening pressure specification** parameter.

When you set **Opening pressure specification** to Pressure differential, the control pressure is  $p_A - p_B$ .

When you set **Opening pressure specification** to Gauge pressure at port A, the control pressure is the difference between the pressure at port **A** and atmospheric pressure.

The cracking pressure and maximum pressure are specified as either a differential value or a gauge value, depending on the setting of the **Opening pressure specification**. If the control pressure exceeds the maximum pressure, the valve opening fraction is 1.

The mass flow rate depends on the pressure differential, and therefore the open area of the valve. The block calculates this as:

$$\dot{m}_A = \lambda \dot{m}_{nom} \left[ \sqrt{\frac{v_{nom}}{2\Delta p_{nom}}} \right] \sqrt{\frac{2}{v_{in}} \frac{\Delta p}{(\Delta p^2 + \Delta p_{lam}^2)^{0.25}}}$$

where:

- $\Delta p$  is the pressure drop over the valve,  $p_A - p_B$ .
- $\Delta p_{lam}$  is the pressure transition threshold between laminar and turbulent flow, which is calculated from the **Laminar flow pressure ratio**,  $B_{lam}$ :

$$\Delta p_{lam} = \frac{(p_A + p_B)}{2}(1 - B_{lam}).$$

- $\dot{m}_{nom}$  is the **Nominal mass flow rate at maximum valve opening**.
- $\Delta p_{nom}$  is the **Nominal pressure drop rate at maximum valve opening**.
- $v_{nom}$  is the nominal inlet specific volume. This value is determined from the fluid properties tabulated data based on the **Nominal inlet specific enthalpy** and **Nominal inlet pressure** parameters.
- $v_{in}$  is the inlet specific volume.

### Fluid Specific Volume Dynamics

When the fluid at the valve inlet is a liquid-vapor mixture, the block calculates the specific volume as:

$$v_{in} = (1 - x_{dyn})v_{liq} + x_{dyn}v_{vap},$$

where:

- $x_{dyn}$  is the inlet vapor quality. The block applies a first-order lag to the inlet vapor quality of the mixture.
- $v_{liq}$  is the liquid specific volume of the fluid.
- $v_{vap}$  is the vapor specific volume of the fluid.

If the inlet fluid is liquid or vapor,  $v_{in}$  is the respective liquid or vapor specific volume.

### Vapor Quality Lag

If the inlet vapor quality is a liquid-vapor mixture, the block applied a first-order time lag:

$$\frac{dx_{dyn}}{dt} = \frac{x_{in} - x_{dyn}}{\tau},$$

where:

- $x_{dyn}$  is the dynamic vapor quality.
- $x_{in}$  is the current inlet vapor quality.
- $\tau$  is the **Inlet phase change time constant**.

If the inlet fluid is a subcooled liquid or superheated vapor,  $x_{dyn}$  is equal to  $x_{in}$ .

### Mass Balance

Mass is conserved in the valve:

$$\dot{m}_A + \dot{m}_B = 0,$$

where:

- $\dot{m}_A$  is the mass flow rate at port **A**.
- $\dot{m}_B$  is the mass flow rate at port **B**.

### Energy Balance

Energy is conserved in the valve:

$$\Phi_A + \Phi_B = 0,$$

where:

- $\Phi_A$  is the energy flow at port **A**.
- $\Phi_B$  is the energy flow at port **B**.

### Assumptions and Limitations

- The block does not model pressure recovery downstream of the valve.
- There is no heat exchange between the valve and the environment.
- The block does not model choked flow.

## Ports

### Conserving

**A** — Fluid port  
two-phase fluid

Fluid entry port.

**B** — Fluid port  
two-phase fluid

Fluid exit port.

## Parameters

**Opening pressure specification** — Control pressure  
Pressure differential (default) | Gauge pressure at port A

Control pressure specification:

- When set to Pressure differential, the valve opens when  $p_A - p_B$  exceeds the **Cracking pressure differential**.
- When set to Gauge pressure at port A, the valve opens when  $p_A - p_{atm}$  exceeds the **Cracking pressure (gauge)**.

**Cracking pressure differential** — Cracking pressure  
0.01 MPa (default) | positive scalar

Valve pressure threshold. When the control pressure,  $p_A - p_B$ , exceeds the opening pressure, the valve begins to open.

**Dependencies**

To enable this parameter, set **Opening pressure specification** to Pressure differential.

**Cracking pressure (gauge)** — Cracking pressure

0.1 MPa (default) | positive scalar

Valve pressure threshold. When the control pressure,  $p_A - p_{atm}$ , exceeds the opening pressure, the valve begins to open.

**Dependencies**

To enable this parameter, set **Opening pressure specification** to Gauge pressure at port A.

**Maximum opening pressure differential** — Maximum valve operational pressure

0.1 MPa (default) | positive scalar

Maximum valve operational pressure. The valve begins to open at the cracking pressure value, and is fully open at  $p_{max}$ .

**Dependencies**

To enable this parameter, set **Opening pressure specification** to Pressure differential.

**Maximum opening pressure (gauge)** — Pressure that fully opens the valve

0.2 MPa (default) | positive scalar

Valve operational pressure at which the valve is fully open. The valve begins to open at the cracking pressure value, and is fully open at  $p_{max}$ .

**Dependencies**

To enable this parameter, set **Opening pressure specification** to Gauge pressure at port A.

**Nominal mass flow rate at maximum opening** — Rated mass flow rate

0.1 kg/s (default) | positive scalar

Mass flow rate through a fully open valve under typical, design, or rated conditions.

**Nominal pressure drop at maximum opening** — Rated pressure drop

0.001 MPa (default) | positive scalar

Pressure drop over a fully open valve under typical, design, or rated conditions.

**Nominal inlet condition specification** — Method of determining inlet fluid state

Temperature (default) | Vapor quality | Vapor void fraction | Specific enthalpy | Specific internal energy

Method of determining inlet fluid state. The valve inlet specific volume is determined from the fluid properties tabulated data based on the **Nominal inlet pressure** and the setting of the **Nominal inlet condition specification** parameters.

**Nominal inlet pressure** — Pressure of fluid entering valve

0.101325 MPa (default) | positive scalar

Valve inlet pressure in typical, design, or rated conditions. The valve inlet specific volume is determined from the fluid properties tabulated data based on the **Nominal inlet pressure** and the setting of the **Nominal inlet condition specification** parameters.

**Nominal inlet temperature** — Fluid temperature

293.15 K (default) | positive scalar

Inlet fluid temperature in nominal operating conditions.

**Dependencies**

To enable this parameter, set **Nominal inlet condition specification** to Temperature.

**Nominal inlet vapor quality** — Inlet vapor quality by mass fraction

0.5 (default) | positive scalar in the range [0,1]

Inlet vapor quality of the mixture by mass fraction in nominal operating conditions. A value of 0 means that the inlet fluid is subcooled liquid. A value of 1 means that the inlet fluid is superheated vapor.

**Dependencies**

To enable this parameter, set **Nominal inlet condition specification** to Vapor quality.

**Nominal inlet vapor void fraction** — Inlet volume fraction

0.5 (default) | positive scalar in the range [0,1]

Inlet mixture volume fraction in nominal operating conditions. A value of 0 means that the inlet fluid is subcooled liquid. A value of 1 means that the inlet fluid is superheated vapor.

**Dependencies**

To enable this parameter, set **Nominal inlet condition specification** to Vapor void fraction.

**Nominal inlet specific enthalpy** — Inlet fluid specific enthalpy

1500 kJ/kg (default) | positive scalar

Inlet specific enthalpy in nominal operating conditions.

**Dependencies**

To enable this parameter, set **Nominal inlet condition specification** to Specific enthalpy.

**Nominal inlet specific internal energy** — Inlet specific internal energy

1500 kJ/kg (default) | positive scalar

Inlet specific internal energy in nominal operating conditions.

**Dependencies**

To enable this parameter, set **Nominal inlet condition specification** to Specific internal energy.

**Cross-sectional area at ports A and B** — Valve port areas

0.01 m<sup>2</sup> (default) | positive scalar

Area of the valve ports **A** and **B**.

**Closed valve leakage as a fraction of nominal flow** — Fractional flow when valve is closed  
1e-6 (default) | positive scalar

Fractional flow rate through the valve when it is fully closed. This parameter contributes to numerical stability by maintaining continuity in the fluid network.

**Smoothing factor** — Numerical smoothing factor  
0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this parameter to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Laminar flow pressure ratio** — Laminar-turbulent transition pressure ratio  
0.999 (default) | positive scalar

Ratio of the valve outlet pressure to valve inlet pressure at which the fluid transitions between the laminar and turbulent regimes. The pressure loss corresponds to the mass flow rate linearly in laminar flows and quadratically in turbulent flows.

**Inlet phase change time constant** — Lag for mixture specific volume  
0.1 s (default) | positive scalar

Time lag for liquid-vapor mixtures in computing the fluid specific volume. This parameter does not influence the specific volume when the inlet fluid is a fully supercooled liquid or fully superheated vapor.

## Compressor (2P)

Two-phase fluid compressor in a thermodynamic cycle

### Libraries:

Simscape / Fluids / Two-Phase Fluid / Fluid Machines

### Description

The Compressor (2P) block represents a dynamic compressor, such as a centrifugal or axial compressor, in a two-phase fluid network. You can parameterize the block analytically based on the design point or by using a tabulated compressor map by setting **Parameterization** to **Analytical** or **Tabulated**, respectively. A positive rotation of port **R** relative to port **C** causes fluid to flow from port **A** to port **B**. Port **R** and port **C** are mechanical rotational conserving ports associated with the compressor shaft and casing, in that order.

The *surge margin* is the ratio between the surge pressure ratio at a given mass flow rate and the operating point pressure ratio minus 1. When you set **Parameterization** to **Tabulated**, the block outputs the surge margin at port **SM**.

The *design point* of the compressor is the design operational pressure ratio across and mass flow rate through the compressor during simulation. The compressor operating point and the point of maximum efficiency do not need to coincide.

The Compressor (2P) block assumes that superheated fluid enters the inlet. You can use the **Report when fluid is not fully vapor** parameter to choose what the block does when the fluid does not meet superheated conditions.

### Compressor Map

The map plots the isentropic efficiency of the compressor between the two extremes of choked flow and surge flow. The map plots the lines of constant corrected shaft speed between the two extremes of choked flow and surge flow. Each corrected speed line tells you how pressure ratio varies with corrected mass flow rate when the shaft spins at the corresponding corrected speed. The variable  $\beta$  indicates the relative position along the corrected speed lines between the two extremes. Choked flow corresponds to  $\beta = 0$ , and surge flow corresponds to  $\beta = 1$ . The map also plots contours of isentropic efficiency as a function of pressure ratio and corrected mass flow rate. This provides a relative indication of how much power the compressor needs to operate at various combinations of pressure ratio and corrected mass flow rate.

### Corrected Mass Flow Rate

Due to the large changes in pressure and temperature inside a compressor, the compressor map plots performance in terms of a corrected mass flow rate. The corrected mass flow rate is adjusted from the inlet mass flow rate with a reference pressure and reference temperature:

$$\dot{m}_{corr} = \dot{m}_A \left( \sqrt{\frac{T_A}{T_{ref}}} / \frac{p_A}{p_{ref}} \right),$$

where:

- $\dot{m}_A$  is the mass flow rate at port **A**.
- $T_A$  is the temperature at port **A**.
- $T_{ref}$  is the **Reference temperature for corrected flow**. When you set **Parameterization** to **Analytical**, this is the inlet temperature at the design operating condition.
- $\dot{m}_{corr}$  is the corrected mass flow rate.

When you set **Parameterization** to **Analytical**, the block uses the **Corrected mass flow rate at design point** parameter.

When you set **Parameterization** to **Tabulated**, the block uses the **Corrected mass flow rate table,  $\dot{m}(N,\beta)$**  parameter.

- $p_A$  is the pressure at port **A**.
- $p_{ref}$  is the **Reference pressure for corrected flow** parameter. When using the analytical parameterization, this is the inlet pressure at the design operating condition.

The block derives  $T_A$  from the specific internal energy,  $u_A$ , and specific pressure,  $p_A$ .

### Corrected Speed

The block also adjusts the shaft speed,  $\omega$ , according to the reference temperature, such that the corrected shaft speed is

$$\omega_{corr} = \frac{\omega}{\sqrt{\frac{T_A}{T_{ref}}}}$$

### Shaft Torque

The block calculates the shaft torque,  $\tau$ , as:

$$\tau = \frac{\dot{m}_A \Delta h_{total}}{\eta_m \omega}$$

where:

- $\Delta h_{total}$  is the change in specific total enthalpy.
- $\eta_m$  is the compressor **Mechanical efficiency**.
- $\omega$  is the relative shaft angular velocity,  $\omega_R - \omega_C$ .

The block relates the efficiency in the compressor map as

$$\Delta h_{total} = \frac{\Delta h_{isen}}{\eta_{isen}}$$

where

- $\Delta h_{isen}$  is the isentropic change in specific total enthalpy.
- $\eta_{isen}$  is the isentropic efficiency.

A threshold region when flow approaches zero ensures that no torque is generated when the flow rate is near zero or reversed.

## Analytical Parameterization

You can generate the compressor map analytically by setting **Parameterization** to **Analytical**. The block fits a model of the compressor map based on Greitzer et al, 2010 to the specified values for the **Corrected speed at design point**, **Pressure ratio at design point**, and **Corrected mass flow rate at design point** parameters. This method does not use  $\beta$  lines and the block does not report a surge margin.

### Pressure Ratio

The block finds the pressure ratio at a given shaft speed and mass flow rate as:

$$\pi = 1 + (\pi_D - 1) \left[ \tilde{N}^{ab} + 2\tilde{N}k \ln \left( 1 - \frac{\tilde{m} - \tilde{N}^b}{k} \right) \right],$$

where:

- $\pi_D$  is the **Pressure ratio at design point** parameter.
- $\tilde{N}$  is the normalized corrected shaft speed,

$$\frac{N}{N_D},$$

where  $N_D$  is the **Corrected speed at design point** parameter.

- $\tilde{m}$  is the normalized corrected mass flow rate,

$$\frac{\dot{m}_{corr}}{\dot{m}_D},$$

where  $\dot{m}_D$  is the **Corrected mass flow rate at design point** parameter.

- $a$  is the **Spine shape, a** parameter.
- $b$  is the **Speed line spread, b** parameter.
- $k$  is the **Speed line roundness, k** parameter.

The *spine* refers to the black line where the isentropic efficiency contours start to bend. The map *speed lines* are the shaft constant-speed lines that intersect the spine perpendicularly.

Reload Data

### Analytical Parameterization Default Compressor Map

#### Isentropic Efficiency Parameterization

When you set **Efficiency specification** to Analytical, the block models variable compressor efficiency as:

$$\eta = \eta_0 \left( 1 - C \left| \frac{\tilde{p}}{\tilde{m}^{a+\Delta a-1}} - \tilde{m} \right|^c - D \left| \frac{\tilde{m}}{\tilde{m}_0} - 1 \right|^d \right),$$

where:

- $\eta_0$  is the **Maximum isentropic efficiency** parameter.
- $C$  is the **Efficiency contour gradient orthogonal to spine, C** parameter.
- $D$  is the **Efficiency contour gradient along spine, D** parameter.
- $c$  is the **Efficiency peak flatness orthogonal to spine, c** parameter.
- $d$  is the **Efficiency peak flatness along spine, d** parameter.
- $\tilde{p}$  is the normalized corrected pressure ratio,

$$\frac{\pi - 1}{\pi_D - 1},$$

where  $\pi_D$  is the **Corrected pressure ratio at design point** parameter.

- $\tilde{m}_0$  is the normalized corrected mass flow rate at which the compressor reaches its **Maximum isentropic efficiency** parameter.

You can adjust the efficiency variables for different performance characteristics.

Alternatively, you can choose a constant efficiency value by using the **Constant isentropic efficiency** parameter.

### **Tabulated Data Parameterization**

When you set **Parameterization** to **Tabulated**, the isentropic efficiency, pressure ratio, and corrected mass flow rate of the compressor are functions of the corrected speed,  $N$ , and the map index,  $\beta$ . The block uses linear interpolation between data points for the efficiency, pressure ratio, and corrected mass flow rate.

If  $\beta$  exceeds 1, compressor surge occurs, and the block assumes the pressure ratio remains at  $\beta = 1$ , while the mass flow rate continues to change. If the simulation conditions fall below  $\beta = 0$ , the block includes the effects of choked flow: the mass flow rate remains at its value at  $\beta = 0$ , while the pressure ratio continues to change. To constrain the compressor performance within the map boundaries, the block extrapolates isentropic efficiency to the nearest point.

You can choose to be notified when the operating point pressure ratio exceeds the surge pressure ratio. Set **Report when surge margin is negative** to **Warning** to receive a warning or to **Error** to stop the simulation when this occurs.

### **Visualizing the Block Compressor Map**

To visualize the block map, right-click the block and select **Fluids > Plot Compressor Map**.

Reload Data

### Tabulated Parameterization Default Compressor Map

#### Continuity Equations

The block conserves mass such that

$$\dot{m}_A + \dot{m}_B = 0,$$

where  $\dot{m}_B$  is the mass flow rate at port **B**.

The block computes the energy balance equation as

$$\Phi_A + \Phi_B + P_{fluid} = 0,$$

where:

- $\Phi_A$  is the energy flow rate at port **A**.
- $\Phi_B$  is the energy flow rate at port **B**.
- $P_{fluid}$  is the hydraulic power delivered to the fluid, which is determined from the change in specific :  $P_{fluid} = \dot{m}_A \Delta h_{total}$ .

### Assumptions and Limitations

- The block assumes that superheated fluid enters at **A**.
- The block only defines compressor map flow from port **A** to port **B**. Reverse flow results may not be accurate.
- The block only represents dynamic compressors.

### Ports

#### Output

**SM** — Surge margin  
physical signal

Physical signal output port associated with the surge margin at a given mass flow rate. The block calculates the surge margin as

$$SM(\dot{m}_{corr}) = \frac{p_{r, surge}(\dot{m}_{corr})}{p_r(\dot{m}_{corr})} - 1.$$

#### Dependencies

To enable this port, set **Parameterization** to Tabulated.

#### Conserving

**A** — Compressor inlet  
two-phase fluid

Two-phase fluid conserving port associated with the compressor inlet.

**B** — Compressor outlet  
two-phase fluid

Two-phase fluid conserving port associated with the compressor outlet.

**C** — Compressor casing  
mechanical rotational

Mechanical rotational conserving port associated with the compressor case.

**R** — Compressor shaft  
mechanical rotational

Mechanical rotational conserving port associated with the compressor shaft.

### Parameters

#### Compressor Map

**Parameterization** — Compressor performance parameterization  
Analytical (default) | Tabulated

Compressor performance parameterization.

- **Analytical:** A pressure ratio corrected mass flow rate curve defines peak compressor performance. You can choose to include isentropic efficiency as a constant or analytically.
- **Tabulated:** A user-supplied compressor map defines the compressor performance. The compressor operating points are determined by linear interpolation between the corrected mass flow rate, pressure ratio, and isentropic efficiency tables at given points in the user-provided corrected shaft speed and  $\beta$  vectors.

**Corrected speed at design point** — Operational corrected shaft speed  
25000 rpm (default) | positive scalar

Shaft speed at the intended compressor pressure ratio and corrected mass flow rate, corrected for temperature.

**Dependencies**

To enable this parameter, set **Parameterization** to Analytical.

**Pressure ratio at design point** — Operational outlet-to-inlet pressure ratio  
2.2 (default) | positive scalar

Outlet-to-inlet pressure ratio at the intended compressor corrected mass flow rate.

**Dependencies**

To enable this parameter, set **Parameterization** to Analytical.

**Corrected mass flow rate at design point** — Operational corrected mass flow rate  
0.20 kg/s (default) | positive scalar

Mass flow rate at the intended compressor pressure ratio, corrected for temperature and pressure.

**Dependencies**

To enable this parameter, set **Parameterization** to Analytical.

**Efficiency specification** — Isentropic efficiency option  
Constant (default) | Analytical

Option to parameterize efficiency using a constant value or analytically. Choose a constant or variable (analytical) model.

**Dependencies**

To enable this parameter, set **Parameterization** to Analytical.

**Maximum isentropic efficiency** — Maximum compressor efficiency  
0.887 (default) | positive scalar in the range (0,1]

Maximum compressor isentropic efficiency. Isentropic efficiency is the ratio of isentropic change to actual change.

**Dependencies**

To enable this parameter, set **Parameterization** to Analytical and **Efficiency specification** to Analytical.

**Minimum isentropic efficiency** — Minimum compressor efficiency  
0.5 (default) | positive scalar in the range (0,1]

Minimum compressor isentropic efficiency. Isentropic efficiency is the ratio of isentropic change to actual change.

**Dependencies**

To enable this parameter, set **Parameterization** to Analytical and **Efficiency specification** to Analytical.

**Pressure ratio at maximum efficiency point** — Pressure ratio at compressor maximum efficiency  
2.1 (default) | positive scalar

Pressure ratio at maximum efficiency. The point of maximum efficiency does not necessarily coincide with the compressor design point.

**Dependencies**

To enable this parameter, set **Parameterization** to Analytical and **Efficiency specification** to Analytical.

**Corrected mass flow rate at maximum efficiency point** — Corrected mass flow rate at compressor maximum efficiency  
0.19 kg/s (default) | positive scalar

Mass flow rate at maximum efficiency, corrected for temperature and pressure. The point of maximum efficiency does not necessarily coincide with the compressor design point.

**Dependencies**

To enable this parameter, set **Parameterization** to Analytical and **Efficiency specification** to Analytical.

**Constant isentropic efficiency** — Constant isentropic efficiency value  
0.8 (default) | positive scalar

Value of constant isentropic efficiency.

**Dependencies**

To enable this parameter, set **Parameterization** to Analytical and **Efficiency specification** to Constant.

**Corrected speed index vector, N** — Vector of corrected shaft speeds  
250 .\* [50, 71, 87, 100] rpm (default) | vector

Vector of corrected shaft speeds.

**Dependencies**

To enable this parameter, set **Parameterization** to Tabulated.

**Beta index vector, beta** — Vector of intervals  
0 : 1 / 5 : 1 (default) | vector of elements in the range [0,1]

Vector of relative positions along the corrected speed lines. Choked flow is defined as  $\beta = 0$  and surge flow is defined at  $\beta = 1$ .  $\beta$  lines are perpendicular to the compressor shaft constant speed lines,  $N$ .

**Dependencies**

To enable this parameter, set **Parameterization** to Tabulated.

**Pressure ratio table, pr(N, beta)** — Compressor map pressure ratio data

[1.1814, 1.2385, 1.2792, 1.3017, 1.3057, 1.3057; 1.3648, 1.5157, 1.6298, 1.691, 1.7011, 1.7032; 1.587, 1.8357, 2.011, 2.0925, 2.1006, 2.1006; 1.8255, 2.28, 2.4777, 2.5225, 2.5633, 2.5389] (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of compressor outlet-to-inlet pressure ratios at the specified corrected shaft speed and  $\beta$  value. The block uses linear interpolation between table elements.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of vector elements in the **Corrected speed index vector, N** parameter.
- $N$  is the number of vector elements in the **Beta index vector, beta** parameter.

**Dependencies**

To enable this parameter, set **Parameterization** to Tabulated.

**Corrected mass flow rate table, mdot(N,beta)** — Compressor map corrected mass flow rate data

[.1503, .1313, .11, .0887, .0668, .0502; .2265, .1999, .1649, .1322, .0992, .0639; .2869, .2545, .216, .1798, .1424, .108; .3275, .2846, .2466, .2285, .209, .1661] kg/s (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of corrected mass flow rates at the specified corrected shaft speed and  $\beta$  value. The block uses linear interpolation between table elements.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of vector elements in the **Corrected speed index vector, N** parameter.
- $N$  is the number of vector elements in the **Beta index vector, beta** parameter.

**Dependencies**

To enable this parameter, set **Parameterization** to Tabulated.

**Isentropic efficiency table, eta(N,beta)** — Compressor map isentropic efficiency data

[.56, .66, .71, .695, .659, .635; .558, .682, .755, .743, .697, .638; .57, .705, .765, .752, .712, .652; .552, .718, .755, .752, .736, .67] (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of compressor isentropic efficiencies at the specified corrected shaft speed and  $\beta$  value. Linear interpolation is employed between table elements.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of vector elements in the **Corrected speed index vector, N** parameter.
- $N$  is the number of vector elements in the **Beta index vector, beta** parameter.

**Dependencies**

To enable this parameter, set **Parameterization** to Tabulated.

**Report when surge margin is negative** — Negative surge margin notification

None (default) | Warning | Error

Whether the block does nothing, generates a warning, or generates an error when it detects a negative surge margin.

**Dependencies**

To enable this parameter, set **Parameterization** to Tabulated.

**Report when fluid is not fully vapor** — Fluid not fully vapor notification  
None (default) | Warning | Error

Whether the block does nothing, generates a warning, or generates an error when it detects fluid that is not fully vapor.

**Map Coefficients**

To enable the **Map Coefficients** parameters, set **Parameterization** to Analytical.

**Spine shape, a** — Spine shape exponent  
1.5 (default) | positive scalar

Exponent in the analytical parameterization of the compressor map that characterizes the spine shape.

**Speed line spread, b** — Constant speed line spacing exponent  
5 (default) | positive scalar

Exponent in the analytical parameterization of the compressor map that characterizes the constant speed line spacing.

**Speed line roundness, k** — Constant speed line shape coefficient  
0.03 (default) | positive scalar

Coefficient in the analytical parameterization of the compressor map that characterizes the constant speed line shape.

**Efficiency peak flatness orthogonal to spine, c** — Flatness orthogonal to spine exponent  
3 (default) | positive scalar

Exponent associated with the compressor map peak flatness orthogonal to the spine.

**Efficiency peak flatness along spine, d** — Along spine flatness exponent  
4 (default) | positive scalar

Exponent associated with the efficiency map peak flatness along the spine.

**Efficiency contour gradient orthogonal to spine, C** — Orthogonal gradient coefficient  
15 (default) | positive scalar

Coefficient associated with the efficiency contour gradient orthogonal to the spine.

**Efficiency contour gradient along spine, D** — Along spine gradient coefficient  
1.0 (default) | positive scalar

Coefficient associated with the efficiency contour gradient along the spine.

## Reference data

### Reference pressure for corrected flow — Correcting pressure

0.101325 MPa (default) | positive scalar

Reference inlet pressure for compressor map. When **Parameterization** is set to **Tabulated**, the data supplier specifies this value. When you set **Parameterization** to **Analytical**, this is the inlet pressure at the design operating condition.

### Reference temperature for corrected flow — Correcting temperature

373.15 K (default) | positive scalar

Reference inlet temperature for compressor map. When you set **Parameterization** to **Tabulated**, the data supplier specifies this value. When you set **Parameterization** to **Analytical**, this is the inlet temperature at the design operating condition.

### Mechanical efficiency — Efficiency of conversion to torque

0.9 (default) | positive scalar in the range [0,1]

Ratio of the power delivered to the fluid flow to the power driving the mechanical shaft.

### Inlet area at port A — Compressor inlet area

0.01 m<sup>2</sup> (default) | positive scalar

Compressor inlet cross-sectional area.

### Outlet area at port B — Compressor outlet area

0.01 m<sup>2</sup> (default) | positive scalar

Compressor outlet cross-sectional area.

## Description

The Compressor (G) block represents a dynamic compressor, such as a centrifugal or axial compressor, in a gas network. You can parameterize the block analytically based on the design point or by using a tabulated compressor map by setting **Parameterization** to **Analytical** or **Tabulated**, respectively. A positive rotation of port **R** relative to port **C** causes fluid to flow from port **A** to port **B**. Port **R** and port **C** are mechanical rotational conserving ports associated with the compressor shaft and casing, in that order.

The *surge margin* is the ratio between the surge pressure ratio at a given mass flow rate and the operating point pressure ratio minus 1. When you set **Parameterization** to **Tabulated**, the block outputs the surge margin at port **SM**.

The *design point* of the compressor is the design operational pressure ratio across and mass flow rate through the compressor during simulation. The compressor operating point and the point of maximum efficiency do not need to coincide.

## Compressor Map

The map plots the isentropic efficiency of the compressor between the two extremes of choked flow and surge flow. The map plots the lines of constant corrected shaft speed between the two extremes of choked flow and surge flow. Each corrected speed line tells you how pressure ratio varies with corrected mass flow rate when the shaft spins at the corresponding corrected speed. The variable  $\beta$  indicates the relative position along the corrected speed lines between the two extremes. Choked flow corresponds to  $\beta = 0$ , and surge flow corresponds to  $\beta = 1$ . The map also plots contours of isentropic efficiency as a function of pressure ratio and corrected mass flow rate. This provides a relative indication of how much power the compressor needs to operate at various combinations of pressure ratio and corrected mass flow rate.

## Corrected Mass Flow Rate

Due to the large changes in pressure and temperature inside a compressor, the compressor map plots performance in terms of a corrected mass flow rate. The corrected mass flow rate is adjusted from the inlet mass flow rate with a reference pressure and reference temperature:

$$\dot{m}_{corr} = \dot{m}_A \left( \sqrt{\frac{T_A}{T_{ref}}} / \frac{p_A}{p_{ref}} \right),$$

where:

- $\dot{m}_A$  is the mass flow rate at port **A**.
- $T_A$  is the temperature at port **A**.

- $T_{ref}$  is the **Reference temperature for corrected flow**. When you set **Parameterization** to **Analytical**, this is the inlet temperature at the design operating condition.
- $\dot{m}_{corr}$  is the corrected mass flow rate.

When you set **Parameterization** to **Analytical**, the block uses the **Corrected mass flow rate at design point** parameter.

When you set **Parameterization** to **Tabulated**, the block uses the **Corrected mass flow rate table,  $\dot{m}(N,\beta)$**  parameter.

- $p_A$  is the pressure at port **A**.
- $p_{ref}$  is the **Reference pressure for corrected flow** parameter. When using the analytical parameterization, this is the inlet pressure at the design operating condition.

The block derives  $T_A$  from the specific internal energy,  $u_A$ , and specific pressure,  $p_A$ .

### Corrected Speed

The block also adjusts the shaft speed,  $\omega$ , according to the reference temperature, such that the corrected shaft speed is

$$\omega_{corr} = \frac{\omega}{\sqrt{\frac{T_A}{T_{ref}}}}$$

### Shaft Torque

The block calculates the shaft torque,  $\tau$ , as:

$$\tau = \frac{\dot{m}_A \Delta h_{total}}{\eta_m \omega}$$

where:

- $\Delta h_{total}$  is the change in specific total enthalpy.
- $\eta_m$  is the compressor **Mechanical efficiency**.
- $\omega$  is the relative shaft angular velocity,  $\omega_R - \omega_C$ .

The block relates the efficiency in the compressor map as

$$\Delta h_{total} = \frac{\Delta h_{isen}}{\eta_{isen}}$$

where

- $\Delta h_{isen}$  is the isentropic change in specific total enthalpy.
- $\eta_{isen}$  is the isentropic efficiency.

A threshold region when flow approaches zero ensures that no torque is generated when the flow rate is near zero or reversed.

### Analytical Parameterization

You can generate the compressor map analytically by setting **Parameterization** to **Analytical**. The block fits a model of the compressor map based on Greitzer et al, 2010 to the specified values for the

**Corrected speed at design point, Pressure ratio at design point, and Corrected mass flow rate at design point** parameters. This method does not use  $\beta$  lines and the block does not report a surge margin.

### Pressure Ratio

The block finds the pressure ratio at a given shaft speed and mass flow rate as:

$$\pi = 1 + (\pi_D - 1) \left[ \tilde{N}^{ab} + 2\tilde{N}k \ln \left( 1 - \frac{\tilde{m} - \tilde{N}^b}{k} \right) \right],$$

where:

- $\pi_D$  is the **Pressure ratio at design point** parameter.
- $\tilde{N}$  is the normalized corrected shaft speed,

$$\frac{N}{N_D},$$

where  $N_D$  is the **Corrected speed at design point** parameter.

- $\tilde{m}$  is the normalized corrected mass flow rate,

$$\frac{\dot{m}_{corr}}{\dot{m}_D},$$

where  $\dot{m}_D$  is the **Corrected mass flow rate at design point**.

- $a$  is the **Spine shape, a** parameter.
- $b$  is the **Speed line spread, b** parameter.
- $k$  is the **Speed line roundness, k** parameter.

The *spine* refers to the black line where the isentropic efficiency contours start to bend. The map *speed lines* are the shaft constant-speed lines that intersect the spine perpendicularly.

Reload Data

### Analytical Parameterization Default Compressor Map

#### Isentropic Efficiency Parameterization

When you set **Efficiency specification** to Analytical, the block models variable compressor efficiency as:

$$\eta = \eta_0 \left( 1 - C \left| \frac{\tilde{p}}{\tilde{m}^{a+\Delta a} - 1} - \tilde{m} \right|^c - D \left| \frac{\tilde{m}}{\tilde{m}_0} - 1 \right|^d \right),$$

where:

- $\eta_0$  is the **Maximum isentropic efficiency** parameter.
- $C$  is the **Efficiency contour gradient orthogonal to spine, C** parameter.
- $D$  is the **Efficiency contour gradient along spine, D** parameter.
- $c$  is the **Efficiency peak flatness orthogonal to spine, c** parameter.
- $d$  is the **Efficiency peak flatness along spine, d** parameter.
- $\tilde{p}$  is the normalized corrected pressure ratio,

$$\frac{\pi - 1}{\pi_D - 1},$$

where  $\pi_D$  is the **Corrected pressure ratio at design point** parameter.

- $\tilde{m}_0$  is the normalized corrected mass flow rate at which the compressor reaches its **Maximum isentropic efficiency** parameter.

You can adjust the efficiency variables for different performance characteristics.

Alternatively, you can choose a constant efficiency value by using the **Constant isentropic efficiency** parameter.

### Tabulated Data Parameterization

When you set **Parameterization** to **Tabulated**, the isentropic efficiency, pressure ratio, and corrected mass flow rate of the compressor are functions of the corrected speed,  $N$ , and the map index,  $\beta$ . The block uses linear interpolation between data points for the efficiency, pressure ratio, and corrected mass flow rate.

If  $\beta$  exceeds 1, compressor surge occurs, and the block assumes the pressure ratio remains at  $\beta = 1$ , while the mass flow rate continues to change. If the simulation conditions fall below  $\beta = 0$ , the block includes the effects of choked flow: the mass flow rate remains at its value at  $\beta = 0$ , while the pressure ratio continues to change. To constrain the compressor performance within the map boundaries, the block extrapolates isentropic efficiency to the nearest point.

You can choose to be notified when the operating point pressure ratio exceeds the surge pressure ratio. Set **Report when surge margin is negative** to **Warning** to receive a warning or to **Error** to stop the simulation when this occurs.

Reload Data

### Tabulated Parameterization Default Compressor Map

#### Continuity Equations

The block conserves mass such that

$$\dot{m}_A + \dot{m}_B = 0,$$

where  $\dot{m}_B$  is the mass flow rate at port **B**.

The block computes the energy balance equation as

$$\Phi_A + \Phi_B + P_{fluid} = 0,$$

where:

- $\Phi_A$  is the energy flow rate at port **A**.
- $\Phi_B$  is the energy flow rate at port **B**.
- $P_{fluid}$  is the hydraulic power delivered to the fluid, which is determined from the change in specific :  $P_{fluid} = \dot{m}_A \Delta h_{total}$ .

## Assumptions and Limitations

- The block assumes that superheated fluid enters at **A**.
- The block only defines compressor map flow from port **A** to port **B**. Reverse flow results may not be accurate.
- The block only represents dynamic compressors.

## Ports

### Conserving

**A** — Gas inlet  
gas

Fluid entry port.

**B** — Gas outlet  
gas

Fluid exit port.

**C** — Compressor casing  
mechanical translational

Port associated with the compressor casing.

**R** — Compressor shaft  
mechanical translational

Port associated with the compressor shaft torque and angular velocity.

### Output

**SM** — Surge margin  
physical signal

Physical signal output port associated with the surge margin at a given mass flow rate. The block calculates the surge margin as

$$SM(\dot{m}_{corr}) = \frac{p_{r, surge}(\dot{m}_{corr})}{p_r(\dot{m}_{corr})} - 1.$$

### Dependencies

To enable this port, set **Parameterization** to Tabulated.

## Parameters

### Compressor Map

**Parameterization** — Compressor performance parameterization  
Analytical (default) | Tabulated

Compressor performance parameterization.

- **Analytical**: A pressure ratio-corrected mass flow rate curve defines peak compressor performance. You can choose to model isentropic efficiency as a constant or analytically.
- **Tabulated**: A user-supplied compressor map defines the compressor performance. The compressor operating points are determined by linear interpolation between the corrected mass flow rate, pressure ratio, and isentropic efficiency tables at given points in the user-provided corrected shaft speed and  $\beta$  vectors. The default map comes from data reported in [3].

**Corrected speed at design point** — Operational corrected shaft speed  
10000 rpm (default) | positive scalar

Shaft speed at the intended compressor pressure ratio and corrected mass flow rate, corrected for temperature.

**Dependencies**

To enable this parameter, set **Parameterization** to **Analytical**.

**Pressure ratio at design point** — Operational outlet-to-inlet pressure ratio  
26 (default) | positive scalar

Outlet-to-inlet pressure ratio at the intended compressor corrected mass flow rate.

**Dependencies**

To enable this parameter, set **Parameterization** to **Analytical**.

**Corrected mass flow rate at design point** — Operational corrected mass flow rate  
30 kg/s (default) | positive scalar

Mass flow rate at the intended compressor pressure ratio, corrected for temperature and pressure.

**Dependencies**

To enable this parameter, set **Parameterization** to **Analytical**.

**Efficiency specification** — Isentropic efficiency model  
**Analytical** (default) | **Constant**

Isentropic efficiency model type. Choose a constant or variable (analytical) model.

**Dependencies**

To enable this parameter, set **Parameterization** to **Analytical**.

**Maximum isentropic efficiency** — Maximum compressor efficiency  
0.887 (default) | positive scalar in the range (0,1]

Maximum compressor isentropic efficiency. Isentropic efficiency is the ratio of isentropic change to actual change.

**Dependencies**

To enable this parameter, set **Parameterization** to **Analytical** and **Efficiency specification** to **Analytical**.

**Corrected mass flow rate at maximum efficiency point** — Corrected mass flow rate at compressor maximum efficiency  
24 kg/s (default) | positive scalar

Mass flow rate at maximum efficiency, corrected for temperature and pressure. The point of maximum efficiency does not necessarily coincide with the compressor design point.

#### Dependencies

To enable this parameter, set **Parameterization** to Analytical and **Efficiency specification** to Analytical.

**Pressure ratio at maximum efficiency point** — Pressure ratio at compressor maximum efficiency  
17 (default) | positive scalar

Pressure ratio at maximum efficiency. The point of maximum efficiency does not necessarily coincide with the compressor design point.

#### Dependencies

To enable this parameter, set **Parameterization** to Analytical and **Efficiency specification** to Analytical.

**Constant efficiency value** — Constant isentropic efficiency value  
0.8 (default) | positive scalar in the range (0,1]

Value of constant isentropic efficiency in the analytical parameterization.

#### Dependencies

To enable this parameter, set **Parameterization** to Analytical and **Efficiency specification** to Constant.

**Corrected speed index vector, N** — Vector of corrected shaft speeds  
100 .\* [50, 60, 70, 75, 80, 85, 90, 95, 100, 110] rpm (default) | vector

Vector of corrected shaft speeds.

#### Dependencies

To enable this parameter, set **Parameterization** to Tabulated.

**Beta index vector, beta** — Vector of intervals  
0 : 1 / 6 : 1 (default) | vector of elements in the range [0,1]

Vector of relative positions along the corrected speed lines. Choked flow is defined as  $\beta = 0$  and surge flow is defined at  $\beta = 1$ .  $\beta$  lines are perpendicular to the compressor shaft constant speed lines,  $N$ .

#### Dependencies

To enable this parameter, set **Parameterization** to Tabulated.

**Pressure ratio table, pr(N,beta)** — Compressor map pressure ratio data  
[1.369, 1.459, 1.587, 1.654, 1.734, 1.775, 1.82; 1.918, 2.075, 2.229, 2.318, 2.405, 2.456, 2.481; 2.706, 2.966, 3.168, 3.334, 3.404, 3.445, 3.435; 3.203, 3.533, 3.833, 4.021, 4.127, 4.135, 4.066; 3.782, 4.222, 4.565, 4.867, 5.065, 5.07, 4.934; 4.302, 4.861, 5.285, 5.821, 6.161, 6.334, 6.142; 4.841, 5.445, 5.988, 6.628, 7.222, 7.623, 7.573; 5.358, 5.997, 6.589, 7.334, 8.012, 8.668, 9; 5.851, 6.491, 7.124, 7.982, 8.754, 9.57, 9.814; 6.707, 7.321, 8.034, 9.047, 9.94, 10.834, 10.998] (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of compressor outlet-to-inlet pressure ratios at the specified corrected shaft speed and  $\beta$  value. Linear interpolation is employed between table elements.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of vector elements in the **Corrected speed index vector**, **N** parameter.
- $N$  is the number of vector elements in the **Beta index vector**, **beta** parameter.

#### Dependencies

To enable this parameter, set **Parameterization** to Tabulated.

**Corrected mass flow rate table, mdot(N,beta)** — Compressor map corrected mass flow rate data [10.45, 10.203, 9.784, 9.526, 9.144, 8.947, 8.615; 13.315, 13.018, 12.525, 11.984, 11.455, 11.086, 10.914; 17.601, 17.204, 16.502, 15.8, 14.903, 14.179, 13.184; 20.331, 19.983, 19.39, 18.492, 17.435, 16.293, 14.895; 23.466, 23.092, 22.572, 21.807, 20.687, 19.3, 17.682; 26.295, 26.091, 25.766, 25.28, 24.453, 23.26, 21.311; 29.013, 28.747, 28.641, 28.412, 28.06, 27.098, 25.306; 31.424, 31.379, 31.273, 31.103, 30.849, 30.484, 29.718; 33.688, 33.606, 33.561, 33.513, 33.392, 33.258, 33.059; 37.678, 37.621, 37.575, 37.598, 37.501, 37.415, 37.413] (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of corrected mass flow rates at the specified corrected shaft speed and  $\beta$  value. Linear interpolation is employed between table elements.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of vector elements in the **Corrected speed index vector**, **N** parameter.
- $N$  is the number of vector elements in the **Beta index vector**, **beta** parameter.

#### Dependencies

To enable this parameter, set **Parameterization** to Tabulated.

**Isentropic efficiency table, eta(N,beta)** — Compressor map isentropic efficiency data [.68, .69, .695, .7, .701, .705, .704; .7, .725, .75, .755, .745, .73, .725; .77, .795, .81, .805, .78, .765, .745; .795, .812, .825, .82, .805, .78, .75; .82, .837, .848, .849, .835, .805, .78; .83, .845, .856, .86, .855, .84, .8; .83, .848, .859, .869, .86, .852, .83; .828, .845, .857, .869, .862, .855, .85; .806, .83, .85, .86, .859, .857, .853; .79, .8, .82, .835, .845, .848, .849] (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of compressor isentropic efficiencies at the specified corrected shaft speed and  $\beta$  value. Linear interpolation is employed between table elements.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of vector elements in the **Corrected speed index vector**, **N** parameter.
- $N$  is the number of vector elements in the **Beta index vector**, **beta** parameter.

#### Dependencies

To enable this parameter, set **Parameterization** to Tabulated.

**Report when surge margin is negative** — Whether to notify if pressure ratio exceeds surge pressure ratio  
None (default) | Warning | Error

Whether to notify if the compressor operating point pressure ratio exceeds the surge pressure ratio at the given corrected mass flow rate.

#### Dependencies

To enable this parameter, set **Parameterization** to Tabulated.

#### Map Coefficients

To enable the **Map Coefficients** parameters, set **Parameterization** to Analytical.

**Spine shape, a** — Spine shape exponent

1.5 (default) | positive scalar

Exponent in the analytical parameterization of the compressor map that characterizes the spine shape.

#### Dependencies

To enable this parameter, set **Parameterization** to Analytical.

**Speed line spread, b** — Constant speed line spacing exponent

5 (default) | positive scalar

Exponent in the analytical parameterization of the compressor map that characterizes the constant speed line spacing.

#### Dependencies

To enable this parameter, set **Parameterization** to Analytical.

**Speed line roundness, k** — Constant speed line shape coefficient

0.03 (default) | positive scalar

Coefficient in the analytical parameterization of the compressor map that characterizes the constant speed line shape.

#### Dependencies

To enable this parameter, set **Parameterization** to Analytical.

**Efficiency peak flatness orthogonal to spine, c** — Exponent characterizing shape of analytical isentropic efficiency

3 (default) | positive scalar

Exponent associated with the compressor map peak flatness orthogonal to the spine.

#### Dependencies

To enable this parameter, set **Parameterization** to Analytical and **Efficiency specification** to Analytical.

**Efficiency peak flatness along spine, d** — Exponent characterizing shape of analytical isentropic efficiency

4 (default) | positive scalar

Exponent associated with the efficiency map peak flatness along the spine.

**Dependencies**

To enable this parameter, set **Parameterization** to Analytical and **Efficiency specification** to Analytical.

**Efficiency contour gradient orthogonal to spine, C** — Coefficient characterizing shape of analytical isentropic efficiency  
15 (default) | positive scalar

Coefficient associated with the efficiency contour gradient orthogonal to the spine.

**Dependencies**

To enable this parameter, set **Parameterization** to Analytical and **Efficiency specification** to Analytical.

**Efficiency contour gradient along spine, D** — Coefficient characterizing shape of analytical isentropic efficiency  
1.0 (default) | positive scalar in the range (0,1]

Coefficient associated with the efficiency contour gradient along the spine.

**Dependencies**

To enable this parameter, set **Parameterization** to Analytical and **Efficiency specification** to Analytical.

**Reference Data**

**Reference pressure for corrected flow** — Correcting pressure  
0.101325 MPa (default) | positive scalar

Reference inlet pressure for compressor map. When **Parameterization** is set to Tabulated, the data supplier specifies this value. When you set **Parameterization** to Analytical, this is the inlet pressure at the design operating condition.

**Reference temperature for corrected flow** — Correcting temperature  
288.15 K (default) | positive scalar

Reference inlet temperature for compressor map. When you set **Parameterization** to Tabulated, the data supplier specifies this value. When you set **Parameterization** to Analytical, this is the inlet temperature at the design operating condition.

**Mechanical efficiency** — Efficiency of conversion to torque  
0.9 (default) | positive scalar in the range [0,1]

Ratio of the power delivered to the fluid flow to the power driving the mechanical shaft.

**Inlet area at port A** — Compressor inlet area  
1 m<sup>2</sup> (default) | positive scalar

Compressor inlet cross-sectional area.

**Outlet area at port B** — Compressor outlet area  
1 m<sup>2</sup> (default) | positive scalar

Compressor outlet cross-sectional area.

## Condenser Evaporator (2P-MA)

Models heat exchange between a moist air network and a network that can undergo phase change

### Libraries:

Simscape / Fluids / Fluid Network Interfaces / Heat Exchangers

### Description

The Condenser Evaporator (2P-MA) block models a heat exchanger with one moist air network, which flows between ports **A2** and **B2**, and one two-phase fluid network, which flows between ports **A1** and **B1**. The heat exchanger can act as a condenser or as an evaporator. The fluid streams can be aligned in parallel, counter, or cross-flow configurations.

### Example Heat Exchanger for Refrigeration Applications

You can model the moist air side as flow within tubes, flow around the two-phase fluid tubing, or by an empirical, generic parameterization. The moist air side comprises air, trace gas, and water vapor that may condense throughout the heat exchange cycle. The block model accounts for energy transfer from the air to the liquid water condensation layer. This liquid layer does not collect on the heat

transfer surface and is assumed to be completely removed from the downstream moist air flow. The moisture condensation rate is returned as a physical signal at port **W**.

The block uses the Effectiveness-NTU (E-NTU) method to model heat transfer through the shared wall. Fouling on the exchanger walls, which increases thermal resistance and reduces the heat exchange between the two fluids, is also modeled. You can also optionally model fins on both the moist air and two-phase fluid sides. Pressure loss due to viscous friction on both sides of the exchanger can be modeled analytically or by generic parameterization, which you can use to tune to your own data.

You can model the two-phase fluid side as flow within a tube or a set of tubes. The two-phase fluid tubes use a boundary-following model to track the sub-cooled liquid (L), vapor-liquid mixture (M), and super-heated vapor (V) in three zones. The relative amount of space a zone occupies in the system is called a *zone length fraction* within the system.

### Zone Length Fractions in the Two-Phase Fluid Piping

The sum of the zone length fractions in the two-phase fluid tubing equals 1. Port **Z** returns the zone length fractions as a vector of physical signals for each of the three phases: [L, M, V].

### Heat Exchanger Configuration

The heat exchanger effectiveness is based on the selected heat exchanger configuration, the fluid properties in each phase, the tube geometry and flow configuration on each side of the exchanger, and the usage and size of fins.

**Flow Arrangement**

The **Flow arrangement** parameter assigns the relative flow paths between the two sides:

- Parallel flow indicates the fluids are moving in the same direction.
- Counter flow indicates the fluids are moving in parallel, but opposite directions.
- Cross flow indicates the fluids are moving perpendicular to each other.

**Thermal Mixing**

When **Flow arrangement** is set to Cross flow, use the **Cross flow arrangement** parameter to indicate whether the two-phase fluid or moist air flows are separated into multiple paths by baffles or walls. Without these separations, the flow can mix freely and is considered *mixed*. Both fluids, one fluid, or neither fluid can be mixed in the cross-flow arrangement. Mixing homogenizes the fluid temperature along the direction of flow of the second fluid, and varies perpendicular to the second fluid flow.

Unmixed flows vary in temperature both along and perpendicular to the flow path of the second fluid.

### Sample Cross-Flow Configurations

Note that the flow direction during simulation does not impact the selected flow arrangement setting. The ports on the block do not reflect the physical positions of the ports in the physical heat exchange system.

All flow arrangements are single-pass, which means that the fluids do not make multiple turns in the exchanger for additional points of heat transfer. To model a multi-pass heat exchanger, you can arrange multiple Condenser Evaporator (2P-MA) blocks in series or in parallel.

For example, to achieve a two-pass configuration on the two-phase fluid side and a single-pass configuration on the moist air side, you can connect the two-phase fluid sides in series and the moist air sides to the same input in parallel (such as two Mass Flow Rate Source blocks with half of the total mass flow rate), as shown below.

### Flow Geometry

The **Flow geometry** parameter sets the moist air flow arrangement as either inside a tube or set of tubes, or perpendicular to a tube bank. You can also specify an empirical, generic configuration. The two-phase fluid always flows inside a tube or set of tubes.

When **Flow geometry** is set to Flow perpendicular to bank of circular tubes, use the **Tube bank grid arrangement** parameter to define the two-phase fluid tube bank alignment as either *Inline* or *Staggered*. The red, downward-pointing arrow indicates the direction of moist air flow. Also indicated in the *Inline* figure are the **Number of tube rows along flow direction** and the **Number of tube segments in each tube row** parameters. Here, *flow direction* refers to the moist air flow, and *tube* refers to the two-phase fluid tubing. The **Length of each tube segment in a tube row** parameter is indicated in the *Staggered* figure.

Number of tube segments  
in each tube row

### Inline

### Staggered

Length of each tube  
segment in a tube row

## Fins

The heat exchanger configuration is without fins when the **Total fin surface area** parameter is set to 0 m<sup>2</sup>. Fins introduce additional surface area for additional heat transfer. Each fluid side has a separate fin area.

## Effectiveness-NTU Heat Transfer

The heat transfer rate is calculated for each fluid phase. In accordance with the three fluid zones that occur on the two-phase fluid side of the heat exchanger, the heat transfer rate is calculated in three sections.

The heat transfer in a zone is calculated as:

$$Q_{zone} = \epsilon C_{\text{Min}}(T_{\text{In},2P} - T_{\text{In},\text{MA}}),$$

where:

- $C_{\text{Min}}$  is the lesser of the heat capacity rates of the two fluids in that zone. The heat capacity rate is the product of the fluid specific heat,  $c_p$ , and the fluid mass flow rate.  $C_{\text{Min}}$  is always positive.
- $T_{\text{In},2P}$  is the zone inlet temperature of the two-phase fluid.
- $T_{\text{In},\text{MA}}$  is the zone inlet temperature of the moist air.
- $\epsilon$  is the heat exchanger effectiveness.

Effectiveness is a function of the heat capacity rate and the number of transfer units,  $NTU$ , and also varies based on the heat exchanger flow arrangement, which is discussed in more detail in “Effectiveness by Flow Arrangement” on page 1-558. The  $NTU$  is calculated as:

$$NTU = \frac{z}{C_{\text{Min}}R},$$

where:

- $z$  is the individual zone length fraction.
- $R$  is the total thermal resistance between the two flows, due to convection, conduction, and any fouling on the tube walls:

$$R = \frac{1}{U_{2P}A_{\text{Th},2P}} + \frac{F_{2P}}{A_{\text{Th},2P}} + R_W + \frac{F_{\text{MA}}}{A_{\text{Th},\text{MA}}} + \frac{1}{U_{\text{MA}}A_{\text{Th},\text{MA}}},$$

where:

- $U$  is the convective heat transfer coefficient of the respective fluid. This coefficient is discussed in more detail in “Two-Phase Fluid Correlations” on page 1-560 and “Moist Air Correlations” on page 1-563.
- $F$  is the **Fouling factor** on the two-phase fluid or moist air side, respectively.
- $R_W$  is the **Thermal resistance through heat transfer surface**.
- $A_{\text{Th}}$  is the heat transfer surface area of the respective side of the exchanger.  $A_{\text{Th}}$  is the sum of the wall surface area,  $A_W$ , and the **Total fin surface area**,  $A_F$ :

$$A_{\text{Th}} = A_W + \eta_F A_F,$$

where  $\eta_F$  is the **Fin efficiency**.

The total heat transfer rate between the fluids is the sum of the heat transferred in the three zones by the subcooled liquid ( $Q_L$ ), liquid-vapor mixture ( $Q_M$ ), and superheated vapor ( $Q_V$ ):

$$Q = \sum Q_Z = Q_L + Q_M + Q_V.$$

### Effectiveness by Flow Arrangement

The heat exchanger effectiveness varies according to its flow configuration and the mixing in each fluid. Below are the formulations for effectiveness calculated in the liquid and vapor zones for each configuration. The effectiveness is  $\epsilon = 1 - \exp(-NTU)$  for all configurations in the mixture zone.

- When **Flow arrangement** is set to Parallel flow:

$$\epsilon = \frac{1 - \exp[-NTU(1 + C_R)]}{1 + C_R}$$

- When **Flow arrangement** is set to Counter flow:

$$\epsilon = \frac{1 - \exp[-NTU(1 - C_R)]}{1 - C_R \exp[-NTU(1 - C_R)]}$$

- When **Flow arrangement** is set to Cross flow and **Cross flow arrangement** is set to Both fluids unmixed:

$$\epsilon = 1 - \exp\left\{\frac{NTU^{0.22}}{C_R} [\exp(-C_R NTU^{0.78}) - 1]\right\}$$

- When **Flow arrangement** is set to Cross flow and **Cross flow arrangement** is set to Both fluids mixed:

$$\epsilon = \left[ \frac{1}{1 - \exp(-NTU)} + \frac{C_R}{1 - \exp(-C_R NTU)} - \frac{1}{NTU} \right]^{-1}$$

When one fluid is mixed and the other unmixed, the equation for effectiveness depends on the relative heat capacity rates of the fluids. When **Flow arrangement** is set to Cross flow and **Cross flow arrangement** is set to either Two-Phase Fluid 1 mixed & Moist Air 2 unmixed or Two-Phase Fluid 1 unmixed & Moist Air 2 mixed:

- When the fluid with  $C_{\max}$  is mixed and the fluid with  $C_{\min}$  is unmixed:

$$\epsilon = \frac{1}{C_R} (1 - \exp\{-C_R [1 - \exp(-NTU)]\})$$

- When the fluid with  $C_{\min}$  is mixed and the fluid with  $C_{\max}$  is unmixed:

$$\epsilon = 1 - \exp\left\{-\frac{1}{C_R} [1 - \exp(-C_R NTU)]\right\}$$

$C_R$  denotes the ratio between the heat capacity rates of the two fluids:

$$C_R = \frac{C_{\min}}{C_{\max}}.$$

### Condensation

On the moist air side, a layer of condensation may form on the heat transfer surface. This liquid layer can influence the amount of heat transferred between the moist air and two-phase fluid. The

equations for E-NTU heat transfer above are given for *dry* heat transfer. To correct for the influence of condensation, the E-NTU equations are additionally calculated with the wet parameters listed below. Whichever of the two calculated heat flow rates results in a larger amount of moist air side cooling is used in heat calculations for each zone [1]. To use this method, the Lewis number is assumed to be close to 1 [1], which is true for moist air.

### E-NTU Quantities Used for Heat Transfer Rate Calculations

	Dry calculation	Wet calculation
Moist air zone inlet temperature	$T_{in,MA}$	$T_{in,wb,MA}$
Heat capacity rate	$\bar{m}_{MA}\bar{c}_{p,MA}$	$\bar{m}_{MA}\bar{c}_{eq,MA}$
Heat transfer coefficient	$U_{MA}$	$U_{MA}\frac{\bar{c}_{eq,MA}}{\bar{c}_{p,MA}}$

where:

- $T_{in,MA}$  is the moist air zone inlet temperature.
- $T_{in,wb,MA}$  is the moist air wet-bulb temperature associated with  $T_{in,MA}$ .
- $\bar{m}_{MA}$  is the dry air mass flow rate.
- $\bar{c}_{p,MA}$  is the moist air heat capacity per unit mass of dry air.
- $\bar{c}_{eq,MA}$  is the equivalent heat capacity. The *equivalent heat capacity* is the change in the moist air specific enthalpy (per unit of dry air),  $\bar{h}_{MA}$ , with respect to temperature at saturated moist air conditions:

$$\bar{c}_{eq,MA} = \left( \frac{\partial \bar{h}_{MA}}{\partial T_{MA}} \right)_s.$$

The mass flow rate of the condensed water vapor leaving the moist air mass flow depends on the relative humidity between the moist air inlet and the channel wall and the heat exchanger NTUs:

$$\dot{m}_{cond} = -\bar{m}_{MA}(W_{wall,MA} - W_{in,MA})\left(1 - e^{-NTU_{MA}}\right),$$

where:

- $W_{wall,MA}$  is the humidity ratio at the heat transfer surface.
- $W_{in,MA}$  is the humidity ratio at the moist air flow inlet.
- $NTU_{MA}$  is the number of transfer units on the moist air side, calculated as:

$$NTU_{MA} = \frac{U_{MA}\frac{\bar{c}_{eq,MA}}{\bar{c}_{p,MA}}A_{Th,MA}}{\bar{m}_{MA}\bar{c}_{eq,MA}}.$$

The energy flow associated with water vapor condensation is based on the difference between the vapor specific enthalpy,  $h_{water,wall}$ , and the specific enthalpy of vaporization,  $h_{fg}$ , for water:

$$\phi_{Cond} = \dot{m}_{cond}(h_{water,wall} - h_{fg}).$$

The condensate is assumed to not accumulate on the heat transfer surface, and does not influence geometric parameters such as tube diameter. The condensed water is assumed to be completely removed from the downstream moist air flow.

## Two-Phase Fluid Correlations

### Heat Transfer Coefficient

The convective heat transfer coefficient varies according to the fluid Nusselt number:

$$U = \frac{Nu k}{D_H},$$

where:

- $Nu$  is the zone mean Nusselt number, which depends on the flow regime.
- $k$  is the fluid phase thermal conductivity.
- $D_H$  is tube hydraulic diameter.

For turbulent flows in the subcooled liquid or superheated vapor zones, the Nusselt number is calculated with the Gnielinski correlation:

$$Nu = \frac{\frac{f_D}{8}(Re - 1000)Pr}{1 + 12.7\sqrt{\frac{f_D}{8}}(Pr^{2/3} - 1)},$$

where:

- $Re$  is the fluid Reynolds number.
- $Pr$  is the fluid Prandtl number.

For turbulent flows in the liquid-vapor mixture zone, the Nusselt number is calculated with the Cavallini-Zecchin correlation:

$$Nu = \frac{a Re_{SL}^b Pr_{SL}^c \left\{ \left[ \left( \sqrt{\frac{\rho_{SL}}{\rho_{SV}}} - 1 \right) x_{Out} + 1 \right]^{1+b} - \left[ \left( \sqrt{\frac{\rho_{SL}}{\rho_{SV}}} - 1 \right) x_{In} + 1 \right]^{1+b} \right\}}{(1+b) \left( \sqrt{\frac{\rho_{SL}}{\rho_{SV}}} - 1 \right) (x_{Out} - x_{In})}.$$

where:

- $Re_{SL}$  is the Reynolds number of the saturated liquid.
- $Pr_{SL}$  is the Prandtl number of the saturated liquid.
- $\rho_{SL}$  is the density of the saturated liquid.
- $\rho_{SV}$  is the density of the saturated vapor.
- $a = 0.05$ ,  $b = 0.8$ , and  $c = 0.33$ .

For laminar flows, the Nusselt number is set by the **Laminar flow Nusselt number** parameter.

For transitional flows, the Nusselt number is a blend between the laminar and turbulent Nusselt numbers.

### Empirical Nusselt Number Formulation

When the **Heat transfer coefficient model** parameter is Colburn equation, the block calculates the Nusselt number for the subcooled liquid and superheated vapor zones by using the empirical Colburn equation

$$Nu = aRe^bPr^c,$$

where  $a$ ,  $b$ , and  $c$  are values in the **Coefficients [a, b, c] for a\*Re<sup>b</sup>\*Pr<sup>c</sup> in liquid zone** and **Coefficients [a, b, c] for a\*Re<sup>b</sup>\*Pr<sup>c</sup> in vapor zone** parameters.

The block calculates the Nusselt number for liquid-vapor mixture zones by using the Cavallini-Zecchin equation with the variables in the **Coefficients [a, b, c] for a\*Re<sup>b</sup>\*Pr<sup>c</sup> in mixture zone** parameter.

### Pressure Loss

The pressure loss due to viscous friction varies depending on flow regime and configuration. The pressure loss calculation uses the overall density, which is the total fluid mass divided by the total fluid volume. When the **Pressure loss model** parameter is Correlation for flow inside tubes, the pressure loss due to friction depends on the Darcy friction factor.

For turbulent flows, when the Reynolds number is above the **Turbulent flow lower Reynolds number limit** parameter, the block calculates the pressure loss due to friction in terms of a calculated Darcy friction factor. The pressure differential between port **A1** and the internal node I1 is:

$$p_{A1} - p_{I1} = \frac{f_{D,A} \dot{m}_{A1} |\dot{m}_{A1}| (L + L_{Add})}{2\rho D_H A_{CS}^2 \left(\frac{L + L_{Add}}{2}\right)},$$

where:

- $\dot{m}_{A1}$  is the total flow rate through port **A1**.
- $f_{D,A}$  is the Darcy friction factor according to the Haaland correlation. When the **Local resistance specification** parameter is Aggregate equivalent length,

$$f_{D,A1} = \left\{ -1.8 \log_{10} \left[ \frac{6.9}{Re_{A1}} + \left( \frac{\epsilon_R}{3.7 D_H} \right)^{1.11} \right] \right\}^{-2},$$

where  $\epsilon_R$  is the value of the **Internal surface absolute roughness** parameter. The friction factor is dependent on the Reynolds number, and the block calculates this value at both ports for each liquid.

- $L$  is the value of the **Total length of each tube** parameter.
- $L_{Add}$  is the value of the **Aggregate equivalent length of local resistances** parameter, which is the equivalent length of a tube that introduces the same amount of loss as the sum of the losses due to other local resistances in the tube.
- $A_{CS}$  is the tube cross-sectional area.

The pressure differential between port **B1** and internal node I1 is:

$$p_{B1} - p_{I1} = \frac{f_{D,B} \dot{m}_{B1} |\dot{m}_{B1}| (L + L_{Add})}{2\rho D_H A_{CS}^2 \left(\frac{L + L_{Add}}{2}\right)},$$

where  $\dot{m}_{B1}$  is the total flow rate through port **B1**.

When the **Local resistance specification** parameter is **Aggregate equivalent length**, the Darcy friction factor at port **B1** is:

$$f_{D,B1} = \left\{ -1.8 \log_{10} \left[ \frac{6.9}{\text{Re}_{B1}} + \left( \frac{\epsilon_R}{3.7 D_H} \right)^{1.11} \right] \right\}^{-2}.$$

When the **Local resistance specification** parameter is **Local loss coefficient**, the Darcy friction factors at ports **A1** and **B1** are

$$f_{D,A1} = \left\{ -1.8 \log_{10} \left[ \frac{6.9}{\text{Re}_{A1}} + \left( \frac{\epsilon_R}{3.7 D_H} \right)^{1.11} \right] \right\}^{-2} + C_{localloss} \left( \frac{D_H}{L} \right)$$

$$f_{D,B1} = \left\{ -1.8 \log_{10} \left[ \frac{6.9}{\text{Re}_{B1}} + \left( \frac{\epsilon_R}{3.7 D_H} \right)^{1.11} \right] \right\}^{-2} + C_{localloss} \left( \frac{D_H}{L} \right)$$

where  $C_{localloss}$  is the value of the **Total local loss coefficient** parameter.

For laminar flows, when the Reynolds number is below the **Laminar flow upper Reynolds number limit** parameter, the block calculates the pressure loss due to friction in terms of the **Laminar friction constant for Darcy friction factor** parameter,  $\lambda$ .  $\lambda$  is a user-defined parameter when **Tube cross-section** is **Generic**. Otherwise, the block calculates the value internally. The pressure differential between port **A1** and internal node I1 is:

$$p_{A1} - p_{I1} = \frac{\lambda \dot{m}_{A1}}{2 \rho D_H^2 A_{CS}} \left( \frac{L + L_{Add}}{2} \right),$$

where  $\mu$  is the fluid dynamic viscosity. The pressure differential between port **B1** and internal node I1 is:

$$p_{B1} - p_{I1} = \frac{\lambda \dot{m}_{B1}}{2 \rho D_H^2 A_{CS}} \left( \frac{L + L_{Add}}{2} \right).$$

For transitional flows, the pressure differential due to viscous friction is a smoothed blend between the values for laminar and turbulent pressure losses.

### Empirical Pressure Loss Formulation

When **Pressure loss model** is set to **Pressure loss coefficient**, the pressure losses due to viscous friction are calculated with an empirical pressure loss coefficient,  $\xi$ .

The pressure differential between port **A1** and internal node I1 is:

$$p_{A1} - p_{I1} = \frac{1}{2} \xi \frac{\dot{m}_{A1} |\dot{m}_{A1}|}{2 \rho A_{CS}^2}.$$

The pressure differential between port **B1** and internal node I1 is:

$$p_{B1} - p_{I1} = \frac{1}{2} \xi \frac{\dot{m}_{B1} |\dot{m}_{B1}|}{2 \rho A_{CS}^2}.$$

## Moist Air Correlations

### Heat Transfer Coefficient for Flows Inside One or More Tubes

When the moist air **Flow geometry** is set to Flow inside one or more tubes, the Nusselt number is calculated according to the Gnielinski correlation in the same manner as two-phase supercooled liquid or superheated vapor. See “Heat Transfer Coefficient” on page 1-560 for more information.

### Heat Transfer Coefficient for Flows Across a Tube Bank

When the moist air **Flow geometry** is set to Flow perpendicular to bank of circular tubes, the Nusselt number is calculated based on the Hagen number,  $Hg$ , and depends on the **Tube bank grid arrangement** setting:

$$Nu = \begin{cases} 0.404Lq^{1/3} \left( \frac{Re+1}{Re+1000} \right)^{0.1}, & \text{Inline} \\ 0.404Lq^{1/3}, & \text{Staggered} \end{cases}$$

where:

$$Lq = \begin{cases} 1.18Pr \left( \frac{4l_T/\pi - D}{l_L} \right) Hg(Re), & \text{Inline} \\ 0.92Pr \left( \frac{4l_T/\pi - D}{l_D} \right) Hg(Re), & \text{Staggered with } l_L \geq D \\ 0.92Pr \left( \frac{4l_T l_L/\pi - D^2}{l_L l_D} \right) Hg(Re), & \text{Staggered with } l_L < D \end{cases}$$

- $D$  is the **Tube outer diameter**.
- $l_L$  is the **Longitudinal tube pitch (along flow direction)**, the distance between the tube centers along the flow direction. *Flow direction* refers to the moist air flow.
- $l_T$  is the **Transverse tube pitch (perpendicular to flow direction)**, shown in the figure below. The transverse pitch is the distance between the centers of the two-phase fluid tubing in one row.
- $l_D$  is the diagonal tube spacing, calculated as  $l_D = \sqrt{\left(\frac{l_T}{2}\right)^2 + l_L^2}$ .

For more information on calculating the Hagen number, see [6].

The longitudinal and transverse pitch distances are the same for both grid bank arrangement types.

### Cross-Section of Two-Phase Fluid Tubing with Pitch Measurements

#### Empirical Nusselt Number Formulation

When the **Heat transfer coefficient model** is set to Colburn equation or when **Flow geometry** is set to Generic, the Nusselt number is calculated by the empirical Colburn equation:

$$\text{Nu} = a\text{Re}^b\text{Pr}^c,$$

where  $a$ ,  $b$ , and  $c$  are the values defined in the **Coefficients [a, b, c] for  $a*\text{Re}^b*\text{Pr}^c$**  parameter.

#### Pressure Loss for Flow Inside Tubes

When the moist air **Flow geometry** is set to Flow inside one or more tubes, the pressure loss is calculated the same way as for two-phase flows, with the respective Darcy friction factor, density, mass flow rates, and pipe lengths of the moist air side. See “Pressure Loss” on page 1-561 for more information.

#### Pressure Loss for Flow Across Tube Banks

When the moist air **Flow geometry** is set to Flow perpendicular to bank of circular tubes, the Hagen number is used to calculate the pressure loss due to viscous friction. The pressure differential between port **A2** and internal node I2 is:

$$p_{A2} - p_{I2} = \frac{1}{2} \frac{\mu^2 N_R}{\rho D^2} \text{Hg}(\text{Re}),$$

where:

- $\mu_{MA}$  is the fluid dynamic viscosity.
- $N_R$  is the **Number of tube rows along flow direction**. This is the number of two-phase fluid tube rows along the moist air flow direction.

The pressure differential between port **B2** and internal node I2 is:

$$p_{B2} - p_{I2} = \frac{1}{2} \frac{\mu^2 N_R}{\rho D^2} \text{Hg}(\text{Re}).$$

### Empirical Pressure Loss Formulation

When the **Pressure loss model** is set to Euler number per tube row or when **Flow geometry** is set to **Generic**, the pressure loss due to viscous friction is calculated with a pressure loss coefficient, in terms of the Euler number,  $Eu$ :

$$Eu = \frac{\xi}{N_R},$$

where  $\xi$  is the empirical pressure loss coefficient.

The pressure differential between port **A2** and internal node I2 is:

$$p_{A2} - p_{I2} = \frac{1}{2} N_R Eu \frac{\dot{m}_{A2} |\dot{m}_{A2}|}{2\rho A_{CS}^2}.$$

The pressure differential between port **B2** and internal node I2 is:

$$p_{B2} - p_{I2} = \frac{1}{2} N_R Eu \frac{\dot{m}_{B2} |\dot{m}_{B2}|}{2\rho A_{CS}^2}.$$

### Conservation Equations

#### Two-Phase Fluid

The total mass accumulation rate in the two-phase fluid is defined as:

$$\frac{dM_{2P}}{dt} = \dot{m}_{A1} + \dot{m}_{B1},$$

where:

- $M_{2P}$  is the total mass of the two-phase fluid.
- $\dot{m}_{A1}$  is the mass flow rate of the fluid at port **A1**.
- $\dot{m}_{B1}$  is the mass flow rate of the fluid at port **B1**.

The flow is positive when flowing into the block through the port.

The energy conservation equation relates the change in specific internal energy to the heat transfer by the fluid:

$$M_{2P} \frac{du_{2P}}{dt} + u_{2P}(\dot{m}_{A1} + \dot{m}_{B1}) = \phi_{A1} + \phi_{B1} - Q,$$

where:

- $u_{2P}$  is the two-phase fluid specific internal energy.
- $\phi_{A1}$  is the energy flow rate at port **A1**.
- $\phi_{B1}$  is the energy flow rate at port **B1**.
- $Q$  is heat transfer rate, which is positive when leaving the two-phase fluid volume.

**Moist Air**

There are three equations for mass conservation on the moist air side: one for the moist air mixture, one for condensed water vapor, and one for the trace gas.

---

**Note** If **Trace gas model** is set to **None** in the Moist Air Properties (MA) block, the trace gas is not modeled in blocks in the moist air network. In the Condenser Evaporator (2P-MA) block, this means that the conservation equation for trace gas is set to 0.

---

The moist air mixture mass accumulation rate accounts for the changes of the entire moist air mass flow through the exchanger ports and the condensation mass flow rate:

$$\frac{dM_{MA}}{dt} = \dot{m}_{A2} + \dot{m}_{B2} - \dot{m}_{Cond}$$

The mass conservation equation for water vapor accounts for the water vapor transit through the moist air side and condensation formation:

$$\frac{dx_w}{dt} M_{MA} + x_w(\dot{m}_{A2} + \dot{m}_{B2} - \dot{m}_{Cond}) = \dot{m}_{w,A2} + \dot{m}_{w,B2} - \dot{m}_{Cond}$$

where:

- $x_w$  is the mass fraction of the vapor.  $\frac{dx_w}{dt}$  is the rate of change of this fraction.
- $\dot{m}_{w,A2}$  is the water vapor mass flow rate at port **A2**.
- $\dot{m}_{w,B2}$  is the water vapor mass flow rate at port **B2**.
- $\dot{m}_{Cond}$  is the rate of condensation.

The trace gas mass balance is:

$$\frac{dx_g}{dt} M_{MA} + x_g(\dot{m}_{A2} + \dot{m}_{B2} - \dot{m}_{Cond}) = \dot{m}_{g,A2} + \dot{m}_{g,B2}$$

where:

- $x_g$  is the mass fraction of the trace gas.  $\frac{dx_g}{dt}$  is the rate of change of this fraction.
- $\dot{m}_{g,A2}$  is the trace gas mass flow rate at port **A2**.
- $\dot{m}_{g,B2}$  is the trace gas mass flow rate at port **B2**.

Energy conservation on the moist air side accounts for the change in specific internal energy due to heat transfer and water vapor condensing out of the moist air mass:

$$M_{MA} \frac{du_{MA}}{dt} + u_{MA}(\dot{m}_{A2} + \dot{m}_{B2} - \dot{m}_{Cond}) = \phi_{A2} + \phi_{B2} + Q - \phi_{Cond}$$

where:

- $\phi_{A2}$  is the energy flow rate at port **A2**.

- $\phi_{B2}$  is the energy flow rate at port **B2**.
- $\phi_{\text{Cond}}$  is the energy flow rate due to condensation.

The heat transferred to or from the moist air,  $Q$ , is equal to the heat transferred from or to the two-phase fluid.

## Ports

### Conserving

**A1** — Two-phase fluid port  
two-phase fluid

Inlet or outlet port associated with the two-phase fluid.

**B1** — Two-phase fluid port  
two-phase fluid

Inlet or outlet port associated with the two-phase fluid.

**A2** — Moist air port  
moist air

Inlet or outlet port associated with the moist air.

**B2** — Moist air port  
moist air

Inlet or outlet port associated with the moist air.

### Output

**Z** — Two-phase fluid zone length fractions  
physical signal

Three-element vector of the zone length fractions in the two-phase fluid channel, returned as a physical signal. The vector takes the form [L, M, V], where L is the sub-cooled liquid, M is the liquid-vapor mixture, and V is the superheated vapor.

**W** — Moist air condensation rate  
physical signal

Water condensation rate in the moist air flow, returned as a physical signal. The condensate does not accumulate on the heat transfer surface.

## Parameters

### Configuration

**Flow arrangement** — Flow path alignment  
Cross flow (default) | Parallel flow | Counter flow

Flow path alignment between the heat exchanger sides. The available flow arrangements are:

- **Parallel flow.** The flows run in the same direction.
- **Counter flow.** The flows run parallel to each other, in the opposite directions.
- **Cross flow.** The flows run perpendicular to each other.

**Cross flow arrangement** — Thermal mixing condition

Two-Phase Fluid 1 unmixed & Moist Air 2 mixed (default) | Both fluids unmixed |  
Two-phase fluid 1 mixed & Moist Air 2 unmixed | Both fluids mixed

Select whether each of the fluids can mix in its channel. Mixed flow means that the fluid is free to move in the transverse direction as it travels along the flow path. Unmixed flow means that the fluid is restricted to travel only along the flow path. For example, a side with fins is considered an unmixed flow.

**Dependencies**

To enable this parameter, set **Flow arrangement** to **Cross flow**.

**Thermal resistance through heat transfer surface** — Wall thermal resistance

0 K/kW (default) | positive scalar

Thermal resistance of the wall that separates the two sides of the heat exchanger. The wall thermal resistance, wall fouling, and fluid convective heat transfer coefficient influence the amount of heat transferred between the flows.

**Cross-sectional area at port A1** — Flow area at port A1

0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the two-phase fluid port **A1**.

**Cross-sectional area at port B1** — Flow area at port B1

0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the two-phase fluid port **B1**.

**Cross-sectional area at port A2** — Flow area at port A2

0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the moist air side port **A2**.

**Cross-sectional area at port B2** — Area normal to flow at port B2

0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the moist air side port **B2**.

**Two-Phase Fluid 1****Number of tubes** — Number of two-phase fluid tubes

25 (default) | positive scalar

Number of two-phase fluid tubes.

**Total length of each tube** — Total length of each two-phase fluid tube

1 m (default) | positive scalar

Total length of each two-phase fluid tube.

**Tube cross section** — Cross-sectional shape of a tube  
Circular (default) | Rectangular | Annular | Generic

Cross-sectional shape of a tube. Use **Generic** to specify an arbitrary cross-sectional geometry.

This parameter specifies the cross-section of one tube.

**Tube inner diameter** — Internal diameter of a single tube  
0.05 m (default) | positive scalar

Internal diameter of the cross-section of one tube. The cross-section and diameter are uniform along the tube. The size of the diameter influences the pressure loss and heat transfer calculations.

**Dependencies**

To enable this parameter, set **Tube cross-section** to **Circular**.

**Tube width** — Internal width of a single tube  
0.05 m (default) | positive scalar

Internal width of the cross-section of one tube. The cross-section and width are uniform along the tube. The width and height influence the pressure loss and heat transfer calculations.

**Dependencies**

To enable this parameter, set **Tube cross-section** to **Rectangular**.

**Tube height** — Internal height of a single tube  
0.05 m (default) | positive scalar

Internal height of one tube. The cross-section and height are uniform along the tube. The width and height influence the pressure loss and heat transfer calculations.

**Dependencies**

To enable this parameter, set **Tube cross-section** to **Rectangular**.

**Annulus inner diameter (heat transfer surface)** — Smaller diameter of annular cross-section  
0.05 m (default) | positive scalar

Smaller diameter of the annular cross-section of one tube. The cross-section and inner diameter are uniform along the tube. The inner diameter influences the pressure loss and heat transfer calculations. Heat transfer occurs through the inner surface of the annulus.

**Dependencies**

To enable this parameter, set **Tube cross-section** to **Annular**.

**Annulus outer diameter** — Larger diameter of annular cross-section  
0.1 m (default) | positive scalar

Larger diameter of the annular cross-section of one tube. The cross-section and outer diameter are uniform along the tube. The outer diameter influences the pressure loss and heat transfer calculations.

**Dependencies**

To enable this parameter, set **Tube cross-section** to **Annular**.

**Cross-sectional area per tube** — Internal area normal to flow in a single tube  
 $0.002 \text{ m}^2$  (default) | positive scalar

Internal flow area of each tube.

**Dependencies**

To enable this parameter, set **Tube cross-section** to Generic.

**Wetted perimeter of tube cross-section for pressure loss** — Perimeter of tube cross-section that fluid touches  
 $0.15 \text{ m}$  (default) | positive scalar

Perimeter of the tube cross-section that the fluid touches. The cross-section and perimeter are uniform along the tube. This value is applied in pressure loss calculations.

**Dependencies**

To enable this parameter, set **Tube cross-section** to Generic.

**Perimeter of tube cross-section for heat transfer** — Perimeter of a single tube for heat transfer calculations  
 $0.15 \text{ m}$  (default) | positive scalar

Tube perimeter for heat transfer calculations. This is often the same as the tube perimeter, but in cases such as the annular cross-section, this may be only the inner or outer diameter, depending on the heat-transferring surface. The cross-section and tube perimeter are uniform along the tube.

**Dependencies**

To enable this parameter, set **Tube cross-section** to Generic.

**Pressure loss model** — Method of pressure loss calculation due to viscous friction  
 Correlation for flow inside tubes (default) | Pressure loss coefficient

Method of pressure loss calculation due to viscous friction. The settings are:

- **Pressure loss coefficient.** Use this setting to calculate the pressure loss based on an empirical loss coefficient.
- **Correlation for flow inside tubes.** Use this setting to calculate the pressure loss based on the pipe flow correlation.

**Pressure loss coefficient,  $\Delta p / (0.5 \cdot \rho \cdot v^2)$**  — Empirical loss coefficient for all pressure losses in channel  
 10 (default)

Empirical loss coefficient for all pressure losses in the channel. This value accounts for wall friction and minor losses due to bends, elbows, and other geometry changes in the channel.

The loss coefficient can be calculated from a nominal operating condition or be tuned to fit experimental data. The loss coefficient is defined as:

$$\xi = \frac{\Delta p}{\frac{1}{2} \rho v^2},$$

where  $\Delta p$  is the pressure drop,  $\rho$  is the two-phase fluid density, and  $v$  is the flow velocity.

**Dependencies**

To enable this parameter, set **Pressure loss model** to Pressure loss coefficient.

**Local resistance specification** — Method for quantifying pressure losses  
Aggregate equivalent length (default) | Local loss coefficient

Method for quantifying pressure losses in the Haaland correlation.

**Dependencies**

To enable this parameter, set **Pressure loss model** to Correlation for flow inside tubes.

**Total local loss coefficient** — Pressure loss coefficient  
0.1 (default) | positive scalar

Local pressure loss coefficient over the system. You can use this parameter to calibrate your system to match experimental results.

**Dependencies**

To enable this parameter, set **Pressure loss model** to Correlation for flow inside tubes and **Local resistance specification** to Local loss coefficient.

**Aggregate equivalent length of local resistances** — Combined length of all local resistances per tube  
0.1 m (default) | positive scalar

Combined length of all local resistances per tube. This value is the length of tubing that results in the same pressure losses as the sum of all minor losses in the tube due to resistances such as bends, tees, or unions. A longer combined length results in larger pressure losses. The block adds the value of this parameter to the **Total length of each tube** parameter in the calculations of pressure loss due to friction.

**Dependencies**

To enable this parameter, set **Pressure loss model** to Correlation for flow inside tubes and **Local resistance specification** to Aggregate equivalent length.

**Internal surface absolute roughness** — Mean surface roughness height  
15e-6 m (default) | positive scalar

Mean height of tube surface defects. A rougher wall results in larger pressure losses in the turbulent regime for pressure loss calculated with the Haaland correlation.

**Dependencies**

To enable this parameter, set either:

- **Pressure loss model**
- **Heat transfer model**

to Correlation for flow inside tubes.

**Laminar flow upper Reynolds number limit** — Largest Reynolds number that indicates laminar flow  
2000 (default) | positive scalar

Largest Reynolds number that indicates laminar flow. Between this value and the **Turbulent flow lower Reynolds number**, the flow regime is transitional.

**Turbulent flow lower Reynolds number limit** — Smallest Reynolds number that indicates turbulent flow

4000 (default) | positive scalar

Smallest Reynolds number that indicates turbulent flow. Between this value and the **Laminar flow upper Reynolds number limit**, the flow regime is transitional.

**Laminar friction constant for Darcy friction factor** — Coefficient of pressure loss due to viscous friction in laminar flows

64 (default) | positive scalar

Coefficient in pressure loss equations for viscous friction in laminar flows. This parameter may also be known as the *shape factor*. The default value corresponds to a circular tube cross-section.

#### Dependencies

To enable this parameter, set **Tube cross section** to Generic and **Pressure loss model** to Correlation for flow inside tubes.

**Heat transfer coefficient model** — Method of calculating heat transfer coefficient between fluid and wall

Correlation for flow inside tubes (default) | Colburn equation

Method of calculating the heat transfer coefficient between the fluid and the wall. The available settings are:

- **Colburn equation**. Use this setting to calculate the heat transfer coefficient with user-defined variables  $a$ ,  $b$ , and  $c$ . In the liquid and vapor zones, the heat transfer coefficient is based on the Colburn equation. In the liquid-vapor mixture zone, the heat transfer coefficient is based on the Cavallini-Zecchin equation.
- **Correlation for flow inside tubes**. Use this setting to calculate the heat transfer coefficient for pipe flows. In the liquid and vapor zones, the heat transfer coefficient is calculated with the Gnielinski correlation. In the liquid-vapor mixture zone, the heat transfer coefficient is calculated with the Cavallini-Zecchin equation.

**Coefficients [a, b, c] for  $a \cdot \text{Re}^b \cdot \text{Pr}^c$  in liquid zone** — Colburn equation coefficients in liquid zone

[.023, .8, .33] (default) | three-element vector of positive scalars

Three-element vector that contains the empirical coefficients of the Colburn equation. Each fluid zone has a distinct Nusselt number, which the block calculates by using the Colburn equation for each zone. The general form of the Colburn equation is:

$$\text{Nu} = a \text{Re}^b \text{Pr}^c.$$

#### Dependencies

To enable this parameter, set **Heat transfer coefficient model** to Colburn equation.

**Coefficients [a, b, c] for  $a \cdot \text{Re}^b \cdot \text{Pr}^c$  in mixture zone** — Cavallini-Zecchin equation coefficients in mixture zone

[.05, .8, .33] (default) | three-element vector of positive scalars

Three-element vector that contains the empirical coefficients for the Cavallini-Zecchin equation. Each fluid zone has a distinct Nusselt number, which the block calculates in the mixture zone by using the Cavallini-Zecchin equation:

$$\text{Nu} = \frac{a \text{Re}_{\text{SL}}^b \text{Pr}_{\text{SL}}^c \left\{ \left[ \left( \sqrt{\frac{\rho_{\text{SL}}}{\rho_{\text{SV}}}} - 1 \right) x_{\text{Out}} + 1 \right]^{1+b} - \left[ \left( \sqrt{\frac{\rho_{\text{SL}}}{\rho_{\text{SV}}}} - 1 \right) x_{\text{In}} + 1 \right]^{1+b} \right\}}{(1+b) \left( \sqrt{\frac{\rho_{\text{SL}}}{\rho_{\text{SV}}}} - 1 \right) (x_{\text{Out}} - x_{\text{In}})}$$

#### Dependencies

To enable this parameter, set **Heat transfer coefficient model** to Colburn equation.

**Coefficients [a, b, c] for  $a \cdot \text{Re}^b \cdot \text{Pr}^c$  in vapor zone** — Colburn equation coefficients in vapor zone

[.023, .8, .33] (default) | three-element vector of positive scalars

Three-element vector that contains the empirical coefficients of the Colburn equation. Each fluid zone has a distinct Nusselt number, which the block calculates by using the Colburn equation for each zone. The general form of the Colburn equation is:

$$\text{Nu} = a \text{Re}^b \text{Pr}^c.$$

#### Dependencies

To enable this parameter, set **Heat transfer coefficient model** to Colburn equation.

**Laminar flow Nusselt number** — Ratio of convective to conductive heat transfer in the laminar flow regime

3.66 (default) | positive scalar

Ratio of convective to conductive heat transfer in the laminar flow regime. The fluid Nusselt number influences the heat transfer rate and depends on the tube cross-section.

#### Dependencies

To enable this parameter, set **Heat transfer coefficient model** to Correlation for flow inside tubes.

**Fouling factor** — Additional thermal resistance due to fouling deposits

0.1 m<sup>2</sup>\*K/kW (default) | positive scalar

Additional thermal resistance due to fouling layers on the surfaces of the wall. In real systems, fouling deposits grow over time. However, the growth is slow enough to be assumed constant during the simulation.

**Total fin surface area** — Total heat transfer surface area of fins

0 m<sup>2</sup> (default) | positive scalar

Total heat transfer surface area of both sides of all fins. For example, if the fin is rectangular, the surface area is double the area of the rectangle.

The total heat transfer surface area is the sum of the channel surface area and the effective fin surface area, which is the product of the **Fin efficiency** and the **Total fin surface area**.

**Fin efficiency** — Ratio of actual-to-ideal transfer rates for fin

0.5 (default) | positive scalar in the range [0,1]

Ratio of actual heat transfer to ideal heat transfer through the fins if the entire fin is at the primary heat transfer surface temperature.

**Initial fluid energy specification** — Initial state of the two-phase fluid

Temperature (default) | Vapor quality | Vapor void fraction | Specific enthalpy | Specific internal energy

Quantity used to describe the initial state of the fluid.

The value for **Initial fluid energy specification** limits the available initial states for the two-phase fluid. When **Initial fluid energy specification** is:

- **Temperature** — Specify an initial state that is a subcooled liquid or superheated vapor. You cannot specify a liquid-vapor mixture because the temperature is constant across the liquid-vapor mixture region.
- **Vapor quality** — Specify an initial state that is a liquid-vapor mixture. You cannot specify a subcooled liquid or a superheated vapor because the liquid mass fraction is 0 and 1, respectively, across the whole region. Additionally, the block limits the pressure to below the critical pressure.
- **Vapor void fraction** — Specify an initial state that is a liquid-vapor mixture. You cannot specify a subcooled liquid or a superheated vapor because the liquid mass fraction is 0 and 1, respectively, across the whole region. Additionally, the block limits the pressure to below the critical pressure.
- **Specific enthalpy** — Specify the specific enthalpy of the fluid. The block does not limit the initial state.
- **Specific internal energy** — Specify the specific internal energy of the fluid. The block does not limit the initial state.

**Initial two-phase fluid pressure** — Fluid pressure at start of simulation

0.101325 MPa (default) | positive scalar

Fluid pressure at the start of the simulation.

**Initial two-phase fluid temperature** — Temperature at start of simulation

293.15 K (default) | positive scalar | two-element vector

Temperature in the two-phase fluid channel at the start of simulation. This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial temperature in the channel. A vector value represents the initial temperature at the inlet and outlet in the form [inlet, outlet]. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

### Dependencies

To enable this parameter, set **Initial fluid energy specification** to Temperature.

**Initial two-phase fluid vapor quality** — Vapor mass fraction at start of simulation

0.5 (default) | positive scalar in the range [0,1] | two-element vector

Vapor mass fraction in the two-phase fluid channel at the start of simulation. This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial vapor quality in the

channel. A vector value represents the initial vapor quality at the inlet and outlet in the form [inlet, outlet]]. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

#### Dependencies

To enable this parameter, set **Initial fluid energy specification** to Vapor quality.

**Initial two-phase fluid vapor void fraction** — Vapor volume fraction at start of simulation  
0.5 (default) | positive scalar in the range [0,1] | two-element vector

Vapor volume fraction in the two-phase fluid channel at the start of simulation. This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial void fraction in the channel. A vector value represents the initial void fraction at the inlet and outlet in the form [inlet, outlet]. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

#### Dependencies

To enable this parameter, set **Initial fluid energy specification** to Vapor void fraction.

**Initial two-phase fluid specific enthalpy** — Enthalpy per unit mass at start of simulation  
1500 kJ/kg (default) | positive scalar | two-element vector

Enthalpy per unit mass in the two-phase fluid channel at the start of simulation. This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial specific enthalpy in the channel. A vector value represents the initial specific enthalpy at the inlet and outlet in the form [inlet, outlet]. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

#### Dependencies

To enable this parameter, set **Initial fluid energy specification** to Specific enthalpy.

**Initial two-phase fluid specific internal energy** — Internal energy per unit mass at start of simulation  
1500 kJ/kg (default) | positive scalar | two-element vector

Internal energy per unit mass in the two-phase fluid channel at the start of simulation. This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial specific internal energy in the channel. A vector value represents the initial specific internal energy at the inlet and outlet in the form [inlet, outlet]. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

#### Dependencies

To enable this parameter, set **Initial fluid energy specification** to Specific internal energy.

### Moist Air 2

**Flow geometry** — Moist air flow configuration  
Flow perpendicular to bank of circular tubes (default) | Flow inside one or more tubes | Generic

Moist air flow path. The flow can run externally over a set of tubes or internal to a tube or set of tubes. You can also specify a generic parameterization based on empirical values.

**Number of tubes** — Number of moist air tubes

25 (default) | positive scalar

Number of moist air tubes. More tubes result in higher pressure losses due to viscous friction, but a larger amount of surface area for heat transfer.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes.

**Total length of each tube** — Total length of each moist air tube

1 m (default) | positive scalar

Total length of each moist air tube.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes.

**Tube cross section** — Cross-sectional shape of a tube

Circular (default) | Rectangular | Annular | Generic

Cross-sectional shape of one tube. Set to Generic to specify an arbitrary cross-sectional geometry.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes.

**Tube inner diameter** — Internal diameter of a single tube

0.05 m (default) | positive scalar

Internal diameter of the cross-section of one tube. The cross-section and diameter are uniform along the tube. The size of the diameter influences the pressure loss and heat transfer calculations.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Circular.

**Tube width** — Internal width of a single tube

0.05 m (default) | positive scalar

Internal width of the cross-section of one tube. The cross-section and width are uniform along the tube. The width and height influence the pressure loss and heat transfer calculations.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Rectangular.

**Tube height** — Internal height of a single tube

0.05 m (default) | positive scalar

Internal height of one tube cross-section. The cross-section and height are uniform along the tube. The width and height influence the pressure loss and heat transfer calculations.

**Dependencies**

To enable this parameter, set **Flow geometry** parameterization of Flow inside one or more tubes and **Tube cross-section** to Rectangular.

**Annulus inner diameter (heat transfer surface)** — Smaller diameter of annular cross-section  
0.05 m (default) | positive scalar

Smaller diameter of the annular cross-section of one tube. The cross-section and inner diameter are uniform along the tube. The inner diameter influences the pressure loss and heat transfer calculations. Heat transfer occurs through the inner surface of the annulus.

**Dependencies**

To enable this parameter, set **Flow geometry** parameterization of Flow inside one or more tubes and **Tube cross-section** to Annular.

**Annulus outer diameter** — Larger diameter of annular cross-section  
0.1 m (default) | positive scalar

Larger diameter of the annular cross-section of one tube. The cross-section and outer diameter are uniform along the tube. The outer diameter influences the pressure loss and heat transfer calculations.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Annular.

**Cross-sectional area per tube** — Internal flow area in each tube  
0.002 m<sup>2</sup> (default) | positive scalar

Internal flow area of each tube.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Generic.

**Wetted perimeter of tube cross-section for pressure loss** — Perimeter of tube cross-section that fluid touches  
0.15 m (default) | positive scalar

Perimeter of the tube cross-section that the fluid touches. The cross-section and perimeter are uniform along the tube. This value is applied in pressure loss calculations.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Generic.

**Perimeter of tube cross-section for heat transfer** — Perimeter of a single tube for heat transfer calculations  
0.15 m (default) | positive scalar

Tube perimeter for heat transfer calculations. This is often the same as the tube perimeter, but in cases such as the annular cross-section, this may be only the inner or outer diameter, depending on the heat-transferring surface. The cross-section and tube perimeter are uniform along the tube.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Generic.

**Pressure loss model** — Method of pressure loss calculation due to viscous friction

Correlation for flow inside tubes (default) | Euler number per tube row | Pressure loss coefficient | Correlation for flow over tube bank

Method of pressure loss calculation due to viscous friction. Different models are available for different flow configurations. The settings are:

- Correlation for flow inside tubes. Use this setting to calculate the pressure loss with the Haaland correlation.
- Pressure loss coefficient. Use this setting to calculate the pressure loss based on an empirical loss coefficient.
- Euler number per tube row. Use this setting to calculate the pressure loss based on an empirical Euler number.
- Correlation for flow over tube bank. Use this setting to calculate the pressure loss based on the Hagen number.

The pressure loss models available depend on the **Flow geometry** setting.

#### Dependencies

When **Flow geometry** is set to Flow inside one or more tubes, **Pressure loss model** can be set to either:

- Pressure loss coefficient.
- Correlation for flow inside tubes.

When **Flow geometry** is set to Flow perpendicular to bank of circular tubes, **Pressure loss model** can be set to either:

- Correlation for flow over tube bank.
- Euler number per tube row.

When **Flow geometry** is set to Generic, the **Pressure loss model** parameter is disabled. Pressure loss is calculated empirically with the **Pressure loss coefficient,  $\Delta_p/(0.5 \cdot \rho \cdot v^2)$**  parameter.

**Pressure loss coefficient,  $\Delta_p/(0.5 \cdot \rho \cdot v^2)$**  — Empirical loss coefficient for all pressure losses in the channel

10 (default) | positive scalar

Empirical loss coefficient for all pressure losses in the channel. This value accounts for wall friction and minor losses due to bends, elbows, and other geometry changes in the channel.

The loss coefficient can be calculated from a nominal operating condition or be tuned to fit experimental data. The pressure loss coefficient is defined as:

$$\xi = \frac{\Delta p}{\frac{1}{2}\rho v^2},$$

where  $\Delta p$  is the pressure drop,  $\rho$  is the two-phase fluid density, and  $v$  is the flow velocity.

#### Dependencies

To enable this parameter, set either:

- **Flow geometry** to Generic.
- **Pressure loss model** to Pressure loss coefficient.

**Local resistance specification** — Method for quantifying pressure losses  
Aggregate equivalent length (default) | Local loss coefficient

Method for quantifying pressure losses in the Haaland correlation.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Pressure loss model** to Correlation for flow inside tubes.

**Total local loss coefficient** — Pressure loss coefficient  
0.1 (default) | positive scalar

Local pressure loss coefficient over the system. You can use this parameter to calibrate your system to match experimental results.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes, **Pressure loss model** to Correlation for flow inside tubes, and **Local resistance specification** to Local loss coefficient.

**Aggregate equivalent length of local resistances** — Combined length of all local resistances per tube  
0.1 m (default) | positive scalar

Combined length of all local resistances per tube. This value is the length of tubing that results in the same pressure losses as the sum of all minor losses in the tube due to resistances such as bends, tees, or unions. A longer combined length results in larger pressure losses. The block adds the value of this parameter to the **Total length of each tube** parameter in the calculations of pressure loss due to friction.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes, **Pressure loss model** to Correlations for flow inside tubes, and **Local resistance specification** to Aggregate equivalent length.

**Internal surface absolute roughness** — Mean surface roughness height  
15e-6 m (default) | positive scalar

Mean height of tube surface defects. A rougher wall results in larger pressure losses in the turbulent regime for pressure loss calculated with the Haaland correlation.

**Dependencies**

To enable this parameter, set either:

- **Pressure loss model**
- **Heat transfer coefficient model**

to Correlation for flow inside tubes.

**Laminar flow upper Reynolds number limit** — Largest Reynolds number that indicates laminar flow

2000 (default) | positive scalar

Largest Reynolds number that indicates laminar flow. Between this value and the **Turbulent flow lower Reynolds number limit**, the flow regime is transitional.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Pressure loss model** to Correlation for flow inside tubes.

**Turbulent flow lower Reynolds number limit** — Smallest Reynolds number that indicates turbulent flow

4000 (default) | positive scalar

Smallest Reynolds number that indicates turbulent flow. Between this value and the **Laminar flow upper Reynolds number limit**, the flow regime is transitional between the laminar and turbulent regimes.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Pressure loss model** to Correlation for flow inside tubes.

**Laminar friction constant for Darcy friction factor** — Coefficient of pressure loss due to viscous friction in laminar flows

64 (default) | positive scalar

Coefficient in pressure loss equations for viscous friction in laminar flows. This parameter is also known as the *shape factor*. The default value corresponds to a circular tube cross-section.

**Dependencies**

To enable this parameter, set **Flow geometry** to Correlation for flow inside tubes, **Tube cross section** to Generic, and **Pressure loss model** to Correlation for flow inside tubes.

**Heat transfer coefficient model** — Method of calculating heat transfer coefficient between fluid and wall

Correlation for flow over tube bank (default) | Colburn equation | Correlation for flow inside tubes

Method of calculating the heat transfer coefficient between the fluid and the wall. The available settings are:

- Colburn equation. Use this setting to calculate the heat transfer coefficient with user-defined variables  $a$ ,  $b$ , and  $c$  of the Colburn equation.

- Correlation for flow over tube bank. Use this setting to calculate the heat transfer coefficient based on the tube bank correlation using the Hagen number.
- Correlation for flow inside tubes. Use this setting to calculate the heat transfer coefficient for pipe flows with the Gnielinski correlation.

### Dependencies

To enable this parameter, set **Flow geometry** to either:

- Flow perpendicular to bank of circular tubes.
- Flow inside one or more tubes.

**Coefficients [a, b, c] for  $a \cdot Re^b \cdot Pr^c$**  — Colburn equation coefficients  
[0.023, 0.8, 0.33] (default) | three-element vector

Three-element vector containing the empirical coefficients of the Colburn equation. The Colburn equation is a formulation for calculating the Nusselt Number. The general form of the Colburn equation is:

$$Nu = aRe^bPr^c.$$

When the **Heat transfer coefficient model** is set to **Colburn equation** and **Flow geometry** is set to Flow inside one or more tubes, or **Flow geometry** is set to Generic, the default Colburn equation is:

$$Nu = 0.023Re^{0.8}Pr^{1/3}.$$

When the **Heat transfer coefficient model** is set to **Colburn equation** and **Flow geometry** is set to Flow perpendicular to bank of circular tubes, the default Colburn equation is:

$$Nu = 0.27Re^{0.63}Pr^{0.36}.$$

### Dependencies

To enable this parameter, set:

#### 1 **Flow geometry** to either:

- Flow inside one or more tubes
- Flow perpendicular to bank of circular tubes

and **Heat transfer coefficient model** to Colburn equation.

#### 2 **Flow geometry** to Generic.

**Laminar flow Nusselt number** — Ratio of convective to conductive heat transfer in laminar flow regime

3.66 (default) | positive scalar

Ratio of convective to conductive heat transfer in the laminar flow regime. The fluid Nusselt number influences the heat transfer rate and depends on the tube cross-section.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes, **Tube cross-section** to Generic, and **Heat transfer parameterization** to Correlation for flow inside tubes.

**Tube bank grid arrangement** — Geometrical placement of tube rows in the bank  
Inline (default) | Staggered

Alignment of tubes in a tube bank. Rows are either in line with their neighbors, or staggered.

- **Inline:** All tube rows are located directly behind each other.
- **Staggered:** Tubes of the one tube row are located at the gap between tubes of the previous tube row.

Tube alignment influences the Nusselt number and the heat transfer rate.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Number of tube rows along flow direction** — Number of tube rows in tube bank  
5 (default) | positive scalar

Number of two-phase fluid tube rows in a tube bank. The rows are aligned with the direction of moist air flow.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Number of tube segments in each tube row** — Number of two-phase fluid tubes in each row of the tube bank  
5 (default) | positive scalar

Number of two-phase fluid tubes in each row of a tube bank. This measurement is perpendicular to the moist air flow.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Length of each tube segment in a tube row** — Length of each two-phase fluid tube  
1 m (default) | positive scalar

Length of each two-phase fluid tube that spans a tube row. All tubes in a tube bank are the same length.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Tube outer diameter** — Outer diameter of a single two-phase fluid tube

0.05 m (default) | positive scalar

Outer diameter of a two-phase fluid tube. The cross-section is uniform along a tube and so the diameter is constant throughout. This value influences the losses in the flow across a tube bank due to viscous friction.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Longitudinal tube pitch (along flow direction)** — Center-to-center distance between two-phase fluid tube rows

0.15 m (default) | positive scalar

Distance between tube centers of the two-phase fluid tubes, aligned with the direction of flow of the moist air.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Transverse tube pitch (perpendicular to flow direction)** — Center-to-center distance between two-phase fluid tubes in a row

0.15 m (default) | positive scalar

Distance between the tube centers in a row of two-phase fluid tubes. This measurement is perpendicular to the moist air flow direction. See “Heat Transfer Coefficient for Flows Across a Tube Bank” on page 1-563 for more information.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Euler number per tube row,  $\Delta p / (N \cdot 0.5 \cdot \rho \cdot v^2)$**  — Euler number for each row of the tube bank

10 (default) | positive scalar

Empirical coefficient for pressure drop across one tube row. The Euler number is the ratio between pressure drop and fluid momentum:

$$Eu = \frac{\Delta p}{N \frac{1}{2} \rho v^2},$$

where  $N$  is the **Number of tube rows along flow direction**,  $\Delta p$  is the pressure drop,  $\rho$  is the moist air mixture density, and  $v$  is the flow velocity.

Each tube row is located in a plane perpendicular to the moist air flow.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes and **Pressure loss model** to Euler number per tube row.

**Minimum free-flow area** — Smallest total flow area between inlet and outlet  
0.01 m<sup>2</sup> (default) | positive scalar

Smallest total flow area between inlet and outlet. If the channel is a collection of ducts, tubes, slots, or grooves, the minimum free-flow area is the sum of the smallest areas.

**Dependencies**

To enable this parameter, set **Flow geometry** to Generic.

**Heat transfer surface area without fins** — Total area of the heat transfer surface excluding fins  
2 m<sup>2</sup> (default) | positive scalar

Total area of the heat transfer surface, excluding fins.

**Dependencies**

To enable this parameter, set **Flow geometry** to Generic.

**Moist air volume inside heat exchanger** — Total volume of moist air in the heat exchanger  
0.05 m<sup>3</sup> (default) | positive scalar

Total volume of moist air in the heat exchanger.

**Dependencies**

To enable this parameter, set **Flow geometry** to Generic.

**Fouling factor** — Additional thermal resistance due to fouling deposits  
0.1 m<sup>2</sup>\*K/kW (default) | positive scalar

Additional thermal resistance due to fouling layers on the surfaces of the wall. In real systems, fouling deposits grow over time. However, the growth is slow enough to be assumed constant during the simulation.

**Total fin surface area** — Total heat transfer surface area of all fins  
0 m<sup>2</sup> (default) | positive scalar

Total heat transfer surface area of both sides of all fins. For example, if the fin is rectangular, the surface area is double the area of the rectangle.

The total heat transfer surface area is the sum of the channel surface area and the effective fin surface area, which is the product of the **Fin efficiency** and the **Total fin surface area**.

**Fin efficiency** — Ratio of actual-to-ideal transfer rates for fin  
0.5 (default) | positive scalar in the range [0,1]

Ratio of actual heat transfer to ideal heat transfer through the fins if the entire fin is at the primary heat transfer surface temperature.

**Initial moist air pressure** — Moist air pressure at start of simulation  
0.101325 MPa (default) | positive scalar

Moist air pressure at the start of the simulation.

**Initial moist air temperature** — Temperature at the start of simulation  
293.15 K (default) | positive scalar | two-element vector

Temperature in the moist air fluid channel at the start of the simulation. This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial temperature in the channel. A vector value represents the initial temperature at the inlet and outlet in the form [inlet, outlet]. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

**Initial moisture specification** — Moisture specification

Relative humidity (default) | Specific humidity | Mole fraction | Humidity ratio

Moisture specification, which can be set as relative humidity, specific humidity, water vapor mole fraction, or humidity ratio.

**Initial moist air relative humidity** — Relative humidity at the start of simulation

0.5 (default) | positive scalar in the range of [0,1] | two-element vector

Relative humidity in the moist air channel at the start of the simulation. The relative humidity is the ratio of the water vapor partial pressure to the water vapor saturation pressure, or the ratio of the water vapor mole fraction to the water vapor mole fraction at saturation.

This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial relative humidity in the channel. A vector value represents the initial relative humidity at the inlet and outlet in the form [inlet, outlet]. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

**Dependencies**

To enable this parameter, set **Initial moisture specification** to Relative humidity.

**Initial moist air specific humidity** — Specific humidity at the start of simulation

0.01 (default) | positive scalar in the range of [0,1] | two-element vector

Specific humidity in the moist air channel at the start of simulation. The specific humidity is the mass fraction of water vapor to the combined total mass of water vapor, trace gas, and dry air.

This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial specific humidity in the channel. A vector value represents the initial specific humidity at the inlet and outlet in the form [inlet, outlet]. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

**Dependencies**

To enable this parameter, set **Initial moisture specification** to Specific humidity.

**Initial moist air water vapor mole fraction** — Mole fraction of water vapor at the start of simulation

0.01 (default) | positive scalar in the range [0,1] | two-element vector

Mole fraction of the water vapor in the moist air channel at the start of simulation. The water vapor mole fraction is relative to the combined molar quantity of water vapor, trace species, and dry air.

This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial vapor mole fraction in the channel. A vector value represents the initial vapor mole fraction at the inlet and outlet in the form [inlet, outlet]. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

**Dependencies**

To enable this parameter, set **Initial moisture specification** to `Mole fraction`.

**Initial moist air humidity ratio** — Humidity ratio at the start of simulation

0.01 (default) | positive scalar in the range [0,1] | two-element vector

Humidity ratio in the moist air channel at the start of the simulation. The humidity ratio is the ratio of the mass of water vapor to the mass of dry air and trace gas.

This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial humidity ratio in the channel. A vector value represents the initial humidity ratio at the inlet and outlet in the form `[inlet, outlet]`. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

**Dependencies**

To enable this parameter, set **Initial moisture specification** to `Humidity ratio`.

**Initial trace gas specification** — Measurement type of trace gas

`Mass fraction` (default) | `Mole fraction`

Measurement type of trace gas.

**Initial moist air trace gas mass fraction** — Amount of trace gas in the moist air channel

0.001 (default) | positive scalar in the range of [0,1] | two-element vector

Amount of trace gas in the moist air channel by mass fraction at the start of the simulation. The mass fraction is relative to the combined total mass of water vapor, trace gas, and dry air.

This parameter can be a scalar or a two-element vector. A scalar value represents the mean trace gas mass fraction in the channel. A vector value represents the initial trace gas mass fraction at the inlet and outlet in the form `[inlet, outlet]`. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

This parameter is ignored if the **Trace gas model** parameter in the Moist Air Properties (MA) block is set to `None`.

**Dependencies**

To enable this parameter, set **Initial trace gas specification** to `Mass fraction`.

**Initial moist air trace gas mole fraction** — Mole fraction of trace gas at the start of simulation

0.001 (default) | positive scalar in the range of [0,1] | two-element vector

Amount of trace gas in the moist air channel by mole fraction at the start of the simulation. The mole fraction is relative to the combined molar total of water vapor, trace gas, and dry air.

This parameter can be a scalar or a two-element vector. A scalar value represents the mean trace gas mole fraction in the channel. A vector value represents the initial trace gas mole fraction at the inlet and outlet in the form `[inlet, outlet]`. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

This parameter is ignored if the **Trace gas model** parameter in the Moist Air Properties (MA) block is set to `None`.

## Dependencies

To enable this parameter, set **Initial trace gas specification** to Mole fraction.

**Relative humidity at saturation** — Relative humidity point of condensation  
1 (default) | positive scalar in the range of [0,1]

Relative humidity point of condensation. Condensation occurs above this value. A value greater than 1 indicates a supersaturated vapor.

## Version History

Introduced in R2019a

### R2023a: Model additional pressure losses by using a local loss coefficient

Set the **Local resistance specification** parameter to Local loss coefficient to specify the new method for quantifying pressure loss. This option allows you to model additional friction losses beyond the loss due the length of the pipes.

## Condenser Evaporator (TL-2P)

Models heat exchange between a thermal liquid network and a network that can undergo phase change

### Libraries:

Simscape / Fluids / Fluid Network Interfaces / Heat Exchangers

### Description

The Condenser Evaporator (TL-MA) block models a heat exchanger with one thermal liquid network, which flows between ports **A1** and **B1**, and one two-phase fluid network, which flows between ports **A2** and **B2**. The heat exchanger can act as a condenser or as an evaporator. The fluid streams can be aligned in parallel, counter, or cross-flow configurations.

### Example Heat Exchanger for Refrigeration Applications

You can model the thermal liquid side as flow within tubes, flow around the two-phase fluid tubing, or by an empirical, generic parameterization.

The block uses the Effectiveness-NTU (E-NTU) method to model heat transfer through the shared wall. Fouling on the exchanger walls, which increases thermal resistance and reduces the heat

exchange between the two fluids, is also modeled. You can also optionally model fins on both the thermal liquid and two-phase fluid sides. Pressure loss due to viscous friction on both sides of the exchanger can be modeled analytically or by generic parameterization, which you can use to tune to your own data.

You can model the two-phase fluid side as flow within a tube or a set of tubes. The two-phase fluid tubes use a boundary-following model to track the sub-cooled liquid (L), vapor-liquid mixture (M), and super-heated vapor (V) in three zones. The relative amount of space a zone occupies in the system is called a *zone length fraction* within the system.

### Zone Length Fractions in the Two-Phase Fluid Piping

The sum of the zone length fractions in the two-phase fluid tubing equals 1. Port **Z** returns the zone length fractions as a vector of physical signals for each of the three phases: [L, M, V].

### Heat Exchanger Configuration

The heat exchanger effectiveness is based on the selected heat exchanger configuration, the fluid properties in each phase, the tube geometry and flow configuration on each side of the exchanger, and the usage and size of fins.

### Flow Arrangement

The **Flow arrangement** parameter assigns the relative flow paths between the two sides:

- Parallel flow indicates the fluids are moving in the same direction.
- Counter flow indicates the fluids are moving in parallel, but opposite directions.
- Cross flow indicates the fluids are moving perpendicular to each other.

**Thermal Mixing**

When **Flow arrangement** is set to Cross flow, use the **Cross flow arrangement** parameter to indicate whether the two-phase fluid or thermal liquid flows are separated into multiple paths by baffles or walls. Without these separations, the flow can mix freely and is considered *mixed*. Both fluids, one fluid, or neither fluid can be mixed in the cross-flow arrangement. Mixing homogenizes the fluid temperature along the direction of flow of the second fluid, and varies perpendicular to the second fluid flow.

Unmixed flows vary in temperature both along and perpendicular to the flow path of the second fluid.

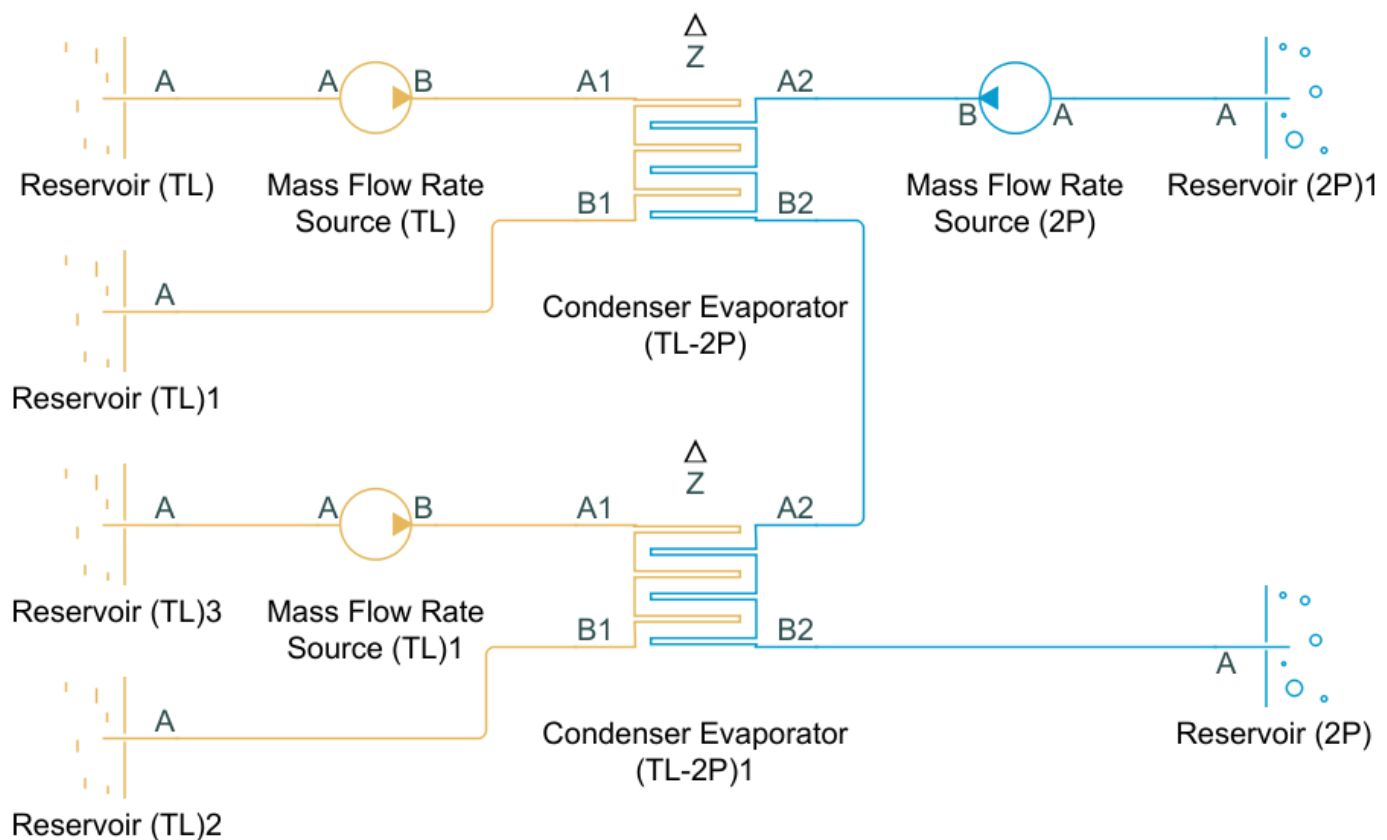

Note that the flow direction during simulation does not impact the selected flow arrangement setting. The ports on the block do not reflect the physical positions of the ports in the physical heat exchanger system.

All flow arrangements are single-pass, which means that the fluids do not make multiple turns in the exchanger for additional points of heat transfer. To model a multi-pass heat exchanger, you can arrange multiple Condenser Evaporator (TL-2P) blocks in series or in parallel.

For example, to achieve a two-pass configuration on the two-phase fluid side and a single-pass configuration on the thermal liquid side, you can connect the two-phase fluid sides in series and the thermal liquid sides to the same input in parallel (such as two Mass Flow Rate Source blocks with half of the total mass flow rate), as shown below.

### Flow Geometry

The **Flow geometry** parameter sets the thermal liquid flow arrangement as either inside a tube or set of tubes, or perpendicular to a tube bank. You can also specify an empirical, generic configuration. The two-phase fluid always flows inside a tube or set of tubes.

When **Flow geometry** is set to Flow perpendicular to bank of circular tubes, use the **Tube bank grid arrangement** parameter to define the two-phase fluid tube bank alignment as either Inline or Staggered. The red, downward-pointing arrow indicates the direction of thermal liquid flow. The Inline figure also shows the **Number of tube rows along flow direction** and the **Number of tube segments in each tube row** parameters. Here, *flow direction* refers to the

thermal liquid flow, and *tube* refers to the two-phase fluid tubing. The **Length of each tube segment in a tube row** parameter is indicated in the Staggered figure.

Number of tube segments  
in each tube row

### Inline

### Staggered

Length of each tube  
segment in a tube row

## Fins

The heat exchanger configuration is without fins when the **Total fin surface area** parameter is set to 0 m<sup>2</sup>. Fins introduce additional surface area for additional heat transfer. Each fluid side has a separate fin area.

## Effectiveness-NTU Heat Transfer

The heat transfer rate is calculated for each fluid phase. In accordance with the three fluid zones that occur on the two-phase fluid side of the heat exchanger, the heat transfer rate is calculated in three sections.

The heat transfer in a zone is calculated as:

$$Q_{zone} = \epsilon C_{\text{Min}}(T_{\text{In},2P} - T_{\text{In},\text{TL}}),$$

where:

- $C_{\text{Min}}$  is the lesser of the heat capacity rates of the two fluids in that zone. The heat capacity rate is the product of the fluid specific heat,  $c_p$ , and the fluid mass flow rate.  $C_{\text{Min}}$  is always positive.
- $T_{\text{In},2P}$  is the zone inlet temperature of the two-phase fluid.
- $T_{\text{In},\text{TL}}$  is the zone inlet temperature of the thermal liquid.
- $\epsilon$  is the heat exchanger effectiveness.

Effectiveness is a function of the heat capacity rate and the number of transfer units,  $NTU$ , and also varies based on the heat exchanger flow arrangement, which is discussed in more detail in “Effectiveness by Flow Arrangement” on page 1-596. The  $NTU$  is calculated as:

$$NTU = \frac{z}{C_{\text{Min}}R},$$

where:

- $z$  is the individual zone length fraction.
- $R$  is the total thermal resistance between the two flows, due to convection, conduction, and any fouling on the tube walls:

$$R = \frac{1}{U_{2P}A_{\text{Th},2P}} + \frac{F_{2P}}{A_{\text{Th},2P}} + R_W + \frac{F_{\text{TL}}}{A_{\text{Th},\text{TL}}} + \frac{1}{U_{\text{TL}}A_{\text{Th},\text{TL}}},$$

where:

- $U$  is the convective heat transfer coefficient of the respective fluid. This coefficient is discussed in more detail in “Two-Phase Fluid Correlations” on page 1-597 and “Thermal Liquid Correlations” on page 1-599.
- $F$  is the **Fouling factor** on the two-phase fluid or thermal liquid side, respectively.
- $R_W$  is the **Thermal resistance through heat transfer surface**.
- $A_{\text{Th}}$  is the heat transfer surface area of the respective side of the exchanger.  $A_{\text{Th}}$  is the sum of the wall surface area,  $A_W$ , and the **Total fin surface area**,  $A_F$ :

$$A_{\text{Th}} = A_W + \eta_F A_F,$$

where  $\eta_F$  is the **Fin efficiency**.

The total heat transfer rate between the fluids is the sum of the heat transferred in the three zones by the subcooled liquid ( $Q_L$ ), liquid-vapor mixture ( $Q_M$ ), and superheated vapor ( $Q_V$ ):

$$Q = \sum Q_Z = Q_L + Q_M + Q_V.$$

### Effectiveness by Flow Arrangement

The heat exchanger effectiveness varies according to its flow configuration and the mixing in each fluid. Below are the formulations for effectiveness calculated in the liquid and vapor zones for each configuration. The effectiveness is  $\epsilon = 1 - \exp(-NTU)$  for all configurations in the mixture zone.

- When **Flow arrangement** is set to Parallel flow:

$$\epsilon = \frac{1 - \exp[-NTU(1 + C_R)]}{1 + C_R}$$

- When **Flow arrangement** is set to Counter flow:

$$\epsilon = \frac{1 - \exp[-NTU(1 - C_R)]}{1 - C_R \exp[-NTU(1 - C_R)]}$$

- When **Flow arrangement** is set to Cross flow and **Cross flow arrangement** is set to Both fluids unmixed:

$$\epsilon = 1 - \exp\left\{\frac{NTU^{0.22}}{C_R} \left[ \exp(-C_R NTU^{0.78}) - 1 \right]\right\}$$

- When **Flow arrangement** is set to Cross flow and **Cross flow arrangement** is set to Both fluids mixed:

$$\epsilon = \left[ \frac{1}{1 - \exp(-NTU)} + \frac{C_R}{1 - \exp(-C_R NTU)} - \frac{1}{NTU} \right]^{-1}$$

When one fluid is mixed and the other unmixed, the equation for effectiveness depends on the relative heat capacity rates of the fluids. When **Flow arrangement** is set to Cross flow and **Cross flow arrangement** is set to either Thermal Liquid 1 mixed & Two-Phase Fluid 2 unmixed or Thermal Liquid 1 unmixed & Two-Phase Fluid 2 mixed:

- When the fluid with  $C_{\max}$  is mixed and the fluid with  $C_{\min}$  is unmixed:

$$\epsilon = \frac{1}{C_R} (1 - \exp\{-C_R [1 - \exp(-NTU)]\})$$

- When the fluid with  $C_{\min}$  is mixed and the fluid with  $C_{\max}$  is unmixed:

$$\epsilon = 1 - \exp\left\{-\frac{1}{C_R} [1 - \exp(-C_R NTU)]\right\}$$

$C_R$  denotes the ratio between the heat capacity rates of the two fluids:

$$C_R = \frac{C_{\min}}{C_{\max}}.$$

## Two-Phase Fluid Correlations

### Heat Transfer Coefficient

The convective heat transfer coefficient varies according to the fluid Nusselt number:

$$U = \frac{Nu k}{D_H},$$

where:

- $Nu$  is the zone mean Nusselt number, which depends on the flow regime.
- $k$  is the fluid phase thermal conductivity.
- $D_H$  is tube hydraulic diameter.

For turbulent flows in the subcooled liquid or superheated vapor zones, the Nusselt number is calculated with the Gnielinski correlation:

$$Nu = \frac{\frac{f_D}{8}(Re - 1000)Pr}{1 + 12.7\sqrt{\frac{f_D}{8}}(Pr^{2/3} - 1)},$$

where:

- $Re$  is the fluid Reynolds number.
- $Pr$  is the fluid Prandtl number.

For turbulent flows in the liquid-vapor mixture zone, the Nusselt number is calculated with the Cavallini-Zecchin correlation:

$$Nu = \frac{a Re_{SL}^b Pr_{SL}^c \left\{ \left[ \left( \sqrt{\frac{\rho_{SL}}{\rho_{SV}}} - 1 \right) x_{Out} + 1 \right]^{1+b} - \left[ \left( \sqrt{\frac{\rho_{SL}}{\rho_{SV}}} - 1 \right) x_{In} + 1 \right]^{1+b} \right\}}{(1+b) \left( \sqrt{\frac{\rho_{SL}}{\rho_{SV}}} - 1 \right) (x_{Out} - x_{In})}.$$

where:

- $Re_{SL}$  is the Reynolds number of the saturated liquid.
- $Pr_{SL}$  is the Prandtl number of the saturated liquid.
- $\rho_{SL}$  is the density of the saturated liquid.
- $\rho_{SV}$  is the density of the saturated vapor.
- $a = 0.05$ ,  $b = 0.8$ , and  $c = 0.33$ .

For laminar flows, the Nusselt number is set by the **Laminar flow Nusselt number** parameter.

For transitional flows, the Nusselt number is a blend between the laminar and turbulent Nusselt numbers.

### Empirical Nusselt Number Formulation

When the **Heat transfer coefficient model** parameter is set to Colburn equation, the Nusselt number for the subcooled liquid and superheated vapor zones is calculated by the empirical the Colburn equation:

$$\text{Nu} = a\text{Re}^b\text{Pr}^c,$$

where  $a$ ,  $b$ , and  $c$  are defined in the **Coefficients [a, b, c] for a\*Re^b\*Pr^c in liquid zone** and **Coefficients [a, b, c] for a\*Re^b\*Pr^c in vapor zone** parameters.

The Nusselt number for liquid-vapor mixture zones is calculated with the Cavallini-Zecchin equation, with the coefficients specified in the **Coefficients [a, b, c] for a\*Re^b\*Pr^c in mixture zone** parameter.

### Pressure Loss

The pressure loss due to viscous friction varies depending on flow regime and configuration. The pressure loss calculation uses the overall density, which is the total fluid mass divided by the total fluid volume. When the **Pressure loss model** parameter is **Correlation for flow inside tubes**, the pressure loss due to friction depends on the Darcy friction factor.

For turbulent flows, when the Reynolds number is above the **Turbulent flow lower Reynolds number limit** parameter, the block calculates the pressure loss due to friction in terms of a calculated Darcy friction factor. The pressure differential between port **A1** and the internal node I1 is:

$$p_{A1} - p_{I1} = \frac{f_{D,A}\dot{m}_{A1}|\dot{m}_{A1}|}{2\rho D_H A_{CS}^2} \left( \frac{L + L_{Add}}{2} \right),$$

where:

- $\dot{m}_{A1}$  is the total flow rate through port **A1**.
- $f_{D,A}$  is the Darcy friction factor according to the Haaland correlation. When the **Local resistance specification** parameter is **Aggregate equivalent length**,

$$f_{D,A1} = \left\{ -1.8 \log_{10} \left[ \frac{6.9}{\text{Re}_{A1}} + \left( \frac{\epsilon_R}{3.7 D_H} \right)^{1.11} \right] \right\}^{-2},$$

where  $\epsilon_R$  is the value of the **Internal surface absolute roughness** parameter. The friction factor is dependent on the Reynolds number, and the block calculates this value at both ports for each liquid.

- $L$  is the value of the **Total length of each tube** parameter.
- $L_{Add}$  is the value of the **Aggregate equivalent length of local resistances** parameter, which is the equivalent length of a tube that introduces the same amount of loss as the sum of the losses due to other local resistances in the tube.
- $A_{CS}$  is the tube cross-sectional area.

The pressure differential between port **B1** and internal node I1 is:

$$p_{B1} - p_{I1} = \frac{f_{D,B}\dot{m}_{B1}|\dot{m}_{B1}|}{2\rho D_H A_{CS}^2} \left( \frac{L + L_{Add}}{2} \right),$$

where  $\dot{m}_{B1}$  is the total flow rate through port **B1**.

When the **Local resistance specification** parameter is **Aggregate equivalent length**, the Darcy friction factor at port **B1** is:

$$f_{D,B1} = \left\{ -1.8 \log_{10} \left[ \frac{6.9}{\text{Re}_{B1}} + \left( \frac{\epsilon_R}{3.7 D_H} \right)^{1.11} \right] \right\}^{-2}.$$

When the **Local resistance specification** parameter is **Local loss coefficient**, the Darcy friction factors at ports **A1** and **B1** are

$$f_{D,A1} = \left\{ -1.8 \log_{10} \left[ \frac{6.9}{\text{Re}_{A1}} + \left( \frac{\epsilon_R}{3.7 D_H} \right)^{1.11} \right] \right\}^{-2} + C_{localloss} \left( \frac{D_H}{L} \right)$$

$$f_{D,B1} = \left\{ -1.8 \log_{10} \left[ \frac{6.9}{\text{Re}_{B1}} + \left( \frac{\epsilon_R}{3.7 D_H} \right)^{1.11} \right] \right\}^{-2} + C_{localloss} \left( \frac{D_H}{L} \right)$$

where  $C_{localloss}$  is the value of the **Total local loss coefficient** parameter.

For laminar flows, when the Reynolds number is below the **Laminar flow upper Reynolds number limit** parameter, the block calculates the pressure loss due to friction in terms of the **Laminar friction constant for Darcy friction factor** parameter,  $\lambda$ .  $\lambda$  is a user-defined parameter when **Tube cross-section** is **Generic**. Otherwise, the block calculates the value internally. The pressure differential between port **A1** and internal node I1 is:

$$p_{A1} - p_{I1} = \frac{\lambda \mu \dot{m}_{A1}}{2 \rho D_H^2 A_{CS}} \left( \frac{L + L_{Add}}{2} \right),$$

where  $\mu$  is the fluid dynamic viscosity. The pressure differential between port **B1** and internal node I1 is:

$$p_{B1} - p_{I1} = \frac{\lambda \mu \dot{m}_{B1}}{2 \rho D_H^2 A_{CS}} \left( \frac{L + L_{Add}}{2} \right).$$

For transitional flows, the pressure differential due to viscous friction is a smoothed blend between the values for laminar and turbulent pressure losses.

### Empirical Pressure Loss Formulation

When **Pressure loss model** is set to **Pressure loss coefficient**, the pressure losses due to viscous friction are calculated with an empirical pressure loss coefficient,  $\xi$ .

The pressure differential between port **A2** and internal node I2 is:

$$p_{A2} - p_{I2} = \frac{1}{2} \xi \frac{\dot{m}_{A2} |\dot{m}_{A2}|}{2 \rho A_{CS}^2}.$$

The pressure differential between port **B2** and internal node I2 is:

$$p_{B2} - p_{I2} = \frac{1}{2} \xi \frac{\dot{m}_{B2} |\dot{m}_{B2}|}{2 \rho A_{CS}^2}.$$

### Thermal Liquid Correlations

#### Heat Transfer Coefficient for Flows Inside One or More Tubes

When the thermal liquid **Flow geometry** is set to **Flow inside one or more tubes**, the Nusselt number is calculated according to the Gnielinski correlation in the same manner as two-phase subcooled liquid or superheated vapor. See "Heat Transfer Coefficient" on page 1-597 for more information.

### Heat Transfer Coefficient for Flows Across a Tube Bank

When the thermal liquid **Flow geometry** is set to Flow perpendicular to bank of circular tubes, the Nusselt number is calculated based on the Hagen number,  $Hg$ , and depends on the **Tube bank grid arrangement** setting:

$$Nu = \begin{cases} 0.404Lq^{1/3} \left( \frac{Re+1}{Re+1000} \right)^{0.1}, & \text{Inline} \\ 0.404Lq^{1/3}, & \text{Staggered} \end{cases}$$

where:

$$Lq = \begin{cases} 1.18Pr \left( \frac{4l_T/\pi - D}{l_L} \right) Hg(Re), & \text{Inline} \\ 0.92Pr \left( \frac{4l_T/\pi - D}{l_D} \right) Hg(Re), & \text{Staggered with } l_L \geq D \\ 0.92Pr \left( \frac{4l_T l_L/\pi - D^2}{l_L l_D} \right) Hg(Re), & \text{Staggered with } l_L < D \end{cases}$$

- $D$  is the **Tube outer diameter**.
- $l_L$  is the **Longitudinal tube pitch (along flow direction)**, the distance between the tube centers along the flow direction. *Flow direction* refers to the thermal liquid flow.
- $l_T$  is the **Transverse tube pitch (perpendicular to flow direction)**, shown in the figure below. The transverse pitch is the distance between the centers of the two-phase fluid tubing in one row.
- $l_D$  is the diagonal tube spacing, calculated as  $l_D = \sqrt{\left(\frac{l_T}{2}\right)^2 + l_L^2}$ .

For more information on calculating the Hagen number, see [3].

The longitudinal and transverse pitch distances are the same for both grid bank arrangement types.

### Cross-Section of Two-Phase Fluid Tubing with Pitch Measurements

#### Empirical Nusselt Number Formulation

When the **Heat transfer coefficient model** is set to Colburn equation or when **Flow geometry** is set to Generic, the Nusselt number is calculated by the empirical the Colburn equation:

$$\text{Nu} = a\text{Re}^b\text{Pr}^c,$$

where  $a$ ,  $b$ , and  $c$  are the values defined in the **Coefficients [a, b, c] for  $a*\text{Re}^b*\text{Pr}^c$**  parameter.

#### Pressure Loss for Flow Inside Tubes

When the thermal liquid **Flow geometry** parameter is Flow inside one or more tubes, the pressure loss is calculated the same way as for two-phase flows, with the respective Darcy friction factor, density, mass flow rates, and pipe lengths of the thermal liquid side. See “Pressure Loss” on page 1-598 for more information.

#### Pressure Loss for Flow Across Tube Banks

When the thermal liquid **Flow geometry** is set to Flow perpendicular to bank of circular tubes, the Hagen number is used to calculate the pressure loss due to viscous friction. The pressure differential between port **A1** and internal node I1 is:

$$p_{A1} - p_{I1} = \frac{1}{2} \frac{\mu^2 N_R}{\rho D^2} \text{Hg}(\text{Re}),$$

where:

- $\mu_{\text{TL}}$  is the fluid dynamic viscosity.
- $N_R$  is the **Number of tube rows along flow direction**. This is the number of two-phase fluid tube rows along the thermal liquid flow direction.

The pressure differential between port **B1** and internal node I1 is:

$$p_{B1} - p_{I1} = \frac{1}{2} \frac{\mu^2 N_R}{\rho D^2} \text{Hg}(\text{Re}).$$

### Empirical Pressure Loss Formulation

When the **Pressure loss model** parameter is Euler number per tube row or when the **Flow geometry** parameter is Generic, the pressure loss due to viscous friction is calculated with a pressure loss coefficient, in terms of the Euler number,  $Eu$ :

$$Eu = \frac{\xi}{N_R},$$

where  $\xi$  is the empirical pressure loss coefficient.

The pressure differential between port **A1** and internal node I1 is:

$$p_{A1} - p_{I1} = \frac{1}{2} N_R Eu \frac{\dot{m}_{A1} |\dot{m}_{A1}|}{2\rho A_{CS}^2}.$$

The pressure differential between port **B1** and internal node I1 is:

$$p_{B1} - p_{I1} = \frac{1}{2} N_R Eu \frac{\dot{m}_{B1} |\dot{m}_{B1}|}{2\rho A_{CS}^2}.$$

### Conservation Equations

#### Two-Phase Fluid

The total mass accumulation rate in the two-phase fluid is defined as:

$$\frac{dM_{2P}}{dt} = \dot{m}_{A2} + \dot{m}_{B2},$$

where:

- $M_{2P}$  is the total mass of the two-phase fluid.
- $\dot{m}_{A2}$  is the mass flow rate of the fluid at port **A2**.
- $\dot{m}_{B2}$  is the mass flow rate of the fluid at port **B2**.

The flow is positive when flowing into the block through the port.

The energy conservation equation relates the change in specific internal energy to the heat transfer by the fluid:

$$M_{2P} \frac{du_{2P}}{dt} + u_{2P}(\dot{m}_{A2} + \dot{m}_{B2}) = \phi_{A2} + \phi_{B2} - Q,$$

where:

- $u_{2P}$  is the two-phase fluid specific internal energy.
- $\phi_{A2}$  is the energy flow rate at port **A2**.
- $\phi_{B2}$  is the energy flow rate at port **B2**.
- $Q$  is heat transfer rate, which is positive when leaving the two-phase fluid volume.

**Thermal Liquid**

The total mass accumulation rate in the thermal liquid is defined as:

$$\frac{dM_{TL}}{dt} = \dot{m}_{A1} + \dot{m}_{B1}.$$

The energy conservation equation is:

$$M_{TL} \frac{du_{TL}}{dt} + u_{TL}(\dot{m}_{A1} + \dot{m}_{B1}) = \phi_{A1} + \phi_{B1} + Q,$$

where:

- $\phi_{A1}$  is the energy flow rate at port **A1**.
- $\phi_{B1}$  is the energy flow rate at port **B1**.

The heat transferred to or from the thermal liquid,  $Q$ , is equal to the heat transferred from or to the two-phase fluid.

**Ports****Conserving**

**A1** — Thermal liquid port  
thermal liquid

Inlet or outlet port associated with the thermal liquid.

**B1** — Thermal liquid port  
thermal liquid

Inlet or outlet port associated with the thermal liquid.

**A2** — Two-phase fluid port  
two-phase fluid

Inlet or outlet port associated with the two-phase fluid.

**B2** — Two-phase fluid port  
two-phase fluid

Inlet or outlet port associated with the two-phase fluid.

**Output**

**Z** — Two-phase fluid zone length fractions  
physical signal

Three-element vector of the zone length fractions in the two-phase fluid channel, returned as a physical signal. The vector takes the form [L, M, V], where L is the sub-cooled liquid, M is the liquid-vapor mixture, and V is the superheated vapor.

## Parameters

### Configuration

**Flow arrangement** — Flow path alignment

Cross flow (default) | Parallel flow | Counter flow

Flow path alignment between heat exchanger sides. The available flow arrangements are:

- **Parallel flow**. The flows run in the same direction.
- **Counter flow**. The flows run parallel to each other, in the opposite directions.
- **Cross flow**. The flows run perpendicular to each other.

**Cross flow arrangement** — Thermal mixing condition in each of the flow channels

Both fluids unmixed (default) | Both fluids mixed | Thermal Liquid 1 mixed & Two-Phase Fluid 2 unmixed | Thermal Liquid 1 unmixed & Two-Phase Fluid 2 mixed

Select whether each of the fluids can mix in its channel. Mixed flow means that the fluid is free to move in the transverse direction as it travels along the flow path. Unmixed flow means that the fluid is restricted to travel only along the flow path. For example, a side with fins is considered an unmixed flow.

### Dependencies

To enable this parameter, set **Flow arrangement** to **Cross flow**.

**Thermal resistance through heat transfer surface** — Wall thermal resistance

0 K/kW (default) | positive scalar

Thermal resistance of the wall separating the two sides of the heat exchanger. The wall thermal resistance, wall fouling, and the fluid convective heat transfer coefficient influence the amount of heat transferred between the flows.

**Cross-sectional area at port A1** — Flow area at port A1

0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the thermal liquid port **A1**.

**Cross-sectional area at port B1** — Flow area at port B1

0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the thermal liquid port **B1**.

**Cross-sectional area at port A2** — Flow area at port A2

0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the two-phase fluid port **A2**.

**Cross-sectional area at port B2** — Flow area at port B2

0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the two-phase fluid port **B2**.

## Thermal Liquid 1

### Flow geometry — Thermal liquid flow configuration

Flow inside one or more tubes (default) | Flow perpendicular to bank of circular tubes | Generic

Thermal liquid flow path. The flow can run externally over a set of tubes or internal to a tube or set of tubes. You can also specify a generic parameterization based on empirical values.

### Number of tubes — Number of thermal liquid tubes

25 (default) | positive scalar

Number of thermal liquid tubes. More tubes result in higher pressure losses due to viscous friction, but a larger amount of surface area for heat transfer.

### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes.

### Total length of each tube — Total length of each thermal liquid tube

1 m (default) | positive scalar

Total length of each thermal liquid tube.

### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes.

### Tube cross section — Cross-sectional shape of a tube

Circular (default) | Rectangular | Annular | Generic

Cross-sectional shape of one tube. Set to Generic to specify an arbitrary cross-sectional geometry.

### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes.

### Tube inner diameter — Internal diameter of a single tube

0.05 m (default) | positive scalar

Internal diameter of the cross-section of one tube. The cross-section and diameter are uniform along the tube. The size of the diameter influences the pressure loss and heat transfer calculations.

### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Circular.

### Tube width — Internal width of a single tube

0.05 m (default) | positive scalar

Internal width of the cross-section of one tube. The cross-section and width are uniform along the tube. The width and height influence the pressure loss and heat transfer calculations.

### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Rectangular.

**Tube height** — Internal height of a single tube

0.05 m (default) | positive scalar

Internal height of one tube. The cross-section and height are uniform along the tube. The width and height influence the pressure loss and heat transfer calculations.

**Dependencies**

To enable this parameter, set **Flow geometry** parameterization of Flow inside one or more tubes and **Tube cross-section** to Rectangular.

**Annulus inner diameter (heat transfer surface)** — Smaller diameter of annular cross-section

0.05 m (default) | positive scalar

Smaller diameter of the annular cross-section of one tube. The cross-section and inner diameter are uniform along the tube. The inner diameter influences the pressure loss and heat transfer calculations. Heat transfer occurs through the inner surface of the annulus.

**Dependencies**

To enable this parameter, set **Flow geometry** parameterization of Flow inside one or more tubes and **Tube cross-section** to Annular.

**Annulus outer diameter** — Larger diameter of annular cross-section

0.1 m (default) | positive scalar

Larger diameter of the annular cross-section of one tube. The cross-section and outer diameter are uniform along the tube. The outer diameter influences the pressure loss and heat transfer calculations.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Annular.

**Cross-sectional area per tube** — Internal flow area in each tube

0.002 m<sup>2</sup> (default) | positive scalar

Internal flow area of each tube.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Generic.

**Wetted perimeter of tube cross-section for pressure loss** — Perimeter of tube cross-section that fluid touches

0.15 m (default) | positive scalar

Perimeter of the tube cross-section that the fluid touches. The cross-section and perimeter are uniform along the tube. This value is applied in pressure loss calculations.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Generic.

**Perimeter of tube cross-section for heat transfer** — Perimeter of a single tube for heat transfer calculations

0.15 m (default) | positive scalar

Tube perimeter for heat transfer calculations. This is often the same as the tube perimeter, but in cases such as the annular cross-section, this may be only the inner or outer diameter, depending on the heat-transferring surface. The cross-section and tube perimeter are uniform along the tube.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Tube cross-section** to Generic.

**Pressure loss model** — Method of pressure loss calculation due to viscous friction

Correlation for flow inside tubes (default) | Euler number per tube row | Pressure loss coefficient | Correlation for flow over tube bank

Method of pressure loss calculation due to viscous friction. Different models are available for different flow configurations. The settings are:

- Correlation for flow inside tubes. Use this setting to calculate the pressure loss with the Haaland correlation.
- Pressure loss coefficient. Use this setting to calculate the pressure loss based on an empirical loss coefficient.
- Euler number per tube row. Use this setting to calculate the pressure loss based on an empirical Euler number.
- Correlation for flow over tube bank. Use this setting to calculate the pressure loss based on the Hagen number.

The pressure loss models available depend on the **Flow geometry** setting.

#### Dependencies

When **Flow geometry** is set to Flow inside one or more tubes, **Pressure loss model** can be set to either:

- Pressure loss coefficient.
- Correlation for flow inside tubes.

When **Flow geometry** is set to Flow perpendicular to bank of circular tubes, **Pressure loss model** can be set to either:

- Correlation for flow over tube bank.
- Euler number per tube row.

When **Flow geometry** is set to Generic, the **Pressure loss model** parameter is disabled. Pressure loss is calculated empirically with the **Pressure loss coefficient,  $\Delta p/(0.5 \cdot \rho \cdot v^2)$**  parameter.

**Pressure loss coefficient,  $\Delta p/(0.5 \cdot \rho \cdot v^2)$**  — Empirical loss coefficient for all pressure losses in the channel

10 (default) | positive scalar

Empirical loss coefficient for all pressure losses in the channel. This value accounts for wall friction and minor losses due to bends, elbows, and other geometry changes in the channel.

The loss coefficient can be calculated from a nominal operating condition or be tuned to fit experimental data. It is defined as:

$$\xi = \frac{\Delta p}{\frac{1}{2}\rho v^2},$$

where  $\Delta p$  is the pressure drop,  $\rho$  is the thermal liquid density, and  $v$  is the flow velocity.

#### Dependencies

To enable this parameter, set either:

- **Flow geometry** to Flow inside one or more tubes and **Pressure loss model** to Pressure loss coefficient.
- **Flow geometry** to Generic.

**Local resistance specification** — Method for quantifying pressure losses  
Aggregate equivalent length (default) | Local loss coefficient

Method for quantifying pressure losses in the Haaland correlation.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Pressure loss model** to Correlation for flow inside tubes.

**Aggregate equivalent length of local resistances** — Combined length of all local resistances per tube

0.1 m (default) | positive scalar

Combined length of all local resistances per tube. This value is the length of tubing that results in the same pressure losses as the sum of all minor losses in the tube due to resistances such as bends, tees, or unions. A longer combined length results in larger pressure losses. The block adds the value of this parameter to the **Total length of each tube** parameter in the calculations of pressure loss due to friction.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes, **Pressure loss model** to Correlations for flow inside tubes, and **Local resistance specification** to Aggregate equivalent length.

**Total local loss coefficient** — Pressure loss coefficient

0.1 (default) | positive scalar

Local pressure loss coefficient over the system. You can use this parameter to calibrate your system to match experimental results.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes, **Pressure loss model** to Correlation for flow inside tubes, and **Local resistance specification** to Local loss coefficient.

**Internal surface absolute roughness** — Mean surface roughness height

15e-6 m (default) | positive scalar

Mean height of tube surface defects. A rougher wall results in larger pressure losses in the turbulent regime for pressure loss calculated with the Haaland correlation.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and either:

- **Pressure loss model**
- **Heat transfer coefficient model**

to Correlation for flow inside tubes.

**Laminar flow upper Reynolds number limit** — Largest Reynolds number that indicates laminar flow

2000 (default) | positive scalar

Largest Reynolds number that indicates laminar flow. Between this value and the **Turbulent flow lower Reynolds number limit**, the flow regime is transitional.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Pressure loss model** to Correlation for flow inside tubes.

**Turbulent flow lower Reynolds number limit** — Smallest Reynolds number that indicates turbulent flow

4000 (default) | positive scalar

Smallest Reynolds number that indicates turbulent flow. Between this value and the **Laminar flow upper Reynolds number limit**, the flow regime is transitional between the laminar and turbulent regimes.

#### Dependencies

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes and **Pressure loss model** to Correlation for flow inside tubes.

**Laminar friction constant for Darcy friction factor** — Coefficient of pressure loss due to viscous friction in laminar flows

64 (default) | positive scalar

Coefficient in pressure loss equations for viscous friction in laminar flows. This parameter is also known as the *shape factor*. The default value corresponds to a circular tube cross-section.

#### Dependencies

To enable this parameter, set **Flow geometry** to Correlation for flow inside tubes, **Tube cross section** to Generic, and **Pressure loss model** to Correlation for flow inside tubes.

**Heat transfer coefficient model** — Method of calculating heat transfer coefficient between fluid and wall

Correlation for flow over tube bank (default) | Colburn equation | Correlation for flow inside tubes

Method of calculating the heat transfer coefficient between the fluid and the wall. The available settings are:

- Colburn equation. Use this setting to calculate the heat transfer coefficient with user-defined variables  $a$ ,  $b$ , and  $c$  of the Colburn equation.
- Correlation for flow over tube bank. Use this setting to calculate the heat transfer coefficient based on the tube bank correlation using the Hagen number.
- Correlation for flow inside tubes. Use this setting to calculate the heat transfer coefficient for pipe flows with the Gnielinski correlation.

#### Dependencies

To enable this parameter, set **Flow geometry** to either:

- Flow perpendicular to bank of circular tubes.
- Flow inside one or more tubes.

**Coefficients [a, b, c] for  $a \cdot Re^b \cdot Pr^c$**  — Colburn equation coefficients  
[0.023, 0.8, 0.33] (default) | three-element vector

Three-element vector containing the empirical coefficients of the Colburn equation. The Colburn equation is a formulation for calculating the Nusselt Number. The general form of the Colburn equation is:

$$Nu = aRe^bPr^c.$$

When the **Heat transfer coefficient model** is set to Colburn equation and **Flow geometry** is set to Flow inside one or more tubes, or **Flow geometry** is set to Generic, the default Colburn equation is:

$$Nu = 0.023Re^{0.8}Pr^{1/3}.$$

When the **Heat transfer coefficient model** is set to Colburn equation and **Flow geometry** is set to Flow perpendicular to bank of circular tubes, the default Colburn equation is:

$$Nu = 0.27Re^{0.63}Pr^{0.36}.$$

#### Dependencies

To enable this parameter, set:

**1 Flow geometry** to either:

- Flow inside one or more tubes
- Flow perpendicular to bank of circular tubes

and **Heat transfer coefficient model** to Colburn equation.

**2 Flow geometry** to Generic.

**Laminar flow Nusselt number** — Ratio of convective to conductive heat transfer in the laminar flow regime

3.66 (default) | positive scalar

Ratio of convective to conductive heat transfer in the laminar flow regime. The fluid Nusselt number influences the heat transfer rate and depends on the tube cross-section.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow inside one or more tubes, **Tube cross-section** to Generic, and **Heat transfer parameterization** to Correlation for flow inside tubes.

**Tube bank grid arrangement** — Geometrical placement of tube rows in the bank  
 Inline (default) | Staggered

Alignment of tubes in a tube bank. Rows are either in line with their neighbors, or staggered.

- **Inline:** All tube rows are located directly behind each other.
- **Staggered:** Tubes of the one tube row are located at the gap between tubes of the previous tube row.

Tube alignment influences the Nusselt number and the heat transfer rate.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Number of tube rows along flow direction** — Number of two-phase fluid tube rows in the tube bank  
 5 (default) | positive scalar

Number of two-phase fluid tube rows in a tube bank. The rows are aligned with the direction of thermal liquid flow.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Number of tube segments in each tube row** — Number of two-phase fluid tubes in each row of the tube bank  
 5 (default) | positive scalar

Number of two-phase fluid tubes in each row of a tube bank. This measurement is perpendicular to the thermal liquid flow.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Length of each tube segment in a tube row** — Length of each two-phase fluid tube  
 1 m (default) | positive scalar

Length of each tube that spans a tube row. All tubes in a tube bank are the same length.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Tube outer diameter** — External diameter of a single two-phase fluid tube

0.05 m (default) | positive scalar

Outer diameter of a two-phase fluid tube. The cross-section is uniform along a tube and so the diameter is constant throughout. This value influences the losses in the flow across a tube bank due to viscous friction.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Longitudinal tube pitch (along flow direction)** — Center-to-center distance between two-phase fluid tube rows

0.15 m (default) | positive scalar

Distance between tube centers of the two-phase fluid tubes, aligned with the direction of flow of the thermal liquid.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Transverse tube pitch (perpendicular to flow direction)** — Center-to-center distance between two-phase fluid tubes in a row

0.15 m (default) | positive scalar

Distance between the tube centers in a row of two-phase fluid tubes. This measurement is perpendicular to the thermal liquid flow direction. See “Heat Transfer Coefficient for Flows Across a Tube Bank” on page 1-600 for more information.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes.

**Euler number per tube row,  $\Delta p / (N \cdot 0.5 \cdot \rho \cdot v^2)$**  — Euler number for each row of the tube bank

10 (default) | positive scalar

Empirical coefficient for pressure drop across one tube row. The Euler number is the ratio between pressure drop and fluid momentum:

$$Eu = \frac{\Delta p}{N \frac{1}{2} \rho v^2},$$

where  $N$  is the **Number of tube rows along flow direction**,  $\Delta p$  is the pressure drop,  $\rho$  is the thermal liquid mixture density, and  $v$  is the flow velocity.

Each tube row is located in a plane perpendicular to the thermal liquid flow.

**Dependencies**

To enable this parameter, set **Flow geometry** to Flow perpendicular to bank of circular tubes and **Pressure loss model** to Euler number per tube row.

**Minimum free-flow area** — Smallest total flow area between inlet and outlet  
 $0.01 \text{ m}^2$  (default) | positive scalar

Smallest total flow area between inlet and outlet. If the channel is a collection of ducts, tubes, slots, or grooves, the minimum free-flow area is the sum of the smallest areas.

**Dependencies**

To enable this parameter, set **Flow geometry** to Generic.

**Heat transfer surface area without fins** — Total area of the heat transfer surface excluding fins  
 $2 \text{ m}^2$  (default) | positive scalar

Total area of the heat transfer surface, excluding fins.

**Dependencies**

To enable this parameter, set **Flow geometry** to Generic.

**Thermal liquid volume inside heat exchanger** — Total volume of thermal liquid in the heat exchanger  
 $0.05 \text{ m}^3$  (default) | positive scalar

Total volume of thermal liquid in the heat exchanger.

**Dependencies**

To enable this parameter, set **Flow geometry** to Generic.

**Fouling factor** — Additional thermal resistance due to fouling deposits  
 $0.1 \text{ m}^2 \cdot \text{K} / \text{kW}$  (default) | positive scalar

Additional thermal resistance due to fouling layers on the surfaces of the wall. In real systems, fouling deposits grow over time. However, the growth is slow enough to be assumed constant during the simulation.

**Total fin surface area** — Total heat transfer surface area of all fins  
 $0 \text{ m}^2$  (default) | positive scalar

Total heat transfer surface area of both sides of all fins. For example, if the fin is rectangular, the surface area is double the area of the rectangle.

The total heat transfer surface area is the sum of the channel surface area and the effective fin surface area, which is the product of the **Fin efficiency** and the **Total fin surface area**.

**Fin efficiency** — Ratio of actual-to-ideal transfer rates for fin  
 $0.5$  (default) | positive scalar in the range  $[0,1]$

Ratio of actual heat transfer to ideal heat transfer through the fins if the entire fin is at the primary heat transfer surface temperature.

**Initial thermal liquid pressure** — Moist air pressure at the start of simulation  
 $0.101325 \text{ MPa}$  (default) | positive scalar

Thermal liquid pressure at the start of the simulation.

**Initial thermal liquid temperature** — Temperature at the start of simulation  
293.15 K (default) | positive scalar | two-element vector

Temperature in the thermal liquid channel at the start of the simulation. This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial temperature in the channel. A vector value represents the initial temperature at the inlet and outlet in the form [inlet, outlet]. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

## Two-Phase Fluid 2

**Number of tubes** — Number of two-phase fluid tubes  
25 (default) | positive scalar

Number of two-phase fluid tubes.

**Total length of each tube** — Total length of each two-phase fluid tube  
1 m (default) | positive scalar

Total length of each two-phase fluid tube.

**Tube cross section** — Cross-sectional shape of a tube  
Circular (default) | Rectangular | Annular | Generic

Cross-sectional shape of a tube. Use **Generic** to specify an arbitrary cross-sectional geometry.

**Tube inner diameter** — Internal diameter of a single tube  
0.05 m (default) | positive scalar

Internal diameter of the cross-section of one tube. The cross-section and diameter are uniform along the tube. The size of the diameter influences the pressure loss and heat transfer calculations.

### Dependencies

To enable this parameter, set **Tube cross-section** to **Circular**.

**Tube width** — Internal width of a single tube  
0.05 m (default) | positive scalar

Internal width of the cross-section of one tube. The cross-section and width are uniform along the tube. The width and height influence the pressure loss and heat transfer calculations.

### Dependencies

To enable this parameter, set **Tube cross-section** to **Rectangular**.

**Tube height** — Internal height of a single tube  
0.05 m (default) | positive scalar

Internal height of one tube. The cross-section and height are uniform along the tube. The width and height influence the pressure loss and heat transfer calculations.

### Dependencies

To enable this parameter, set **Tube cross-section** to **Rectangular**.

**Annulus inner diameter (heat transfer surface)** — Smaller diameter of annular cross-section  
 $0.05 \text{ m}$  (default) | positive scalar

Smaller diameter of the annular cross-section of one tube. The cross-section and inner diameter are uniform along the tube. The inner diameter influences the pressure loss and heat transfer calculations. Heat transfer occurs through the inner surface of the annulus.

**Dependencies**

To enable this parameter, set **Tube cross-section** to Annular.

**Annulus outer diameter** — Larger diameter of annular cross-section  
 $0.1 \text{ m}$  (default) | positive scalar

Larger diameter of the annular cross-section of one tube. The cross-section and outer diameter are uniform along the tube. The outer diameter influences the pressure loss and heat transfer calculations.

**Dependencies**

To enable this parameter, set **Tube cross-section** to Annular.

**Cross-sectional area per tube** — Internal area normal to flow in a single tube  
 $0.002 \text{ m}^2$  (default) | positive scalar

Internal flow area of each tube.

**Dependencies**

To enable this parameter, set **Tube cross-section** to Generic.

**Wetted perimeter of tube cross-section for pressure loss** — Perimeter of tube cross-section that fluid touches  
 $0.15 \text{ m}$  (default) | positive scalar

Perimeter of the tube cross-section that the fluid touches. The cross-section and perimeter are uniform along the tube. This value is applied in pressure loss calculations.

**Dependencies**

To enable this parameter, set **Tube cross-section** to Generic.

**Perimeter of tube cross-section for heat transfer** — Perimeter of a single tube for heat transfer calculations  
 $0.15 \text{ m}$  (default) | positive scalar

Tube perimeter for heat transfer calculations. This is often the same as the tube perimeter, but in cases such as the annular cross-section, this may be only the inner or outer diameter, depending on the heat-transferring surface. The cross-section and tube perimeter are uniform along the tube.

**Dependencies**

To enable this parameter, set **Tube cross-section** to Generic.

**Pressure loss model** — Method of pressure loss calculation due to viscous friction  
 Correlation for flow inside tubes (default) | Pressure loss coefficient

Method of pressure loss calculation due to viscous friction. The settings are:

- **Pressure loss coefficient.** Use this setting to calculate the pressure loss based on an empirical loss coefficient.
- **Correlation for flow inside tubes.** Use this setting to calculate the pressure loss based on the pipe flow correlation.

**Pressure loss coefficient,  $\Delta p / (0.5 \cdot \rho \cdot v^2)$**  — Empirical loss coefficient for all pressure losses in the channel  
10 (default)

Empirical loss coefficient for all pressure losses in the channel. This value accounts for wall friction and minor losses due to bends, elbows, and other geometry changes in the channel.

The loss coefficient can be calculated from a nominal operating condition or be tuned to fit experimental data. It is defined as:

$$\xi = \frac{\Delta p}{\frac{1}{2} \rho v^2},$$

where  $\Delta p$  is the pressure drop,  $\rho$  is the two-phase fluid density, and  $v$  is the flow velocity.

#### Dependencies

To enable this parameter, set **Pressure loss model** to Pressure loss coefficient.

**Local resistance specification** — Method for quantifying pressure losses  
Aggregate equivalent length (default) | Local loss coefficient

Method for quantifying pressure losses in the Haaland correlation.

#### Dependencies

To enable this parameter, set **Pressure loss model** to Correlation for flow inside tubes.

**Aggregate equivalent length of local resistances** — Combined length of all local resistances per tube  
0.1 m (default) | positive scalar

Combined length of all local resistances per tube. This value is the length of tubing that results in the same pressure losses as the sum of all minor losses in the tube due to resistances such as bends, tees, or unions. A longer combined length results in larger pressure losses. The block adds the value of this parameter to the **Total length of each tube** parameter in the calculations of pressure loss due to friction.

#### Dependencies

To enable this parameter, set **Pressure loss model** to Correlation for flow inside tubes and **Local resistance specification** to Aggregate equivalent length.

**Total local loss coefficient** — Pressure loss coefficient  
0.1 (default) | positive scalar

Local pressure loss coefficient over the system. You can use this parameter to calibrate your system to match experimental results.

**Dependencies**

To enable this parameter, set **Pressure loss model** to Correlation for flow inside tubes and **Local resistance specification** to Local loss coefficient.

**Internal surface absolute roughness** — Mean surface roughness height  
15e-6 m (default) | positive scalar

Mean height of tube surface defects. A rougher wall results in larger pressure losses in the turbulent regime for pressure loss calculated with the Haaland correlation.

**Dependencies**

To enable this parameter, set either:

- **Pressure loss model**
- **Heat transfer coefficient model**

to Correlation for flow inside tubes.

**Laminar flow upper Reynolds number limit** — Largest Reynolds number that indicates laminar flow  
2000 (default) | positive scalar

Largest Reynolds number that indicates laminar flow. Between this value and the **Turbulent flow lower Reynolds number**, the flow regime is transitional.

**Dependencies**

To enable this parameter, set **Pressure loss model** to Correlations for tubes.

**Turbulent flow lower Reynolds number limit** — Smallest Reynolds number that indicates turbulent flow  
4000 (default) | positive scalar

Smallest Reynolds number that indicates turbulent flow. Between this value and the **Laminar flow upper Reynolds number limit**, the flow regime is transitional.

**Dependencies**

To enable this parameter, set **Pressure loss model** to Correlations for tubes.

**Laminar friction constant for Darcy friction factor** — Coefficient of pressure loss due to viscous friction in laminar flows  
64 (default) | positive scalar

Coefficient in pressure loss equations for viscous friction in laminar flows. This parameter may also be known as the *shape factor*. The default value corresponds to a circular tube cross-section.

**Dependencies**

To enable this parameter, set **Pressure loss model** to Correlations for tubes.

**Heat transfer coefficient model** — Method of calculating heat transfer coefficient between fluid and wall  
Correlation for flow inside tubes (default) | Colburn equation

Method of calculating the heat transfer coefficient between the fluid and the wall. The available settings are:

- **Colburn equation.** Use this setting to calculate the heat transfer coefficient with user-defined variables  $a$ ,  $b$ , and  $c$ . In the liquid and vapor zones, the heat transfer coefficient is based on the Colburn equation. In the liquid-vapor mixture zone, the heat transfer coefficient is based on the Cavallini-Zecchin equation.
- **Correlation for flow inside tubes.** Use this setting to calculate the heat transfer coefficient for pipe flows. In the liquid and vapor zones, the heat transfer coefficient is calculated with the Gnielinski correlation. In the liquid-vapor mixture zone, the heat transfer coefficient is calculated with the Cavallini-Zecchin equation.

**Coefficients [a, b, c] for  $a \cdot \text{Re}^b \cdot \text{Pr}^c$  in liquid zone** — Colburn equation coefficients in liquid zone

[.023, .8, .33] (default) | three-element vector of positive scalars

Three-element vector containing the empirical coefficients of the Colburn equation. Each fluid zone has a distinct Nusselt number, which is calculated by the Colburn equation per zone. The general form of the Colburn equation is:

$$\text{Nu} = a \text{Re}^b \text{Pr}^c.$$

#### Dependencies

To enable this parameter, set **Heat transfer coefficient model** to Colburn equation.

**Coefficients [a, b, c] for  $a \cdot \text{Re}^b \cdot \text{Pr}^c$  in mixture zone** — Cavallini-Zecchin equation coefficients in mixture zone

[.05, .8, .33] (default) | three-element vector of positive scalars

Three-element vector containing the empirical coefficients of the Cavallini-Zecchin equation. Each fluid zone has a distinct Nusselt number, which is calculated in the mixture zone by the Cavallini-Zecchin equation:

$$\text{Nu} = \frac{a \text{Re}_{\text{SL}}^b \text{Pr}_{\text{SL}}^c \left\{ \left[ \left( \sqrt{\frac{\rho_{\text{SL}}}{\rho_{\text{SV}}}} - 1 \right) x_{\text{Out}} + 1 \right]^{1+b} - \left[ \left( \sqrt{\frac{\rho_{\text{SL}}}{\rho_{\text{SV}}}} - 1 \right) x_{\text{In}} + 1 \right]^{1+b} \right\}}{(1+b) \left( \sqrt{\frac{\rho_{\text{SL}}}{\rho_{\text{SV}}}} - 1 \right) (x_{\text{Out}} - x_{\text{In}})}.$$

#### Dependencies

To enable this parameter, set **Heat transfer coefficient model** to Colburn equation.

**Coefficients [a, b, c] for  $a \cdot \text{Re}^b \cdot \text{Pr}^c$  in vapor zone** — Colburn equation coefficients in vapor zone

[.023, .8, .33] (default) | three-element vector of positive scalars

Three-element vector containing the empirical coefficients of the Colburn equation. Each fluid zone has a distinct Nusselt number, which is calculated by the Colburn equation per zone. The general form of the Colburn equation is:

$$\text{Nu} = a \text{Re}^b \text{Pr}^c.$$

**Dependencies**

To enable this parameter, set **Heat transfer coefficient model** to Colburn equation.

**Laminar flow Nusselt number** — Ratio of convective to conductive heat transfer in the laminar flow regime

3.66 (default) | positive scalar

Ratio of convective to conductive heat transfer in the laminar flow regime. The fluid Nusselt number influences the heat transfer rate and depends on the tube cross-section.

**Dependencies**

To enable this parameter, set **Heat transfer coefficient model** to Correlation for flow inside tubes.

**Fouling factor** — Additional thermal resistance due to fouling deposits

$0.1 \text{ m}^2 \cdot \text{K}/\text{kW}$  (default) | positive scalar

Additional thermal resistance due to fouling layers on the surfaces of the wall. In real systems, fouling deposits grow over time, however, the growth is slow enough to be assumed constant during the simulation.

**Total fin surface area** — Total heat transfer surface area of fins

$0 \text{ m}^2$  (default) | positive scalar

Total heat transfer surface area of both sides of all fins. For example, if the fin is rectangular, the surface area is double the area of the rectangle.

The total heat transfer surface area is the sum of the channel surface area and the effective fin surface area, which is the product of the **Fin efficiency** and the **Total fin surface area**.

**Fin efficiency** — Ratio of actual-to-ideal transfer rates for fin

0.5 (default) | positive scalar in the range [0,1]

Ratio of actual heat transfer to ideal heat transfer through the fins if the entire fin is at the primary heat transfer surface temperature.

**Initial fluid energy specification** — Initial state of the two-phase fluid

Temperature (default) | Vapor quality | Vapor void fraction | Specific enthalpy | Specific internal energy

Quantity used to describe the initial state of the fluid.

The value for **Initial fluid energy specification** limits the available initial states for the two-phase fluid. When **Initial fluid energy specification** is:

- **Temperature** — Specify an initial state that is a subcooled liquid or superheated vapor. You cannot specify a liquid-vapor mixture because the temperature is constant across the liquid-vapor mixture region.
- **Vapor quality** — Specify an initial state that is a liquid-vapor mixture. You cannot specify a subcooled liquid or a superheated vapor because the liquid mass fraction is 0 and 1, respectively, across the whole region. Additionally, the block limits the pressure to below the critical pressure.
- **Vapor void fraction** — Specify an initial state that is a liquid-vapor mixture. You cannot specify a subcooled liquid or a superheated vapor because the liquid mass fraction is 0 and 1,

respectively, across the whole region. Additionally, the block limits the pressure to below the critical pressure.

- **Specific enthalpy** — Specify the specific enthalpy of the fluid. The block does not limit the initial state.
- **Specific internal energy** — Specify the specific internal energy of the fluid. The block does not limit the initial state.

**Initial two-phase fluid pressure** — Fluid pressure at the start of simulation

0.101325 MPa (default) | positive scalar

Fluid pressure at the start of the simulation.

**Initial two-phase fluid temperature** — Temperature at the start of simulation

293.15 K (default) | positive scalar | two-element vector

Temperature in the two-phase fluid channel at the start of simulation. This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial temperature in the channel. A vector value represents the initial temperature at the inlet and outlet in the form [inlet, outlet]. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

#### **Dependencies**

To enable this parameter, set **Initial fluid energy specification** to Temperature.

**Initial two-phase fluid vapor quality** — Vapor mass fraction at the start of simulation

0.5 (default) | positive scalar in the range [0,1] | two-element vector

Vapor mass fraction in the two-phase fluid channel at the start of simulation. This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial vapor quality in the channel. A vector value represents the initial vapor quality at the inlet and outlet in the form [inlet, outlet]. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

#### **Dependencies**

To enable this parameter, set **Initial fluid energy specification** to Vapor quality.

**Initial two-phase fluid vapor void fraction** — Vapor volume fraction at the start of simulation

0.5 (default) | positive scalar in the range [0,1] | two-element vector

Vapor volume fraction in the two-phase fluid channel at the start of simulation. This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial void fraction in the channel. A vector value represents the initial void fraction at the inlet and outlet in the form [inlet, outlet]. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

#### **Dependencies**

To enable this parameter, set **Initial fluid energy specification** to Vapor void fraction.

**Initial two-phase fluid specific enthalpy** — Enthalpy per unit mass at the start of simulation

1500 kJ/kg (default) | positive scalar | two-element vector

Enthalpy per unit mass in the two-phase fluid channel at the start of simulation. This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial specific enthalpy in the

channel. A vector value represents the initial specific enthalpy at the inlet and outlet in the form [inlet, outlet]. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

### Dependencies

To enable this parameter, set **Initial fluid energy specification** to Specific enthalpy.

**Initial two-phase fluid specific internal energy** — Internal energy per unit mass at the start of simulation

1500 kJ/kg (default) | positive scalar | two-element vector

Internal energy per unit mass in the two-phase fluid channel at the start of simulation. This parameter can be a scalar or a two-element vector. A scalar value represents the mean initial specific internal energy in the channel. A vector value represents the initial specific internal energy at the inlet and outlet in the form [inlet, outlet]. The block calculates a linear gradient between the two ports. The inlet and the outlet ports are identified according to the initial flow direction.

### Dependencies

To enable this parameter, set **Initial fluid energy specification** to Specific internal energy.

## Version History

Introduced in R2020b

### R2023a: Model additional pressure losses by using a local loss coefficient

Set the **Local resistance specification** parameter to Local loss coefficient to specify the new method for quantifying pressure loss. This option allows you to model additional friction losses beyond the loss due the length of the pipes .

# Constant Head Tank

(To be removed) Hydraulic reservoir where pressurization and fluid level remain constant regardless of volume change

---

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

---

## Library

Low-Pressure Blocks

## Description

The Constant Head Tank block represents a pressurized hydraulic reservoir, in which fluid is stored under a specified pressure. The size of the tank is assumed to be large enough to neglect the pressurization and fluid level change due to fluid volume. The block accounts for the fluid level elevation with respect to the tank bottom, as well as for pressure loss in the connecting pipe that can be caused by a filter, fittings, or some other local resistance. The loss is specified with the pressure loss coefficient. The block computes the volume of fluid in the tank and exports it outside through the physical signal port V.

The fluid volume value does not affect the results of simulation. It is introduced merely for information purposes. It is possible for the fluid volume to become negative during simulation, which signals that the fluid volume is not enough for the proper operation of the system. By viewing the results of the simulation, you can determine the extent of the fluid shortage.

For reasons of computational robustness, the pressure loss in the connecting pipe is computed with the equations similar to that used in the Fixed Orifice block:

$$q = \sqrt{\frac{1}{K}} \cdot A_p \sqrt{\frac{2}{\rho}} \cdot \frac{p_{loss}}{(p_{loss}^2 + p_{cr}^2)^{1/4}}$$

$$p_{cr} = K \frac{\rho}{2} \left( \frac{Re_{cr} \cdot \nu}{d} \right)^2$$

The Critical Reynolds number is set to 15.

The pressure at the tank inlet is computed with the following equations:

$$p = p_{elev} - p_{loss} + p_{pr}$$

$$p_{elev} = \rho \cdot g \cdot H$$

$$A_p = \frac{\pi \cdot d^2}{4}$$

where

$p$	Pressure at the tank inlet
$p_{elev}$	Pressure due to fluid level
$p_{loss}$	Pressure loss in the connecting pipe
$p_{pr}$	Pressurization
$\rho$	Fluid density
$g$	Acceleration of gravity
$H$	Fluid level with respect to the bottom of the tank
$K$	Pressure loss coefficient
$A_p$	Connecting pipe area
$d$	Connecting pipe diameter
$q$	Flow rate
$p_{cr}$	Minimum pressure for turbulent flow

Connection T is a hydraulic conserving port associated with the tank inlet. Connection V is a physical signal port. The flow rate is considered positive if it flows into the tank.

## Parameters

### Pressurization

Gage pressure acting on the surface of the fluid in the tank. It can be created by a gas cushion, membrane, bladder, or piston, as in bootstrap reservoirs. This parameter must be greater than or equal to zero. The default value is 0, which corresponds to a tank connected to atmosphere.

### Fluid level

The fluid level with respect to the tank bottom. This parameter must be greater than zero. The default value is 1 m.

### Initial fluid volume

The initial volume of fluid in the tank. This parameter must be greater than zero. The default value is 0.2 m<sup>3</sup>.

### Inlet pipeline diameter

The diameter of the connecting pipe. This parameter must be greater than zero. The default value is 0.02 m.

### Pipeline pressure loss coefficient

The value of the pressure loss coefficient, to account for pressure loss in the connecting pipe. This parameter must be greater than zero. The default value is 1.2.

## Ports

The block has the following ports:

T

Hydraulic conserving port associated with the tank inlet.

V

Physical signal port that outputs the volume of fluid in the tank.

### Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Valves / Flow Control Valves

### Description

Counterbalance valves are used in hydraulic systems working with an overriding (run-away) or suspended load. They are designed to create backpressure at the return line of the actuator to prevent losing control over the load. The following illustration shows a counterbalance valve schematic.

If a directional valve (not shown in the picture) is shifted into position that lowers the load, then the fluid from the rod chamber of the cylinder can exit only if pressure at port P (pilot pressure) and port L (load pressure) create enough force to overcome the spring force and open the valve. In statics, the valve is described with the equation

$$F_0 + c \cdot x = p_{pilot} \cdot A_{pilot} + p_{load} \cdot A_{load} - p_{back} \cdot A_{back} \quad (1-5)$$

where

$F_0$	Spring setting
$c$	Spring rate
$x$	Valve opening
$p_{pilot}$	Pilot pressure (pressure at port P)
$p_{load}$	Load pressure (pressure at port L)
$p_{back}$	Backpressure (pressure at return port B)
$A_{pilot}$	Valve effective area at pilot port P
$A_{load}$	Valve effective area at load port L
$A_{back}$	Valve effective area at return port B

Counterbalance valve, classified by type, is an internally-externally piloted valve because both the pilot pressure and the load pressure tend to open the valve. After minor rearrangements, Equation 1 takes the form

$$p_{set} + c_p \cdot x = p_{pilot} \cdot k_{pilot} + p_{load} - p_{back} \cdot k_{back} \quad (1-6)$$

$$p_{set} = F_0/A_{load}$$

$$c_p = c/A_{load}$$

$$k_{pilot} = A_{pilot}/A_{load}$$

$$k_{back} = A_{back}/A_{load}$$

where

$p_{set}$	Valve pressure setting
$c_p$	Spring pressure stiffness (Pa/m)
$x$	Valve opening
$k_{pilot}$	Pilot ratio
$k_{back}$	Backpressure ratio

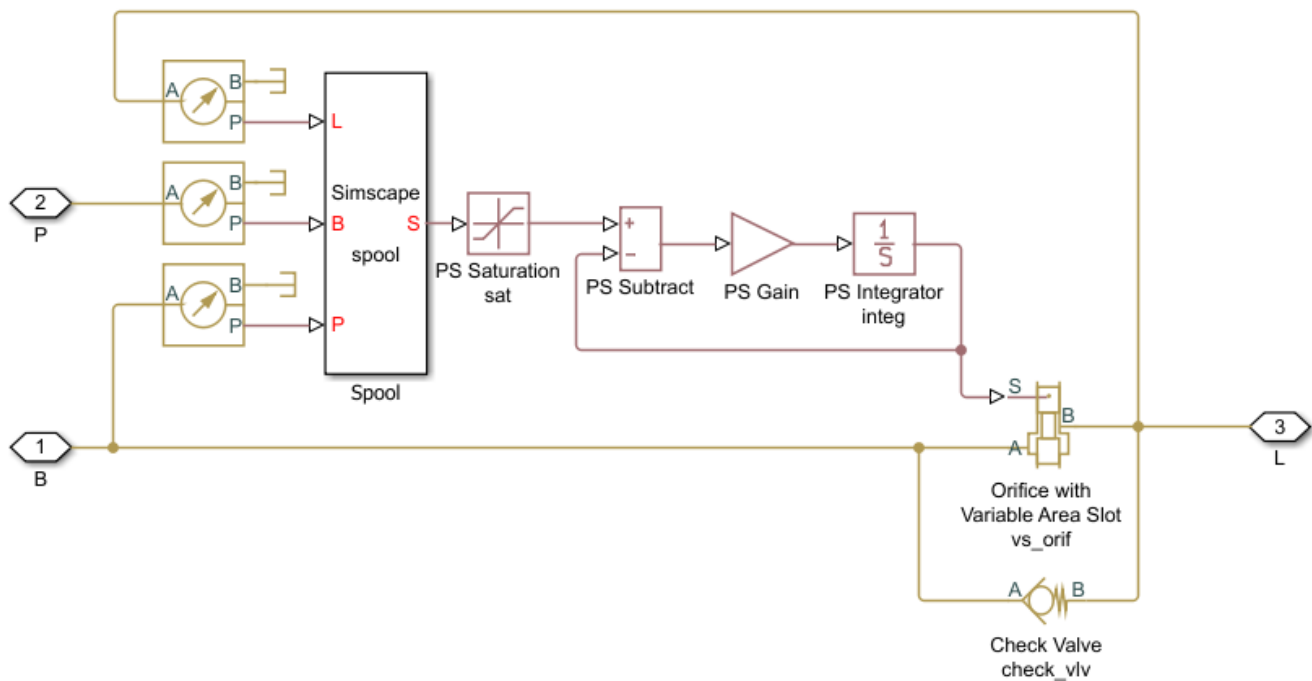

The valve displacement is determined from Equation 2:

$$x = \frac{p_{pilot} \cdot k_{pilot} + p_{load} - p_{back} \cdot k_{back} - p_{set}}{c_p} \quad (1-7)$$

$$0 \leq x \leq x_{max}$$

where  $x_{max}$  is the maximum valve displacement.

The Counterbalance Valve block can be represented as the following structural model.

The pressure sensors measure pressure at respective ports and convey their values to the Fcn block, which, together with the PS Saturation block, performs calculations in accordance with Equation 3. The valve displacement is passed through the first order lag block, built of the PS Subtract, PS Gain, and PS Integrator blocks, to account for valve dynamics. The gain of the PS Gain block is set to  $1/T$ , where  $T$  is the time constant. The Variable Orifice and Check Valve blocks simulate the counterbalance valve orifice and check valve. In the actual Counterbalance Valve block model, the operations performed by the sensors and the Fcn block are executed in the block equation section.

The Counterbalance Valve block is essentially a data-sheet-based model. Depending on data listed in the manufacturer's catalogs or data sheets for your particular valve, you can choose one of the following model parameterization options:

- By maximum area and opening — Use this option if the data sheet provides only the orifice maximum area and the control member maximum stroke.
- By area vs. opening table — Use this option if the catalog or data sheet provides a table of the orifice passage area based on the control member displacement.

In the latter case, the PS Saturation block in the structural model is replaced with the PS Lookup Table (1D) block, and you can choose from three interpolation and two extrapolation methods.

Connections L and B are hydraulic conserving ports associated with the load and backpressure ports of the valve. The hydraulic conserving port P is associated with the pilot port. The block positive direction is from port L to port B. Positive pressure at port P opens the valve.

### Assumptions and Limitations

- Valve dynamics are approximated by introducing the first order lag between the pressure sensors and the variable orifice control member displacement.

- Inertia, friction, or hydraulic forces acting on the valve control member are not taken into account.

## Ports

### Conserving

**P** — Pilot port  
isothermal liquid

Hydraulic conserving port associated with the valve pilot port.

**L** — Load port  
isothermal liquid

Hydraulic conserving port associated with the valve load port.

**B** — Backpressure port  
isothermal liquid

Hydraulic conserving port associated with the valve backpressure port.

## Parameters

### Basic parameters

**Valve pressure setting** — Cracking pressure at port L  
50e5 Pa (default) | positive scalar

The parameter specifies the pressure at port **L** necessary to start opening the valve. The setting is controlled with the valve spring.

**Valve spring stiffness** — Spring stiffness at port L  
1e8 Pa/m (default) | positive scalar

The valve spring pressure stiffness  $c_p$ .

**Pilot ratio** — Ratio of pilot to load chamber area  
3 (default) | positive scalar

The ratio between the effective areas of the control member face in the pilot chamber and in the load chamber. This is one of the fundamental valve characteristics in a catalog or data sheet. The default value is 3.

**Backpressure ratio** — Ratio of back pressure port to load port area  
4 (default) | positive scalar

The ratio between the effective area of the control member, onto which the backpressure acts, and the load chamber valve area. There is a wide variety of counterbalance valves with compensated or partially-compensated backpressure. The parameter can take zero value if the valve is completely compensated.

**Time constant** — Valve opening time constant  
0.06 s (default) | positive scalar

The valve dynamics are approximated with the first order lag. This parameter is the time constant of the lag.

**Leakage area** — Open area of fully closed valve

1e-9 m<sup>2</sup> (default) | positive scalar

The total area of possible leaks in the completely closed orifice and check valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the orifice or check valve is completely closed. The parameter value must be greater than 0.

### Variable orifice

**Variable orifice parameterization** — Method of variation

By maximum area and opening (default) | By area vs. opening table

Select one of the following methods for specifying the orifice:

- **By maximum area and opening** — Provide values for the maximum orifice area and the maximum orifice opening. The passage area is linearly dependent on the control member displacement, that is, the orifice is closed at the initial position of the control member (zero displacement), and the maximum opening takes place at the maximum displacement.
- **By area vs. opening table** — Provide tabulated data of orifice openings and corresponding orifice areas. The passage area is determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.

**Orifice maximum area** — Maximum opened area

8e-5 m<sup>2</sup> (default) | positive scalar

Specify the area of a fully opened orifice. The parameter value must be greater than zero. This parameter is used if **Variable orifice parameterization** is set to **By maximum area and opening**.

**Orifice maximum opening** — Maximum opened length

5e-3 m (default) | positive scalar

Specify the maximum displacement of the control member. The parameter value must be greater than zero. This parameter is used if **Variable orifice parameterization** is set to **By maximum area and opening**.

**Tabulated orifice opening** — Control member length tabulated data

[-.002, 0, .005, .015] (default) | numerical array

Specify the vector of input values for orifice openings as a one-dimensional array. The input values vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in meters, are [-2e-3, 0, 5e-3, 15e-3]. This parameter is used if **Variable orifice parameterization** is set to **By area vs. opening table**. **Tabulated orifice openings** values will be used together with **Tabulated orifice area** values for one-dimensional table lookup.

**Tabulated orifice area** — Open area tabulated data

[1e-09, 4e-09, 1e-05, 1.02e-05] (default) | numerical array

Specify the vector of orifice areas as a one-dimensional array. The vector must be of the same size as the orifice openings vector. All the values must be positive. The default values, in m<sup>2</sup>, are

[1e-12, 4e-12, 1.e-5, 1.02e-5]. This parameter is used if **Variable orifice parameterization** is set to **By area vs. opening table**.

#### **Interpolation method** — Tabular interpolation

Linear (default) | Smooth

This parameter is used if **Variable orifice parameterization** is set to **By area vs. opening table**. Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- **Linear** — Select this option to get the best performance.
- **Smooth** — Select this option to produce a continuous curve with continuous first-order derivatives.

For more information on interpolation algorithms, see the PS Lookup Table (1D) block reference page.

#### **Extrapolation method** — Tabular extrapolation

Linear (default) | Nearest

This parameter is used if **Variable orifice parameterization** is set to **By area vs. opening table**. Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- **Linear** — Select this option to produce a curve with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.
- **Nearest** — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see the PS Lookup Table (1D) block reference page.

#### **Orifice flow discharge coefficient** — Orifice discharge coefficient

0.7 (default) | positive scalar

Semi-empirical parameter for orifice capacity characterization. Its value depends on the geometrical properties of the orifice, and usually is provided in textbooks or manufacturer data sheets.

#### **Orifice laminar transition specification** — Method for identifying fluid regime transition

Pressure ratio (default) | Reynolds number

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Orifice laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Orifice critical Reynolds number** parameter.

#### **Orifice laminar flow pressure ratio** — Pressure ratio at fluid regime transition

0.999 (default) | positive scalar

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Orifice laminar transition specification** parameter is set to `Pressure ratio`.

**Orifice critical Reynolds number** — Upper limit to laminar flow  
12 (default) | positive scalar

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12. This parameter is visible only if the **Orifice laminar transition specification** parameter is set to `Reynolds number`.

### Check valve

**Check valve maximum passage area** — Maximum valve open area  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Valve passage maximum cross-sectional area.

**Check valve cracking pressure** — Threshold for valve opening  
0.3e5 Pa (default) | positive scalar

Pressure level at which the orifice of the valve starts to open.

**Check valve maximum opening pressure** — Valve maximum pressure  
1.2e5 Pa (default) | positive scalar

Pressure differential across the valve needed to fully open the valve. Its value must be higher than the cracking pressure. The default value is 1.2e5 Pa.

**Check valve flow discharge coefficient** — Discharge coefficient  
0.7 (default)

Semi-empirical parameter for valve capacity characterization. Its value depends on the geometrical properties of the orifice, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.7.

**Check valve laminar transition specification** — Method for identifying fluid regime transition  
`Pressure ratio` (default) | `Reynolds number`

Select how the block transitions between the laminar and turbulent regimes:

- `Pressure ratio` — The transition from laminar to turbulent regime is smooth and depends on the value of the **Check valve laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- `Reynolds number` — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Check valve critical Reynolds number** parameter.

**Check valve laminar flow pressure ratio** — Pressure ratio at fluid regime transition  
0.999 (default) | positive scalar

Pressure ratio at which the flow transitions between laminar and turbulent regimes. This parameter is visible only if the **Check valve laminar transition specification** parameter is set to `Pressure ratio`.

**Check valve critical Reynolds number** — Upper limit to laminar flow through check valve  
12 (default) | positive scalar

The maximum Reynolds number for laminar flow. The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches this value. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12. This parameter is visible only if the **Check valve laminar transition specification** parameter is set to Reynolds number.

## Version History

**Introduced in R2012b**

**R2023a: To be removed**

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Counterbalance Valve (IL)

High-pressure regulation valve in an isothermal liquid system

### Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Pressure Control Valves

### Description

The Counterbalance Valve (IL) block represents a counterbalance pressure control valve in an isothermal liquid network. A counterbalance valve is common in applications where high-pressure events are common or when a task requires high-pressure controlled manipulation at production speeds. This includes tasks such as overloading hydraulics or lowering suspended loads. The valve functions under the force balance between a spring, the back pressure at port **B**, and the load pressure at port **L**. The valve responds to changes in the pilot line pressure. When the pilot pressure exceeds the back pressure, the valve begins to open.

There is no flow between ports **B** and **P** or ports **L** and **P**.

This figure shows a typical counterbalance valve cutaway.

### Valve Opening

The block balances the forces of the counterbalance valve, such that

$$p_{pilot}A_{pilot} + p_{load}A_{load} = p_{back}A_{back} + F_{set} + k_{spring}x_{spool}$$

where:

- $p_{pilot}$  is the pressure at port **P**.
- $p_{load}$  is the pressure at port **L**.
- $p_{back}$  is the pressure at port **B**.
- $F_{set}$  is the accumulated force due to the spring.
- $k_{spring}$  is the spring constant.
- $x_{spool}$  is the linear position of the relief stage spool body. This position is relative to the unpressurized installed position.

The block sets the pressure-acting areas  $A_{pilot}$ ,  $A_{load}$ , and  $A_{back}$  according to the **Pilot ratio** parameter,  $R_{pilot}$ , such that

$$R_{pilot} = \frac{A_{pilot}}{A_{load}},$$

and the **Back pressure ratio** parameter,  $R_{back}$ , such that

$$R_{back} = \frac{A_{back}}{A_{load}}.$$

A ratio of 4:1 or 3:1 is typical for counterbalance valves.

The preset force,  $F_{spring}$ , represents the combined spring preloading and spring force at port **B**. This force is a function of  $p_{set}$ , the **Set pressure differential** parameter, such that

$$F_{set} = p_{set}A_{load}.$$

This figure shows the schematic from the “Counterbalance Valve With Test Harness” example where the pressure ports control the valve by acting on surfaces with differential area. The arrows show the direction of force due to pressure or spring force acting on the relief stage body. The gray sections represent a single, solid body that moves to the right when the relief stage opens. The check valve travels to the left when it opens.

## Opening Parameterization

The block accepts linear or tabulated parameterizations. The check valve portion of the block operates identically to the Check Valve (IL) block.

### Linear Parameterization

When you set **Opening parameterization** to Linear - Area vs. pressure, the block calculates the valve opening area, such that

$$A_{valve} = \hat{p}(A_{max} - A_{leak}) + A_{leak}.$$

The block calculates the normalized control pressure,  $\hat{p}$ , as

$$\hat{p} = \frac{(p_{load} + p_{pilot}R_{pilot} - p_{back}R_{back}) - p_{set}}{(p_{max} - p_{set})},$$

where  $p_{max}$  is the **Maximum opening pressure differential** parameter.

The normalized check valve pressure is

$$\hat{p} = \frac{p_{control} - p_{cracking}}{p_{max} - p_{cracking}},$$

where:

- $p_{cracking}$  is the **Cracking pressure differential** parameter.
- $p_{max}$  is the check valve **Maximum opening pressure differential** parameter.

When the valve is in a near-open or near-closed position in the linear parameterization, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the control pressure between  $p_{cracking}$  and  $p_{max}$ . For more information, see “Numerical Smoothing”.

### Tabulated Area Parameterization

When you set **Opening parameterization** to Tabulated data - Area vs. pressure, the block uses the same equations as for the linear parameterization but with tabulated data. The tabulated data represents area with respect to a given control pressure, where  $P_{control} = p_{load} + p_{pilot}R_{pilot} - p_{back}R_{back}$ . The first element of the **Pressure differential vector** parameter is the set pressure, which is the control pressure when the relief stage begins to open. The last element defines the control pressure when the valve is fully open.

### Tabulated Flow Rate Parameterization

When you set **Opening parameterization** to Tabulated data - Volumetric flow rate vs. pressure, the volumetric flow rate equations refer to these quantities:

- $\bar{\rho}_{valve}$  is the simulated average density of relief stage flow.
- $K$  is the flow coefficient through the relief stage.
- $\Delta p_{valve}$  is the pressure drop across the relief stage during flow.
- $\Delta p_{crit}$  is the critical pressure drop across the relief stage during flow.
- $p_{control}$  is the simulated control pressure.

- $p_{control,TLU,Ref}$  is an internally derived lookup table of changing control pressures.
- $p_{set}$  is the set pressure differential.
- $Re_{crit}$  is the **Critical Reynolds number** parameter.
- $C_d$  is the **Discharge coefficient** parameter.
- $\nu$  is the kinematic viscosity.
- $K_{TLU,Ref}$  is an internally derived lookup table of changing flow coefficients as a function of valve area.
- $\dot{V}_{TLU,Ref}$  is the reference volumetric flow rate vector.
- $p_{pilot,Ref}$ ,  $p_{back,Ref}$ ,  $p_{load,Ref}$  are the pilot pressure, back pressure, and load pressure for the user-provided **Reference volumetric flow rate vector** parameter, respectively.

The block calculates the mass flow rate for the relief stage such that

$$\dot{m}_{valve} = \bar{\rho}_{valve} K \frac{\Delta p_{valve}}{(\Delta p_{valve}^2 + \Delta p_{crit}^2)^{1/4}},$$

where:

$$\begin{aligned} \Delta p_{valve} &= p_{load} - p_{back} \\ \Delta p_{crit} &= \frac{\pi \sqrt{2} \bar{\rho}_{valve}}{8 C_d} (Re_{crit} \nu) \end{aligned}$$

$$K = \text{tablelookup}(p_{control,TLU,Ref}, K_{TLU,Ref}, p_{control}, \text{interpolation} = \text{linear}, \text{extrapolation} = \text{nearest})$$

Liquid flows from the load port to the back port. The block extrapolates  $K$  to the nearest point after it calculates  $K_{TLU,Ref}$  as

$$K_{TLU,Ref} = \frac{\dot{V}_{TLU,Ref}}{\sqrt{\Delta p_{valve,TLU,ref}}},$$

where  $\Delta p_{valve,TLU,ref} = p_{load,Ref} - p_{back,Ref}$ . The block calculates the control pressure as

$$p_{control} = R_{pilot} p_{pilot} + p_{load} - R_{back} p_{back}$$

and the reference control vector as

$$p_{control,TLU,Ref} = R_{pilot} p_{pilot,Ref} + p_{load,Ref} - R_{back} p_{back,Ref} + p_{offset}$$

where:

$$p_{pilot,Ref} = 1 \text{ atm}$$

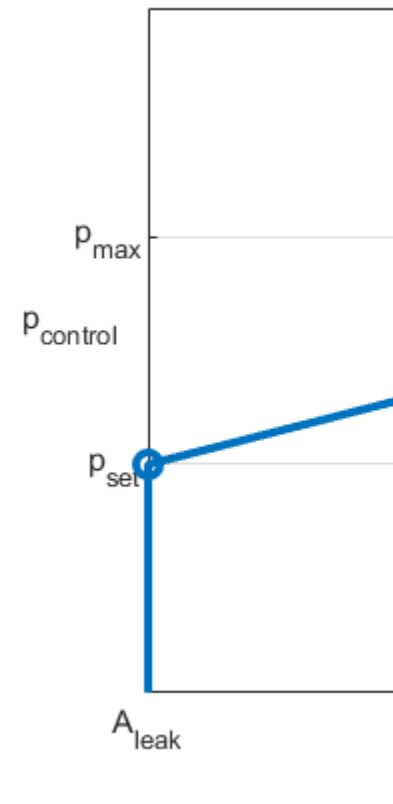

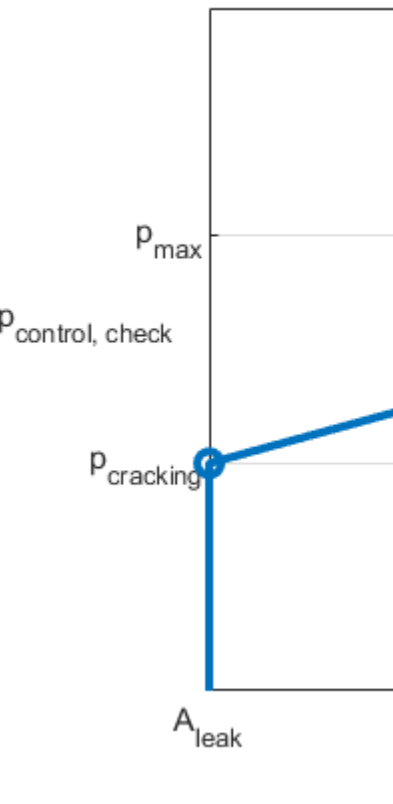

$$p_{back,Ref} = 1 \text{ atm}$$

$$p_{load,Ref} = p_{back,Ref} + \Delta p_{valve,TLU,Ref}$$

The block internally derives  $\Delta p_{flow,Ref}$  which is the pressure drop for fluid flow in the specified reference curve. The block calculates  $p_{offset}$  internally as

$$p_{offset} = p_{set} - R_{pilot} p_{pilot,Ref} - p_{load,Ref}(1) + R_{back} p_{back,Ref}$$

The table shows how the block controls the relief and check stages opening areas depending the **Opening area** parameter setting.

Opening parameterization	Relief stage	Check stage
Linear - Area vs. pressure	 <p>The graph shows a blue line representing the relationship between pressure and area. ### Predefined Parameterization

You can populate the block with pre-parameterized manufacturing data, which allows you to model a specific supplier component.

To load a predefined parameterization:

- 1 In the block dialog box, next to **Selected part**, click the "<click to select>" hyperlink next to **Selected part** in the block dialogue box settings.
- 2 The Block Parameterization Manager window opens. Select a part from the menu and click **Apply all**. You can narrow the choices using the **Manufacturer** drop down menu.
- 3 You can close the **Block Parameterization Manager** menu. The block now has the parameterization that you specified.
- 4 You can compare current parameter settings with a specific supplier component in the Block Parameterization Manager window by selecting a part and viewing the data in the **Compare selected part with block** section.

**Note** Predefined block parameterizations use available data sources to supply parameter values. The block substitutes engineering judgement and simplifying assumptions for missing data. As a result, expect some deviation between simulated and actual physical behavior. To ensure accuracy, validate the simulated behavior against experimental data and refine your component models as necessary.

To learn more, see “List of Pre-Parameterized Components”.

## Assumptions and Limitations

- The block operates in only the internal drain-external pilot, non-vented configuration.
- When you set **Opening parameterization** to **Tabulated data - Volumetric flow rate vs. pressure**, the block uses values of volumetric flow rate with respect to the pressure drop across the relief stage to generate reference curves. The block assumes that the pilot port and back port are open to atmospheric pressure.

## Ports

### Conserving

**L** — Liquid port  
isothermal liquid

Isothermal liquid conserving port associated with the load.

**B** — Liquid port  
isothermal liquid

Isothermal liquid conserving port associated with the back pressure of the valve.

**P** — Pressure port  
isothermal liquid

Pilot pressure port.

## Parameters

### Model Parameterization

**Opening parameterization** — Opening parameterization

Linear - Area vs. pressure (default) | Tabulated data - Area vs. pressure |  
Tabulated data - Volumetric flow rate vs. pressure

Method of modeling the opening of the valve. When you select **Linear - Area vs. pressure** or **Tabulated data - Area vs. pressure**, the block relates the opening area to the control pressure. When you select **Tabulated data - Volumetric flow rate vs. pressure**, the block takes a reference flow rate and pressure differential curve for the relief and check stages of the counterbalance valve, where the pressure at the back port and pilot port corresponds to 1 atm in the reference curve for the relief stage.

**Set pressure differential** — Initial spring compression pressure  
5 MPa (default) | nonnegative scalar

Pressure differential to lift the relief stage. Use this parameter to adjust the set pressure supplied by the data sheet.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Linear - Area vs. pressure or Tabulated data - Volumetric flow rate vs. pressure.

**Pressure differential vector** — Relief stage pressure drop values

5 : 0.2 : 6 MPa (default) | 1-by-*n* vector

Vector of pressure differential values for the relief stage. The vector elements must correspond one-to-one with the elements in the **Opening area vector** parameter. You must enter the elements in ascending order. This vector defines the control pressures that govern valve opening and shutting. The first element in the vector defines the set pressure, which is the control pressure when the relief stage just begins to open. The last element defines the control pressure for which the valve is fully open.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Tabulated data - Area vs. pressure.

**Reference pressure differential vector** — Pressure drop across relief stage

5 : 0.2 : 6 MPa (default) | vector

Vector of pressure drops across the relief stage. The vector elements must correspond one-to-one with the elements in the **Reference volumetric flow rate vector** parameter.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Tabulated data - Volumetric flow rate vs. pressure.

**Reference volumetric flow rate vector** — Flow rate through relief stage

[6.4e-09, .0013, .0027, .0041, .0055, .007] m<sup>3</sup>/s (default) | vector

Vector of flow rates through the relief stage. The vector elements must correspond one-to-one with the elements in the **Reference pressure differential vector** parameter.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Tabulated data - Volumetric flow rate vs. pressure.

**Maximum opening pressure differential** — Maximum relief valve pressure

6 MPa (default) | positive scalar

The maximum relief valve pressure.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Linear - Area vs. pressure.

**Maximum opening area** — Relief stage maximum open area

1e-4 m<sup>2</sup> (default) | positive scalar

Maximum open area of the relief stage orifice.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Linear - Area vs. pressure.

**Leakage area** — Gap area when valve is in fully closed position

1e-10 m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the valve is in the fully closed position. Any area smaller than this value is saturated to the specified leakage area. This value contributes to numerical stability by maintaining continuity in the flow.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Linear - Area vs. pressure.

**Pilot ratio** — Pilot area ratio

3 (default) | positive scalar

Ratio of the pressure-acting area of the pilot to the pressure-acting area of the load.

**Back pressure ratio** — Back pressure area ratio

4 (default) | positive scalar

Ratio of the back pressure pressure-acting area to the load pressure-acting area.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Correction factor that accounts for discharge losses in theoretical flows.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-shut positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Opening area vector** — Relief stage opening areas

[1e-10, 2e-05, 4e-05, 6e-05, 8e-05, .0001] m<sup>2</sup> (default) | 1-by-n vector

Vector of relief stage opening areas. The vector elements must correspond one-to-one with the elements in the **Pressure differential vector** parameter. List the elements in ascending order. All elements must be greater than 0.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Tabulated data - Area vs. pressure.

**Opening dynamics** — Whether to introduce flow lag due to orifice opening

off (default) | on

Whether to account for the transient effects to the fluid system due to opening the valve. Selecting **Opening dynamics** approximates the opening conditions by introducing a first-order lag in the pressure response. The **Opening time constant** parameter also impacts the modeled opening dynamics.

When enabled, these dynamics apply to the relief stage and not the check stage of the counterbalance valve.

**Opening time constant** — Orifice opening time constant

0.1 s (default) | positive scalar

Constant that captures the time required for the fluid to reach steady-state conditions when opening or closing the valve from one position to another. This parameter impacts the modeled opening dynamics.

#### **Dependencies**

To enable this parameter, select **Opening dynamics**.

#### **Check Valve**

**Cracking pressure differential** — Set pressure for check valve operation

0.01 MPa (default) | positive scalar

Pressure differential that lifts the check valve.

#### **Dependencies**

To enable this parameter, set **Valve parameterization** to Linear - Area vs. pressure.

**Maximum opening pressure differential** — Maximum pressure in valve

0.1 MPa (default) | positive scalar

Maximum valve pressure. This parameter bounds the pressures at the valve exit to maintain physical values during simulation.

#### **Dependencies**

To enable this parameter, set **Valve parameterization** to Linear - Area vs. pressure.

**Maximum opening area** — Maximum open area

1e-4 m<sup>2</sup> (default) | positive scalar

Maximum open area of the check valve in the load line. Internally, this check valve is in parallel with the relief stage.

#### **Dependencies**

To enable this parameter, set **Valve parameterization** to Linear - Area vs. pressure.

**Pressure differential vector** — Pressure differential for check valve operation

[0.01 : 0.01 : 0.1] MPa (default) | 1-by-n vector

Vector of pressure differentials for the check valve stage.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Tabulated data - Area vs. pressure or Tabulated data - Volumetric flow rate vs. pressure.

**Opening area vector** — Check stage opening areas

[1e-10, 1e-05, 2e-05, 3e-05, 4e-05, 5e-05, 6e-05, 7.5e-05, 8.5e-05, .0001] m<sup>2</sup> (default) | 1-by-*n* vector

Vector of opening areas for the check valve stage. The vector elements must correspond one-to-one with the elements in the **Pressure differential vector** parameter.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Tabulated data - Area vs. pressure.

**Volumetric flow rate vector** — Check stage volumetric flow rates

[.000358, .045, .11, .191, .284, .39, .505, .63, .764, .905] .\* 1e-3 m<sup>3</sup>/s (default) | 1-by-*n* vector

Vector of volumetric flow rates for the check valve stage. The elements of this vector must correspond to the elements in the **Pressure differential vector** parameter.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Tabulated data - Volumetric flow rate vs. pressure.

## Version History

**Introduced in R2020a****R2022b: Opening parameterization options include volumetric flow rate**

You can set **Opening parameterization** to Tabulated data - Volumetric flow rate vs. pressure. This selection enables these new parameters:

- **Set pressure differential**
- **Reference pressure differential vector**
- **Reference volumetric flow rate vector**
- **Volumetric flow rate vector**

To improve clarity:

- The Linear option has been renamed to Linear - Area vs. pressure.
- The Tabulated option has been renamed to Tabulated data - Area vs. pressure

**R2022b: Access pre-parameterized block options**

You can now select from available pre-parameterization options. Available manufacturers are Rexroth Bosch Group and Sun Hydraulics.

## Cross-Junction (IL)

Cross-junction in an isothermal liquid network

### Libraries:

Simscape / Fluids / Isothermal Liquid / Pipes & Fittings

### Description

The Cross-Junction (IL) block represents a four-way junction in an isothermal liquid network. The block abstracts the fluid interactions depending on the direction of flow at each port, where ports **A** and **C** are the main line and ports **B** and **D** are the branch line. The block defines four unique flow configurations: diverging flow, converging flow, perpendicular flow, and colliding flow. All four configurations can occur in the same block during a simulation. You only need to supply parameters for each condition that the block experiences. The block conserves mass such that

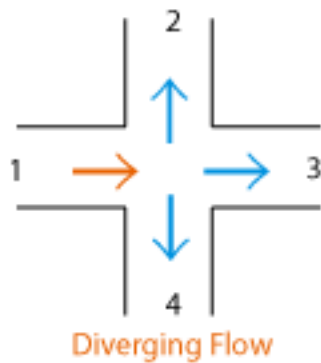

$$\dot{m}_A + \dot{m}_B + \dot{m}_C + \dot{m}_D = 0,$$

where  $\dot{m}_i$  is the mass flow rate for a given port,  $i$ .

The possible flow configurations are:

- Diverging flow — Flow enters at node 1 and exits at nodes 2, 3, and 4.
- Converging flow — Flow enters at nodes 1, 2, and 4 and exits at node 3.
- Perpendicular flow — Flow enters at nodes 1 and 2 and exits at nodes 3 and 4.
- Colliding flow — Flow enters at nodes 1 and 3 and exits at nodes 2 and 4.

This figure demonstrates these configurations.

The block takes advantage of simplifying assumptions to reduce the total number of parameters that you need to provide. The block treats the junction as symmetrical about both the horizontal and vertical planes such that  $A_1 = A_3$ , and  $A_2 = A_4$ , where  $A_{1,2,3,4}$  is the area of the corresponding port in the figure. Using this symmetry, the block assumes the loss coefficients from 1 to 2 and from 1 to 4 are identical during diverging, converging, and colliding flow.

During simulation, the block continually checks the direction of flow at each port and compares the result to the four possible flow configurations. When the block determines the flow configuration, it adjusts the node that each port corresponds to. For example, when the block experiences diverging flow where the fluid enters at port **C** and exits at ports **A**, **B**, and **D**, it assigns node 1 to port **C** as in the figure.

If you use two-element vectors to specify the flow coefficients, the block uses the first or second element depending on whether node 1 aligns with the main line or the branch line. The first element corresponds to node 1 at port **A** or **C**, and the second element corresponds to node 1 at port **B** or **D**. The block determines which coefficient and which vector element to use, then computes the pressure difference to conserve momentum such that

$$p_i - p_1 = I_i + \frac{k_i/2 \dot{m}_i \sqrt{\dot{m}_i^2 + \dot{m}_{\text{threshold}}^2}}{\bar{\rho} A_i^2},$$

where:

- $\bar{\rho}$  is the average fluid density.
- $p_i$  is the pressure for a given port,  $i$ .
- $p_1$  is the pressure at node 1.
- $k_i$  is the flow coefficient that the block assigns to a given port,  $i$ . This value can be either the turning flow or straight flow coefficient, depending on the port.
- $I_i$  is the fluid inertia for a given port,  $i$ .

The block calculates the inertia for each port as

$$I_A = \dot{m}_A \frac{\sqrt{\pi A_{\text{side}}}}{A_{\text{main}}}$$

$$I_B = \dot{m}_B \frac{\sqrt{\pi A_{\text{main}}}}{A_{\text{side}}}$$

$$I_C = \dot{m}_C \frac{\sqrt{\pi A_{\text{side}}}}{A_{\text{main}}}$$

$$I_D = \dot{m}_D \frac{\sqrt{\pi A_{\text{main}}}}{A_{\text{side}}}$$

The block uses mode charts to determine the value of  $k_i$ . This table describes the conditions and coefficients for each operational mode.

Flow Scenario	$\dot{m}_A$	$\dot{m}_B$	$\dot{m}_C$	$\dot{m}_D$	$k_A$	$k_B$	$k_C$	$k_D$

isothermal liquid

Isothermal liquid conserving port.

## Parameters

### Junction Properties

**Main line area (A,C)** — Area of main path  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the main flow path from port **A** to port **C**.

**Branch line area (B,D)** — Area of branch path  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the branch flow path from port **B** to port **D**.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the junction.

**Diverging flow loss coefficients** — Option to specify loss coefficients for diverging flow  
On (default) | Off

Whether to specify loss coefficients for diverging flow.

**Converging flow loss coefficients** — Option to specify loss coefficients for converging flow  
On (default) | Off

Whether to specify loss coefficients for converging flow.

**Perpendicular flow loss coefficients** — Option to specify loss coefficients for perpendicular flow  
Off (default) | On

Whether to specify loss coefficients for perpendicular flow.

**Colliding flow loss coefficients** — Option to specify loss coefficients for colliding flow  
Off (default) | On

Whether to specify loss coefficients for colliding flow.

### Diverging Flow Coefficients

**Diverging flow straight loss coefficient** — Diverging flow straight loss coefficient  
[1.12, 1.12] (default) | positive scalar or vector

Loss coefficient for the straight portion of the diverging flow. When you specify this parameter as a vector, the first element represents the loss coefficient when ports **A** or **C** align to reference node 1. The second element represents when ports **B** or **D** align to reference node 1. The block behaves the same for all orientations when you use a scalar.

**Dependencies**

To enable this parameter, select the **Diverging flow loss coefficients** parameter.

**Diverging flow turning loss coefficient** — Diverging flow turning loss coefficient  
[1.12, 1.12] (default) | positive scalar or vector

Loss coefficient for the turning portions of the diverging flow. When you specify this parameter as a vector, the first element represents the loss coefficient when ports **A** or **C** align to reference node 1. The second element represents when ports **B** or **D** align to reference node 1. The block behaves the same for all orientations when you use a scalar.

**Dependencies**

To enable this parameter, select the **Diverging flow loss coefficients** parameter.

**Converging Flow Coefficients**

**Converging flow straight loss coefficient** — Converging flow straight loss coefficient  
[1.12, 1.12] (default) | positive scalar or vector

Loss coefficient for the straight portion of the converging flow. When you specify this parameter as a vector, the first element represents the loss coefficient when ports **A** or **C** align to reference node 1. The second element represents when ports **B** or **D** align to reference node 1. The block behaves the same for all orientations when you use a scalar.

**Dependencies**

To enable this parameter, select the **Converging flow loss coefficients** parameter.

**Converging flow turning loss coefficient** — Converging flow turning loss coefficient  
[1.12, 1.12] (default) | positive scalar or vector

Loss coefficient for the turning portions of the converging flow. When you specify this parameter as a vector, the first element represents the loss coefficient when ports **A** or **C** align to reference node 1. The second element represents when ports **B** or **D** align to reference node 1. The block behaves the same for all orientations when you use a scalar.

**Dependencies**

To enable this parameter, select the **Converging flow loss coefficients** parameter.

**Perpendicular Flow Coefficients**

**Perpendicular flow turning to inflow loss coefficient** — Perpendicular flow turning to inflow loss coefficient  
[1.12, 1.12] (default) | positive scalar or vector

Loss coefficient for the flow turning to inflow in the perpendicular flow. When you specify this parameter as a vector, the first element represents the loss coefficient when ports **A** or **C** align to reference node 1. The second element represents when ports **B** or **D** align to reference node 1. The block behaves the same for all orientations when you use a scalar.

**Dependencies**

To enable this parameter, select the **Perpendicular flow loss coefficients** parameter.

**Perpendicular flow turning to outflow loss coefficient** — Perpendicular flow turning to outflow loss coefficient

[1.12, 1.12] (default) | positive scalar or vector

Loss coefficient for the flow turning to outflow in the perpendicular flow. When you specify this parameter as a vector, the first element represents the loss coefficient when ports **A** or **C** align to reference node 1. The second element represents when ports **B** or **D** align to reference node 1. The block behaves the same for all orientations when you use a scalar.

#### **Dependencies**

To enable this parameter, select the **Perpendicular flow loss coefficients** parameter.

**Perpendicular flow straight loss coefficient** — Perpendicular flow straight loss coefficient

[1.12, 1.12] (default) | positive scalar or vector

Loss coefficient for the straight portion of the perpendicular flow. When you specify this parameter as a vector, the first element represents the loss coefficient when ports **A** or **C** align to reference node 1. The second element represents when ports **B** or **D** align to reference node 1. The block behaves the same for all orientations when you use a scalar.

#### **Dependencies**

To enable this parameter, select the **Perpendicular flow loss coefficients** parameter.

### **Colliding Flow Coefficients**

**Colliding flow turning loss coefficient** — Colliding flow turning loss coefficient

[1.12, 1.12] (default) | positive scalar or vector

Loss coefficient for the turning portion of the colliding flow. When you specify this parameter as a vector, the first element represents the loss coefficient when ports **A** or **C** align to reference node 1. The second element represents when ports **B** or **D** align to reference node 1. The block behaves the same for all orientations when you use a scalar.

#### **Dependencies**

To enable this parameter, select the **Colliding flow loss coefficients** parameter.

**Colliding flow straight loss coefficient** — Colliding flow straight loss coefficient

[1.12, 1.12] (default) | positive scalar or vector

Loss coefficient for the turning portion of the colliding flow. When you specify this parameter as a vector, the first element represents the loss coefficient when ports **A** or **C** align to reference node 1. The second element represents when ports **B** or **D** align to reference node 1. The block behaves the same for all orientations when you use a scalar.

#### **Dependencies**

To enable this parameter, select the **Colliding flow loss coefficients** parameter.

## Cross-Junction (TL)

Cross-junction in a thermal liquid network

**Libraries:**

Simscape / Fluids / Thermal Liquid / Pipes & Fittings

### Description

The Cross-Junction (TL) block represents a four-way junction in an thermal liquid network. The block abstracts the fluid interactions depending on the direction of flow at each port, where ports **A** and **C** are the main line and ports **B** and **D** are the branch line. The block defines four unique flow configurations: diverging flow, converging flow, perpendicular flow, and colliding flow. All four configurations can occur in the same block during a simulation. You only need to supply parameters for each condition that the block experiences. The block conserves mass such that

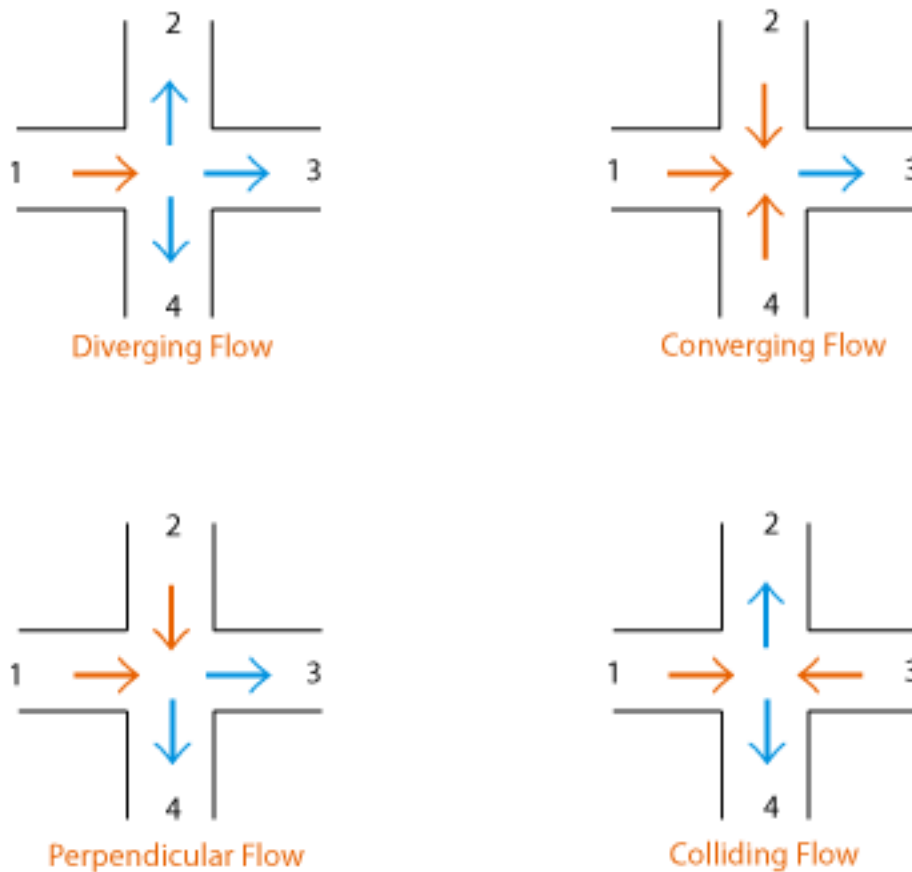

$$\dot{m}_A + \dot{m}_B + \dot{m}_C + \dot{m}_D = 0,$$

where  $\dot{m}_i$  is the mass flow rate for a given port,  $i$ .

The possible flow configurations are:

- Diverging flow — Flow enters at node 1 and exits at nodes 2, 3, and 4.
- Converging flow — Flow enters at nodes 1, 2, and 4 and exits at node 3.
- Perpendicular flow — Flow enters at nodes 1 and 2 and exits at nodes 3 and 4.
- Colliding flow — Flow enters at nodes 1 and 3 and exits at nodes 2 and 4.

This figure demonstrates these configurations.

The block takes advantage of simplifying assumptions to reduce the total number of parameters that you need to provide. The block treats the junction as symmetrical about both the horizontal and vertical planes such that  $A_1 = A_3$ , and  $A_2 = A_4$ , where  $A_{1,2,3,4}$  is the area of the corresponding port in the figure. Using this symmetry, the block assumes the loss coefficients from 1 to 2 and from 1 to 4 are identical during diverging, converging, and colliding flow.

During simulation, the block continually checks the direction of flow at each port and compares the result to the four possible flow configurations. When the block determines the flow configuration, it adjusts the node that each port corresponds to. For example, when the block experiences diverging flow where the fluid enters at port **C** and exits at ports **A**, **B**, and **D**, it assigns node 1 to port **C** as in the figure.

If you use two-element vectors to specify the flow coefficients, the block uses the first or second element depending on whether node 1 aligns with the main line or the branch line. The first element corresponds to node 1 at port **A** or **C**, and the second element corresponds to node 1 at port **B** or **D**. The block determines which coefficient and which vector element to use, then computes the pressure difference to conserve momentum such that

$$p_i - p_1 = I_i + \frac{k_i/2 \dot{m}_i \sqrt{\dot{m}_i^2 + \dot{m}_{threshold}^2}}{\bar{\rho} A_i^2},$$

where:

- $\bar{\rho}$  is the average fluid density.
- $p_i$  is the pressure for a given port,  $i$ .
- $p_1$  is the pressure at node 1.
- $k_i$  is the flow coefficient that the block assigns to a given port,  $i$ . This value can be either the turning flow or straight flow coefficient, depending on the port.
- $I_i$  is the fluid inertia for a given port,  $i$ .

The block calculates the inertia for each port as

$$I_A = \dot{m}_A \frac{\sqrt{\pi A_{side}}}{A_{main}}$$

$$I_B = \dot{m}_B \frac{\sqrt{\pi A_{main}}}{A_{side}}$$

$$I_C = \dot{m}_C \frac{\sqrt{\pi A_{side}}}{A_{main}}$$

$$I_D = \dot{m}_D \frac{\sqrt{\pi A_{main}}}{A_{side}}$$

The block uses mode charts to determine the value of  $k_i$ . This table describes the conditions and coefficients for each operational mode.

Flow Scenario	$\dot{m}_A$	$\dot{m}_B$	$\dot{m}_C$	$\dot{m}_D$	$k_A$	$k_B$	$k_C$	$k_D$

Stagnant	-	-	-	-	1 or last valid	1 or last valid	1 or last valid	1 or last valid

The flow is stagnant when the mass flow rate conditions do not match any defined flow scenario. The block uses these parameters to calculate the flow coefficients.

- $k_{div,straight,main}$  and  $k_{div,straight,side}$  are the first and second elements **Diverging flow straight loss coefficient** parameter, respectively.
- $k_{div,turning,main}$  and  $k_{div,turning,side}$  are the first and second elements **Diverging flow turning loss coefficient** parameter, respectively.
- $k_{conv,straight,main}$  and  $k_{conv,straight,side}$  are the first and second elements **Converging flow straight loss coefficient** parameter, respectively.
- $k_{conv,turning,main}$  and  $k_{conv,turning,side}$  are the first and second elements **Converging flow turning loss coefficient** parameter, respectively.
- $k_{perp,straight,main}$  and  $k_{perp,straight,side}$  are the first and second elements **Perpendicular flow straight loss coefficient** parameter, respectively.
- $k_{perp,turning\ in,main}$  and  $k_{perp,turning\ in,side}$  are the first and second elements **Perpendicular flow straight loss coefficient** parameter, respectively.
- $k_{perp,turning\ out,main}$  and  $k_{perp,turning\ out,side}$  are the first and second elements **Perpendicular flow straight loss coefficient** parameter, respectively.
- $k_{coll,straight,main}$  and  $k_{coll,straight,side}$  are the first and second elements **Colliding flow straight loss coefficient** parameter, respectively.
- $k_{coll,turning,main}$  and  $k_{coll,turning,side}$  are the first and second elements **Colliding flow turning loss coefficient** parameter, respectively.

The block conserves energy such that

$$\varphi_A + \varphi_B + \varphi_C + \varphi_D = 0.$$

## Ports

### Conserving

**A** — Liquid port  
thermal liquid

Thermal liquid conserving port.

**B** — Liquid port  
thermal liquid

Thermal liquid conserving port.

**C** — Liquid port  
thermal liquid

Thermal liquid conserving port.

**D** — Liquid port  
thermal liquid

Thermal liquid conserving port.

## Parameters

### Junction Properties

**Main line area (A,C)** — Area of main path  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the main flow path from port **A** to port **C**.

**Branch line area (B,D)** — Area of branch path  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the branch flow path from port **B** to port **D**.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the junction.

**Diverging flow loss coefficients** — Option to specify loss coefficients for diverging flow  
on (default) | off

Whether to specify loss coefficients for diverging flow.

**Converging flow loss coefficients** — Option to specify loss coefficients for converging flow  
on (default) | off

Whether to specify loss coefficients for converging flow.

**Perpendicular flow loss coefficients** — Option to specify loss coefficients for perpendicular flow  
off (default) | on

Whether to specify loss coefficients for perpendicular flow.

**Colliding flow loss coefficients** — Option to specify loss coefficients for colliding flow  
off (default) | on

Whether to specify loss coefficients for colliding flow.

### Diverging Flow Coefficients

**Diverging flow straight loss coefficient** — Diverging flow straight loss coefficient  
[1.12, 1.12] (default) | positive scalar or vector

Loss coefficient for the straight portion of the diverging flow. When you specify this parameter as a vector, the first element represents the loss coefficient when ports **A** or **C** align to reference node 1.

The second element represents when ports **B** or **D** align to reference node 1. The block behaves the same for all orientations when you use a scalar.

**Dependencies**

To enable this parameter, select **Diverging flow loss coefficients**.

**Diverging flow turning loss coefficient** — Diverging flow turning loss coefficient  
[ 1.12, 1.12 ] (default) | positive scalar or vector

Loss coefficient for the turning portions of the diverging flow. When you specify this parameter as a vector, the first element represents the loss coefficient when ports **A** or **C** align to reference node 1. The second element represents when ports **B** or **D** align to reference node 1. The block behaves the same for all orientations when you use a scalar.

**Dependencies**

To enable this parameter, select **Diverging flow loss coefficients**.

**Converging Flow Coefficients**

**Converging flow straight loss coefficient** — Converging flow straight loss coefficient  
[ 1.12, 1.12 ] (default) | positive scalar or vector

Loss coefficient for the straight portion of the converging flow. When you specify this parameter as a vector, the first element represents the loss coefficient when ports **A** or **C** align to reference node 1. The second element represents when ports **B** or **D** align to reference node 1. The block behaves the same for all orientations when you use a scalar.

**Dependencies**

To enable this parameter, select **Converging flow loss coefficients**.

**Converging flow turning loss coefficient** — Converging flow turning loss coefficient  
[ 1.12, 1.12 ] (default) | positive scalar or vector

Loss coefficient for the turning portions of the converging flow. When you specify this parameter as a vector, the first element represents the loss coefficient when ports **A** or **C** align to reference node 1. The second element represents when ports **B** or **D** align to reference node 1. The block behaves the same for all orientations when you use a scalar.

**Dependencies**

To enable this parameter, select **Converging flow loss coefficients**.

**Perpendicular Flow Coefficients**

**Perpendicular flow turning to inflow loss coefficient** — Perpendicular flow turning to inflow loss coefficient  
[ 1.12, 1.12 ] (default) | positive scalar or vector

Loss coefficient for the flow turning to inflow in the perpendicular flow. When you specify this parameter as a vector, the first element represents the loss coefficient when ports **A** or **C** align to reference node 1. The second element represents when ports **B** or **D** align to reference node 1. The block behaves the same for all orientations when you use a scalar.

**Dependencies**

To enable this parameter, select **Perpendicular flow loss coefficients**.

**Perpendicular flow turning to outflow loss coefficient** — Perpendicular flow turning to outflow loss coefficient

[1.12, 1.12] (default) | positive scalar or vector

Loss coefficient for the flow turning to outflow in the perpendicular flow. When you specify this parameter as a vector, the first element represents the loss coefficient when ports **A** or **C** align to reference node 1. The second element represents when ports **B** or **D** align to reference node 1. The block behaves the same for all orientations when you use a scalar.

**Dependencies**

To enable this parameter, select **Perpendicular flow loss coefficients**.

**Perpendicular flow straight loss coefficient** — Perpendicular flow straight loss coefficient

[1.12, 1.12] (default) | positive scalar or vector

Loss coefficient for the straight portion of the perpendicular flow. When you specify this parameter as a vector, the first element represents the loss coefficient when ports **A** or **C** align to reference node 1. The second element represents when ports **B** or **D** align to reference node 1. The block behaves the same for all orientations when you use a scalar.

**Dependencies**

To enable this parameter, select **Perpendicular flow loss coefficients**.

**Colliding Flow Coefficients**

**Colliding flow turning loss coefficient** — Colliding flow turning loss coefficient

[1.12, 1.12] (default) | positive scalar or vector

Loss coefficient for the turning portion of the colliding flow. When you specify this parameter as a vector, the first element represents the loss coefficient when ports **A** or **C** align to reference node 1. The second element represents when ports **B** or **D** align to reference node 1. The block behaves the same for all orientations when you use a scalar.

**Dependencies**

To enable this parameter, select **Colliding flow loss coefficients**.

**Colliding flow straight loss coefficient** — Colliding flow straight loss coefficient

[1.12, 1.12] (default) | positive scalar or vector

Loss coefficient for the turning portion of the colliding flow. When you specify this parameter as a vector, the first element represents the loss coefficient when ports **A** or **C** align to reference node 1. The second element represents when ports **B** or **D** align to reference node 1. The block behaves the same for all orientations when you use a scalar.

**Dependencies**

To enable this parameter, select **Colliding flow loss coefficients**.

# Cylinder Cushion

(To be removed) Cushion in hydraulic cylinders

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Hydraulic Cylinders

## Description

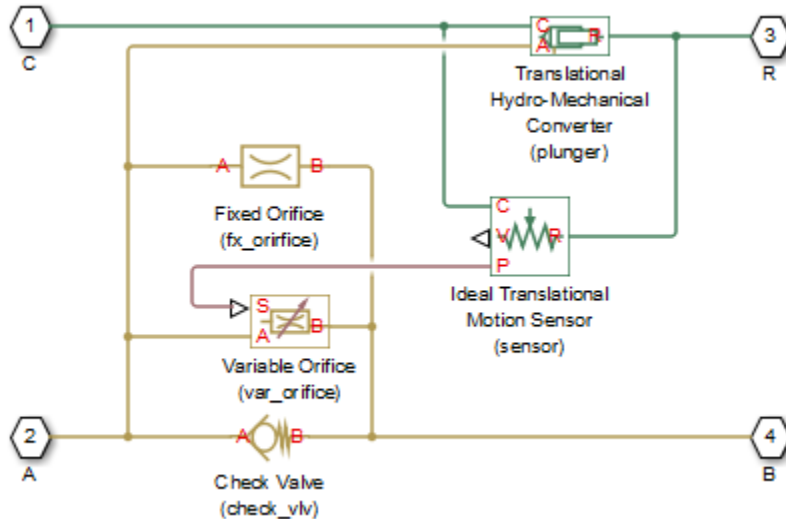

The Cylinder Cushion block models a hydraulic cylinder cushion, the device that decelerates the cylinder rod near the end of the stroke by restricting the flow rate leaving the cylinder chamber. The figure shows a typical design of a cylinder cushion [1] on page 1-672.

As the piston moves toward the cap (to the left in the figure), the cushioning bush enters the chamber in the cap and creates an additional resistance to the fluid leaving the chamber. The bush profile determines the desired deceleration. Near the end of the stroke, the fluid flows through the gap

between the bush and the cap and through the cushioning valve with constant cross-sectional area. The check valve located between the chambers allows free flow to the piston chamber to ease the piston breakaway from the end position.

The block is implemented as a structural model that replicates a cushioning device, as shown in this diagram.

The Variable Orifice block represents a variable gap between the bush and the cavity machined in the end cap. The lookup table of the Variable Orifice block implements the relationship between the orifice area and the piston displacement. The Fixed Orifice and the Check Valve blocks simulate the cushioning valve and the check valve installed between chambers. The Translational Hydro-Mechanical Converter represents a plunger created by the bush and the cavity. The Ideal Translational Motion Sensor block monitors the piston displacement and conveys it (with the initial piston position accounted) to the Variable Orifice block. The names assigned to the nested blocks in the model are shown in parentheses.

The block develops a cushioning effect for the flow rate from port B to port A. The check valve in the block is oriented from port **A** to port **B**.

You can use this block with any of the cylinder blocks in the library to model a single-acting or double-acting cylinder with cushion. The following diagram shows the model of a double-sided hydraulic cylinder with cushion built from a Double-Acting Hydraulic Cylinder block and two Cylinder Cushion blocks.

You can adjust the cushioning effect by changing the area of the fixed orifice and the profile of the cushioning bush (variable orifice). Specify the profile using the one-dimensional lookup table of the orifice area versus piston displacement. The next figure shows a typical configuration of a double-acting cylinder with the double-sided cushioning, similar to the model shown in the block diagram above.

To ensure cushioning on both sides of the stroke, set the variable orifice area of the left cushion ( $A_L$ ) and the right cushion ( $A_R$ ) similar to the profile shown in the figure. The origin of the plot is located at the position where the piston touches the cap. If the cylinder acts in the negative direction, the piston displacements are negative, and you must make the profile specification in the fourth quadrant.

The following figure shows a typical motion diagram of a cylinder with the double-sided cushioning.

The cushions are set to provide deceleration at  $\sim 10$  mm before the end of the stroke. The stroke of the cylinder is 10 cm, and the initial position of the piston is 0.04 m. The plot shows the velocity (yellow line) and motion (magenta line) profiles.

Connections **A** and **B** are hydraulic conserving ports associated with the device hydraulic inlet and outlet. Connection **R** is a mechanical translational conserving port that connects to the cylinder rod. Connection **C** is a mechanical translational conserving port that connects to the cylinder clamping structure.

## Ports

### Conserving

**A** — Cylinder inlet  
isothermal liquid

Hydraulic conserving port connected to the cylinder inlet.

**B** — Cylinder outlet  
isothermal liquid

Hydraulic conserving port connected to the cylinder outlet.

**R** — Rod  
isothermal liquid

Mechanical translational conserving port connected to the cylinder rod.

**C** — Mechanical reference  
isothermal liquid

Mechanical translational conserving port connected to the cylinder clamping structure.

## Parameters

### Cushion piston

**Cushion piston area** — Cross-sectional area  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Addition of the cushion to a cylinder converts the respective cylinder into two cylinders, rigidly connected and acting in parallel, with the total effective area equal to the piston area before addition. This parameter sets the area of the cushion piston, which is the face area of the cushion bush.

**Piston initial displacement** — Piston initial offset from cap A  
 $0$  (default) | positive scalar

The distance between the cylinder piston and cap A at the start of simulation. The default value is  $0$ , which corresponds to the fully retracted position of the piston.

**Piston orientation** — Piston direction of movement  
 Acts in positive direction (default) | Acts in negative direction

Piston orientation with respect to the globally assigned positive direction. Since the cushion piston is part of the cylinder piston, its orientation must be the same as the orientation of the cylinder piston at the side the cushion is attached to. Similar to a cylinder model, if pressure applied at port A exerts force in the negative direction, set the parameter to **Acts in negative direction**.

### Fixed orifice

**Fixed orifice area** — Cross-sectional open area  
 $1e-6 \text{ m}^2$  (default)

The area of the fixed orifice installed between cushion chambers.

**Fixed orifice flow discharge coefficient** — Discharge coefficient for fixed orifice  
 $0.7$  (default) | positive scalar

Semi-empirical coefficient that is used in the computation of flow rate through the fixed orifice.

**Fixed orifice critical Reynolds number** — Transition Reynolds number for fixed orifices  
 $10$  (default) | positive scalar

The maximum Reynolds number for laminar flow through the fixed orifice. The transition from laminar to turbulent regime is supposed to take place when the Reynolds number reaches this value. The value of the parameter depends on the orifice geometrical profile. You can find the recommendations on the parameter value in hydraulic textbooks.

### Variable orifice

**Tabulated piston displacements** — Piston displacement for tabular parameterization of orifice area  
 $[-2, 10, 11, 89, 90, 102]$  mm (default)

Vector of input values for piston displacements, specified as a one-dimensional array. The input values vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of

values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The **Tabulated piston displacements** values are used together with **Tabulated orifice area** values for one-dimensional table lookup. Due to the nature of the cylinder hard stops, the piston can move below zero and above the stroke value. It is good practice to account for piston deformation and provide piston displacements beyond the ideal stroke range to avoid extrapolation.

**Tabulated orifice area** — Orifice area for tabular parameterization of orifice area  
[.004, .006, 9, 9, 9, 9] cm<sup>2</sup> (default)

Vector of orifice areas, specified as a one-dimensional array. The vector must be the same size as the piston displacements vector. All the values must be positive.

**Variable orifice interpolation method** — Tabular interpolation  
Linear (default) | Smooth

Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- **Linear** — Select this option to get the best performance.
- **Smooth** — Select this option to produce a continuous curve with continuous first-order derivatives.

For more information on interpolation algorithms, see the PS Lookup Table (1D) block reference page.

**Variable orifice extrapolation method** — Tabular extrapolation  
Linear (default) | Nearest

Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- **Linear** — Select this option to produce a curve with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.
- **Nearest** — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see the PS Lookup Table (1D) block reference page.

**Variable orifice flow discharge coefficient** — Discharge coefficient for variable orifices  
0.7 (default) | positive scalar

Semi-empirical coefficient that is used in the computation of flow rate through the variable orifice.

**Variable orifice critical Reynolds number** — Transition Reynolds number for variable orifices  
10 (default) | positive scalar

The maximum Reynolds number for laminar flow through the variable orifice. The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches this value. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks.

**Variable orifice leakage area** — Open area when orifice is in fully closed position  
1e-12 m<sup>2</sup> (default) | positive scalar

The total area of possible leaks in the completely closed orifice. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0.

### Check valve

#### Check valve maximum area — Maximum open area

1e-4 m<sup>2</sup> (default) | positive scalar

Valve passage maximum cross-sectional area. The default value is 1e-4 m<sup>2</sup>.

#### Check valve cracking pressure — Threshold operating pressure

0.5e5 Pa (default) | positive scalar

Pressure level at which the orifice of the valve starts to open.

#### Check valve full opening pressure — Pressure that fully opens the valve

1.5e5 Pa (default)

Pressure differential across the valve needed to fully open the valve. Its value must be higher than the cracking pressure.

#### Check valve flow discharge coefficient — Discharge coefficient

0.7 (default) | positive scalar

Semi-empirical coefficient that is used in the computation of flow rate through the check valve.

#### Check valve critical Reynolds number — Transition Reynolds number for check valve flows

10 (default) | positive scalar

The maximum Reynolds number for laminar flow through the check valve. The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches this value.

#### Check valve leakage area — Open area when valve is fully closed

1e-12 m<sup>2</sup> (default) | positive scalar

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0.

# Cylinder Cushion (IL)

Cushion in cylinder in isothermal liquid network

## Libraries:

Simscape / Fluids / Isothermal Liquid / Actuators / Auxiliary Components

## Description

The Cylinder Cushion (IL) block models a cylinder cushion in an isothermal liquid network. The cushion decelerates the cylinder rod as it approaches the end of a stroke by restricting the flow rate leaving the cylinder chamber. This figure below shows a typical cylinder cushion design [1].

Typical Cylinder Cushion Design

As the piston moves toward the cap (to the left in the figure), the plunger (the cushioning bush) enters the chamber in the cap and creates an additional resistance to the fluid leaving the cylinder chamber. The piston deceleration starts when the plunger enters the opening in the cap and closes the main fluid exit. In this state, the fluid flows through the gap between the cylinder and the cap through a cushioning valve. This restricts the flow rate leaving the cylinder chamber and reduces the initial speed of the piston.

The device contains a check valve between the cylinder and the cap. The check valve eases piston response during retraction by providing a flow path between the cap and cylinder chamber.

The cylinder cushion is a composite of a variable orifice, a fixed orifice, and a check valve. The variable orifice provides a variable opening between the plunger and end cap cavity. The fixed orifice connects the piston chamber to the cushion chamber. The check valve provides a flow path between the cushion chamber and the piston chamber during piston retraction only.

The Cylinder Cushion (IL) block is a composite component that consists of these blocks shown in the figure:

- A Local Restriction (IL) block that models the cushioning valve.
- A Check Valve (IL) block that models the check valve.
- An Orifice (IL) block that models the variable gap between the plunger and the end cap.
- An Ideal Translational Motion Sensor block that converts the separation between the plunger and the cavity in the end cap into a physical signal. This signal controls the opening of the Orifice (IL) block.

The Cylinder Cushion (IL) block is an actuator building block. A single-acting or double-acting actuator can optionally include cylinder cushions to slow piston motion near the ends of the stroke. This prevents extreme impacts when the piston is stopped by the end caps.

Ports **A** and **B** are isothermal liquid conserving ports associated with the chamber inlet and outlet, respectively. Port **R** is a mechanical translational conserving port connected with the piston plunger. Port **C** is a mechanical translational conserving port that corresponds to the cylinder clamping structure. The block develops a cushioning effect for the flow rate from port **B** to port **A**. The check valve in the block is oriented from port **A** to port **B**.

#### Equation for Area of Variable Orifice

In the variable orifice, it is assumed that when the plunger is far away from the cushion, the orifice area is fully open and equal to  $\pi D_{plunger}^2/4$ , where  $D_{plunger}$  is the diameter of the circular plunger. Also, when the plunger is in the cushion, the orifice is fully closed and the orifice area is equal to the leakage area. As the plunger moves close to the cushion, the fluid flows radially from the cylinder chamber to the cap chamber through the gap between the plunger and the opening in the cap. Therefore, it can be assumed that the orifice area changes linearly with piston displacement between

the maximum area and the leakage area. The orifice area for a given position of the piston is calculated as:

$$S = \begin{cases} S_{leak}, & \varepsilon x_{piston} \leq L_{plunger} \\ S_{max}, & \varepsilon x_{piston} \geq L_{plunger} + \frac{D_{plunger}}{4} \\ \frac{S_{max} - S_{leak}}{\frac{D_{plunger}}{4}} (\varepsilon x_{piston} - L_{plunger}) + S_{leak}, & L_{plunger} < \varepsilon x_{piston} < L_{plunger} + \frac{D_{plunger}}{4} \end{cases}$$

where:

- $S$  is the orifice area for a given position of the piston.
- $S_{leak}$  is the value of the **Leakage area between plunger and cushion sleeve** parameter.
- $S_{max}$  is the maximum size of the orifice, which is equal to the value of the **Cushion plunger cross-sectional area** parameter.
- $x_{piston}$  is the displacement of the piston. The initial displacement of the piston  $x_{0,piston}$  is the value of the **Actuator piston initial displacement** parameter.
- $\varepsilon$  is 1 when the **Actuator mechanical orientation** parameter is Pressure at A causes positive displacement of R relative to C and is -1 when the **Actuator mechanical orientation** parameter is Pressure at A causes negative displacement of R relative to C.
- $L_{plunger}$  is the value of the **Cushion plunger length** parameter.
- $D_{plunger}$  is the value of the **Cushion plunger diameter** parameter.

### Numerically-Smoothed Area and Pressure

You can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smooths the orifice area and the check valve pressure range. The orifice area is smoothly saturated between the **Leakage area between plunger and cushion sleeve** and **Cushion plunger cross-sectional area** parameters while the valve pressure is saturated between the **Check valve cracking pressure differential** and **Check valve maximum pressure differential** parameters. For more information, see “Numerical Smoothing”.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Entry port of the liquid to the cushion chamber.

**B** — Liquid port  
isothermal liquid

Exit port of the liquid from the cushion chamber

**R** — Rod  
mechanical translational

Mechanical translational conserving port connected with the piston plunger velocity and force.

**C** — Case

mechanical translational

Mechanical translational conserving port connected to the cylinder reference structure.

## Parameters

### Cushion Plunger

**Cushion plunger cross-sectional area** — Cross-sectional area of cushion plunger

1e-4 m<sup>2</sup> (default) | positive scalar

Area of the cross-section of the cushion plunger, which is assumed to be circular. The area is equal to  $\pi D_{plunger}^2/4$ , where  $D_{plunger}$  is the diameter of the circular plunger.

**Cushion plunger length** — Length of cushion plunger

1e-3 m (default) | positive scalar

Length of the cushion plunger.

**Actuator piston initial displacement** — Initial displacement of attached piston

0 m (default) | scalar

Displacement of the piston in the cylinder at the start of simulation. This displacement determines the initial area of the variable orifice that models the variable gap between the plunger and the end cap.

### Dependencies

If the **Actuator mechanical orientation** block parameter is set to Pressure at A causes positive displacement of R relative to C, the value of the piston initial displacement must be positive or zero.

If the **Actuator mechanical orientation** block parameter is set to Pressure at A causes negative displacement of R relative to C, the value of the piston initial displacement must be negative or zero.

**Actuator mechanical orientation** — Piston displacement direction

Pressure at A causes positive displacement of R relative to C (default) | Pressure at A causes negative displacement of R relative to C

Piston displacement direction of the connected actuator block. If this parameter is set to Pressure at A causes positive displacement of R relative to C, the piston extends when **R - C** is positive. If this parameter is set to Pressure at A causes negative displacement of R relative to C, the piston retracts when **R - C** is positive.

### Valves

**Cushion orifice area** — Orifice area of cushioning valve

1e-6 m<sup>2</sup> (default) | positive scalar

Constant orifice area of the valve through which the fluid flows from the cylinder chamber to the cap chamber when the plunger is inside the opening in the cap.

**Leakage area between plunger and cushion sleeve** — Total leakage area when the plunger is inside the cap opening

1e-7 m<sup>2</sup> (default) | positive scalar

Total area of possible leaks when the plunger is inside the cap opening (the cushion sleeve). The area of the variable orifice modeling gap between the plunger and the cushion sleeve is equal to this leakage area when the displacement of the piston is less than or equal to the **Cushion plunger length** parameter.

**Check valve cracking pressure differential** — Pressure differential at which the check valve starts to open

0.01 MPa (default) | positive scalar

Minimum pressure differential across the check valve at which the valve starts to open. The check valve allows free flow of the liquid from the cushion chamber to the piston chamber but does not allow flow in the opposite direction.

**Check valve maximum pressure differential** — Pressure differential needed to fully open the check valve

0.1 MPa (default) | positive scalar

Pressure differential across the check valve needed to fully open the valve. The value of this parameter must be greater than the **Check valve cracking pressure differential** parameter. The check valve allows free flow of the liquid from the cushion chamber to the piston chamber but does not allow flow in the opposite direction.

**Check valve maximum area** — Opening area when check valve is fully open

1e-4 m<sup>2</sup> (default) | positive scalar

Passage area of the check valve when the valve is fully open.

**Check valve leakage area** — Total leakage area when check valve is fully closed

1e-10 m<sup>2</sup> (default) | positive scalar

Total area of possible leaks when the check valve is fully closed.

**Smoothing factor** — Amount of smoothing to apply to check valve and variable orifice opening area functions

0.01 (default) | positive scalar

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

# Cylinder Friction

(To be removed) Friction in hydraulic cylinders

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Hydraulic Cylinders

## Description

The Cylinder Friction block simulates friction in the contact between moving bodies in hydraulic cylinders. Use this block as a building block in combination with double- and single-acting cylinders to develop a cylinder model with friction. The block simulates the friction force as a function of relative velocity and pressure, and assumes this force is the sum of the Stribeck, Coulomb, and viscous components. The Coulomb friction force consists of the preload force, which is caused by the seal squeeze during assembly, and the force proportional to the pressure. The sum of the Coulomb and Stribeck friction forces at zero velocity is the breakaway friction force. For more information, see the Translational Friction block reference page.

The block approximates the friction force as

$$F = F_C \cdot (1 + (K_{brk} - 1) \cdot \exp(-c_v |v|)) \text{sign}(v) + f_{vfr} \cdot v$$

$$F_C = F_{pr} + f_{cfr}(\rho_A + \rho_B)$$

where:

$F$	Friction force
$F_C$	Coulomb friction
$F_{pr}$	Preload force
$f_{cfr}$	Coulomb friction coefficient
$\rho_A, \rho_B$	Pressures in cylinder chambers
$K_{brk}$	Breakaway friction force increase coefficient
$c_v$	Transition coefficient
$v$	Relative velocity in the contact
$f_{vfr}$	Viscous friction coefficient

To avoid discontinuity at  $v = 0$ , the block introduces a small region,  $|v| \leq v_{th}$ , around zero velocity where the friction force is linearly proportional to velocity

$$F = K \cdot v$$

$$K = \frac{F_C(1 + (K_{brk} - 1) \cdot \exp(-c_v v_{th})) + f_{vfr} \cdot v_{th}}{v_{th}}$$

where:

$K$	Proportionality coefficient
$v_{th}$	Velocity threshold

**R** and **C** are mechanical translational conserving ports associated with the rod and case, respectively. **A** and **B** are hydraulic conserving ports that you connect to ports **A** and **B** of the cylinder block, as shown in this illustration. The force generated by the block always opposes relative motion between the rod and the case.

## Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

## Ports

### Conserving

**A** — Cylinder inlet  
hydraulic

Hydraulic conserving port connected to the cylinder inlet.

**B** — Cylinder outlet  
hydraulic

Hydraulic conserving port connected to the cylinder outlet.

**R** — Cylinder rod

mechanical translational

Mechanical translational conserving port associated with the cylinder rod.

**C** — Cylinder clamping structure

mechanical translational

Mechanical translational conserving port associated with the cylinder clamping structure.

## Parameters

**Preload force** — Preload force caused by seal squeeze during assembly

10 N (default) | nonnegative scalar

Preload force caused by the seal squeeze during assembly.

**Coulomb friction force coefficient** — Proportionality coefficient for Coulomb friction force

1e-6 N/Pa (default) | nonnegative scalar

Coulomb friction coefficient. This value defines the proportionality between the Coulomb friction force and the pressure in cylinder chambers.

**Breakaway friction increase coefficient** — Friction force increase over Coulomb friction

1 (default) | scalar greater than or equal to 1

Friction force increase over the Coulomb friction. The Coulomb friction force, multiplied by this coefficient, is breakaway friction force.

**Viscous friction coefficient** — Proportionality coefficient between viscous friction force and relative velocity

100 N/(m/s) (default) | nonnegative scalar

Proportionality coefficient between the viscous friction force and the relative velocity.

**Transition approximation coefficient** — Approximation of transition between breakaway and Coulomb frictions

10 s/m (default) | positive scalar

Value of the coefficient  $c_v$ , which the block uses for the approximation of the transition between the breakaway and the Coulomb frictions. Assign this value based on the following considerations: the Stribeck friction component reaches approximately 5% of its steady-state value at velocity  $3/c_v$ , and 2% at velocity  $4/c_v$ , which makes it possible to develop an approximate relationship  $c_v \approx 4/v_{\min}$ , where  $v_{\min}$  is the relative velocity at which friction force has its minimum value. The default value, 10 s/m, corresponds to a minimum friction at a velocity of about 0.4 m/s.

**Linear region velocity threshold** — Small vicinity near zero velocity where friction force is linearly proportional to relative velocity

1e-4 m/s (default) | positive scalar

Small vicinity near zero velocity where the friction force is linearly proportional to the relative velocity. It is recommended that you use values in the range between 1e-6 and 1e-4 m/s.

Double-Acting Hydraulic Cylinder | Single-Acting Hydraulic Cylinder

## Cylinder Friction (IL)

Adds friction to cylinders with moving components

### Libraries:

Simscape / Fluids / Isothermal Liquid / Actuators / Auxiliary Components

### Description

The Cylinder Friction (IL) block models friction on a moving cylinder. The total friction is a combination of Stribeck, Coulomb, and viscous effects. The Coulomb friction component includes any initial force applied by the seal and the influence of pressure in the cylinder.

The Stribeck and viscous forces are calculated in the same way as for the Simscape Foundational Library Translational Friction block.

### The Stribeck Friction and Viscous Friction Forces

The Stribeck friction force is the dominating friction component at low velocities. It is calculated as:

$$F_{Stribeck} = \sqrt{2e}(R_{break,Coulomb} - 1) \cdot F_C \left( \frac{v}{v_{static,th}} \right) e^{-\left( \frac{v}{v_{static,th}} \right)^2},$$

where:

- $R_{break,Coulomb}$  is the ratio of the breakaway force to the Coulomb force:  $R_{Break,Coulomb} = \frac{F_{break}}{F_{Coulomb}}$ .
- $v$  is the velocity of the cylinder,  $v = v_R - v_C$ .
- $v_{static,th}$  is the threshold velocity for static torque:

$$v_{static,th} = \sqrt{2}v_{break},$$

where  $v_{break}$  is the **Breakaway friction velocity**. A transition range is established between 0 and the threshold velocity for static torque to ensure smooth modeling of the friction force.

- $F_C$  is introduced in “The Coulomb Friction Force” on page 1-684 section below.

The viscous friction force is based on the **Viscous friction coefficient** of the working fluid,  $f_{viscous}$ , and is proportional to the cylinder velocity:

$$F_{viscous} = f_{viscous}v.$$

### The Coulomb Friction Force

The Coulomb friction force is a force that acts normal to the friction surface. The cylinder motion creates a radial stress inside the fixed cylinder casing, which increases as the cylinder compresses the internal fluid. The radial stress is normal to the cylinder motion, and results in a Coulomb friction force that opposes cylinder motion.

The Coulomb frictional force is calculated as:

$$F_{Coulomb} = F_c \tanh\left(\frac{\nu}{\nu_{Coulomb,th}}\right),$$

where  $\nu$  is the relative velocity between ports **R** and **C** ( $\nu_R - \nu_C$ ), and  $\nu_{Coulomb,th}$  is the threshold velocity for Coulomb force:

$$\nu_{Coulomb,th} = \frac{\nu_{break}}{10}.$$

Note that the threshold velocity for Coulomb force is a different quantity than the threshold velocity for the static force, which is used to calculate the Stribeck friction force, although they both act as a threshold region to ensure smooth modeling of the Coulomb and Stribeck forces.

$F_C$  is the force contribution from seal preloading (the **Preload force**) and the pressure in the cylinder:

$$F_C = F_{preload} + f_{Coulomb}(P_A + P_B),$$

where  $f_{Coulomb}$  is the **Coulomb friction force coefficient**.  $P_A$  and  $P_B$ , the pressures at cylinder ports **A** and **B**, are gauge pressures with respect to the environmental pressure, specified either as atmospheric or another user-defined value in the **Environment pressure specification** parameter.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Liquid entry or exit point to the orifice.

**B** — Liquid port  
isothermal liquid

Liquid entry or exit point to the orifice.

**C** — Mechanical port velocity, m/s  
mechanical translational

Mechanical port for cylinder housing motion, in m/s.

**R** — Mechanical port velocity, m/s  
mechanical translational

Mechanical port for cylinder rod motion, in m/s.

## Parameters

**Breakaway to Coulomb friction force ratio** — Ratio of breakaway force to Coulomb friction force  
1.2 (default) | positive scalar

Ratio of the breakaway force to the Coulomb friction force.

**Breakaway friction velocity** — Threshold for motion against friction force  
0.1 m/s (default) | positive scalar

Threshold for movement against friction force.

**Preload force** — Initial force in cylinder due to seal assembly  
20 N (default) | scalar

Initial force in the cylinder due to seal assembly.

**Coulomb friction force coefficient** — Coulomb friction force coefficient  
1e-6 N/Pa (default) | positive scalar

Coulomb friction force coefficient.

**Viscous friction coefficient** — Viscous friction coefficient  
100 N/(m/s) (default) | positive scalar

Viscous friction coefficient. This parameter is used to calculate the viscous friction force.

**Environment pressure specification** — Pressure reference source  
Atmospheric pressure (default) | Specified pressure

Identifies pressure reference for the Coulomb friction calculation.

**Environment pressure** — User-defined pressure reference  
0.101325 MPa (default) | positive scalar

User-defined pressure reference for the Coulomb friction calculation.

#### **Dependencies**

To enable this parameter, set **Environment pressure specification** to Specified pressure.

# Hydraulic Double-Acting Valve Actuator

(To be removed) Double-acting hydraulic valve actuator

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Library

Valve Actuators

## Description

Use the Hydraulic Double-Acting Valve Actuator block as a pilot actuator for directional, pressure, or flow control valves in applications where all the forces, except spring force, and flow consumption can be neglected. The actuator consists of two single-acting actuators acting against each other. Each single-acting actuator consists of a piston, centering spring, and centering washer. When control pressure is applied to either hydraulic port, only one centering spring is compressed by its washer while the other butts against the valve body and exerts no force on the spool. When both control pressures are released, the springs force the washers against the valve body, and the spool centers between them. This design allows each actuator to have a different spring, preload force, and piston area.

As pressure applied to the piston develops enough force to overcome the spring preload, the piston moves to the opposite position until it reaches its maximum stroke. Pressure applied at port X shifts

the valve in the  $x$ -direction, overcoming the spring located in the Y chamber. Pressure applied at port Y shifts the valve in the  $y$ -direction, overcoming the spring located in the X chamber.

The actuator is simulated according to the following equations:

$$F = p_x \cdot A_x - p_y \cdot A_y$$

$$L_x = \frac{str_x}{F_{maxx} - F_{prx}}$$

$$L_y = \frac{str_y}{F_{maxy} - F_{pry}}$$

If  $F \geq 0$ ,

$$s = \begin{cases} 0 & \text{for } F \leq F_{pry} \\ L_y \cdot (F - F_{pry}) \cdot or & \text{for } F_{pry} < F < F_{maxy} \\ str_y \cdot or & \text{for } F \geq F_{maxy} \end{cases}$$

If  $F < 0$ ,

$$s = \begin{cases} 0 & \text{for } |F| \leq F_{prx} \\ -L_x \cdot (|F| - F_{prx}) \cdot or & \text{for } F_{prx} < |F| < F_{maxx} \\ -str_x \cdot or & \text{for } |F| \geq F_{maxx} \end{cases}$$

where

$F$	Force acting on the valve
$s$	Piston displacement
$p_x$	Pressure in the actuator X chamber
$p_y$	Pressure in the actuator Y chamber
$A_x$	Valve face area in the X chamber
$A_y$	Valve face area in the Y chamber
$str_x$	Valve stroke in $x$ -direction
$str_y$	Valve stroke in $y$ -direction
$F_{prx}$	Chamber X spring preload force
$F_{maxx}$	Chamber X spring maximum force
$F_{pry}$	Chamber Y spring preload force
$F_{maxy}$	Chamber Y spring maximum force
$or$	Actuator orientation with respect to the globally assigned positive direction. If pressure applied at port X moves the piston in positive direction, $or$ equals 1. If pressure applied at port X moves the piston in negative direction, $or$ equals -1.

Connections X and Y are hydraulic conserving ports associated with the valve chambers. Connection P is a physical signal port whose output corresponds to piston displacement. Pressure applied at port X moves the piston in the positive or negative direction depending on the value of the **Actuator orientation** parameter.

## Basic Assumptions and Limitations

- The flow consumption associated with the valve motion is assumed to be negligible.
- The inertia, friction, and hydraulic axial forces are assumed to be small and are not taken into account.
- The clearances between the valve and the washers are not taken into account.

## Parameters

### Piston area at port X

Effective piston area at port X. The parameter value must be greater than zero. The default value is  $2e-4 \text{ m}^2$ .

### Piston area at port Y

Effective piston area at port Y. The parameter value must be greater than zero. The default value is  $2e-4 \text{ m}^2$ .

### Preload force at port X

Spring preload force at port X. The default value is 0.

### Preload force at port Y

Spring preload force at port Y. The default value is 0.

### Spring maximum force at port X

Chamber X spring maximum force. The parameter value must be greater than the spring preload force. The default value is 50 N.

### Spring maximum force at port Y

Chamber Y spring maximum force. The parameter value must be greater than the spring preload force. The default value is 50 N.

### Piston stroke at port X

Piston stroke in chamber X. The parameter value must be greater than or equal to zero. The default value is  $5e-3 \text{ m}$ .

### Piston stroke at port Y

Piston stroke in chamber Y. The parameter value must be greater than or equal to zero. The default value is  $5e-3 \text{ m}$ .

### Actuator orientation

Specifies actuator orientation with respect to the globally assigned positive direction. The actuator can be installed in two different ways, depending upon whether it moves the piston in the positive or in the negative direction when pressure is applied at its inlet. If pressure applied at port X moves the piston in the negative direction, set the parameter to `Acts in negative direction`. The default value is `Acts in positive direction`.

### Restricted Parameters

When your model is in Restricted editing mode, you cannot modify the following parameter:

- **Actuator orientation**

All other block parameters are available for modification.

## Ports

The block has the following ports:

X

Hydraulic conserving port associated with the valve X chamber.

Y

Hydraulic conserving port associated with the valve Y chamber.

P

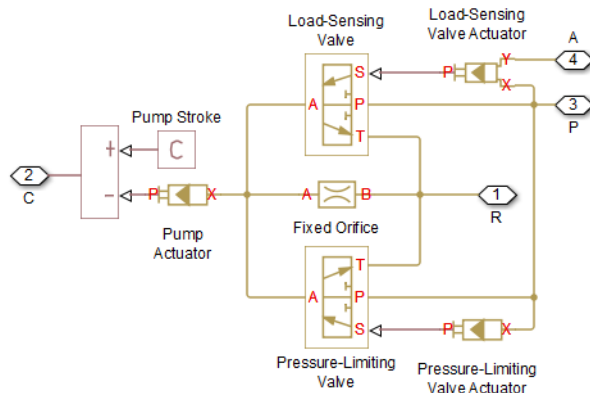

Physical signal port that outputs piston displacement.

## Examples

The following illustration shows a typical control unit of a variable-displacement pump that provides load sensing and pressure limiting (see [1] on page 1-691). In the unit, the load-sensing compensator varies the pump displacement to maintain a preset pressure differential across the variable orifice, while the pressure-limiting compensator does not allow the pump pressure to exceed the pressure limit.

The “Hydraulic Motor Driven by Load-Sensing Variable-Displacement Pump” example implements this type of control. The next illustration shows the schematic of the Control block in the example model.

There are three hydraulic valve actuators in the model:

- Pressure-Limiting Valve Actuator — A single-acting actuator that controls the Pressure-Limiting Valve.
- Pump Actuator — A single-acting valve actuator that acts on the pump displacement control device (yoke control).
- Load-Sensing Valve Actuator — A double-acting valve actuator that controls the Load-Sensing Valve. Its output is proportional to the difference between the pump pressure (port P) and the load pressure (port A).

Open the example model to see the parameter settings for the blocks.

## Double-Acting Actuator (IL)

Linear conversion of pressure differential to actuation in an isothermal liquid system

### Libraries:

Simscape / Fluids / Isothermal Liquid / Actuators

### Description

The Double-Acting Actuator (IL) block represents the linear conversion of a pressure differential between two chambers to piston motion. The piston actuation is controlled by the pressure differential acting on the piston plate that separates the chambers. The motion of the piston when it is near full extension or full retraction is limited by one of four hard stop models. Fluid compressibility is optionally modeled in both piston chambers.

Ports **A** and **B** are isothermal liquid inlets. Port **C** represents the actuator casing, while piston velocity is returned at port **R**. When the piston position is calculated internally, it is reported at port **p**, and when the position is set by a connection to a Simscape Multibody™ joint, it is received as a physical signal at port **p**.

You can define the piston displacement direction with the **Mechanical orientation** parameter. If the mechanical orientation is set to **Pressure at A causes positive displacement of R relative to C**, the piston extends when the pressure differential  $p_A - p_B$  is positive. If **Mechanical orientation** is set to **Pressure at A causes negative displacement of R relative to C**, the piston retracts for a positive pressure difference between the liquid and gas chambers.

### Displacement

The piston displacement is measured as the position at port **R** relative to port **C**. The **Mechanical orientation** identifies the direction of piston displacement. The piston displacement is neutral, or  $\theta$ , when the chamber A volume is equal to the chamber dead volume. When displacement is received as an input, ensure that the derivative of the position is equal to the piston velocity. This is automatically the case when the input is received from a Translational Multibody Interface block connection to a Simscape Multibody joint.

### Hard Stop Model

To avoid mechanical damage to an actuator when it is fully extended or fully retracted, an actuator typically displays nonlinear behavior when the piston approaches these limits. The Double-Acting Actuator (IL) block models this behavior with a choice of four hard stop models, which model the material compliance through a spring-damper system. The hard stop models are:

- Stiffness and damping applied smoothly through transition region, damped rebound.
- Full stiffness and damping applied at bounds, undamped rebound.
- Full stiffness and damping applied at bounds, damped rebound.
- Based on coefficient of restitution

The hard stop force is modeled when the piston is at its upper or lower bound. The boundary region is within the **Transition region** of the **Piston stroke** or piston initial displacement. Outside of this region,  $F_{HardStop} = 0$ .

For more information about these settings, see the Translational Hard Stop block page.

### Cushion

You can optionally model cushioning toward the extremes of the piston stroke. Modeling cylinder end cushioning slows the piston motion as it approaches its maximum extension within its respective chamber, which is defined in **Piston stroke**. For more information on the functionality of a cylinder cushion, see Cylinder Cushion (IL).

### Friction

You can optionally model friction against piston motion. When you select **Cylinder friction effect**, the resulting friction is a combination of Stribeck, Coulomb, and viscous effects. The pressure difference is measured between the chamber pressure and the environment pressure. For more information on the friction model and its limitations, see the Cylinder Friction block.

### Leakage

You can optionally model leakage between the liquid chambers and the piston reservoir. When you select **Internal leakage**, Poiseuille flow is modeled between the piston and cylinder. This block uses the Simscape Foundation Library Laminar Leakage (IL) block. The flow rate is calculated as:

$$\dot{m} = \frac{\frac{\pi}{128} \left( d_0^4 - d_i^4 - \frac{(d_0^2 - d_i^2)^2}{\log(d_0/d_i)} \right)}{\nu L} (p_A - p_{env}),$$

where:

- $\nu$  is the fluid kinematic viscosity.
- $L$  is the piston length,  $\mathbf{p} - P_0$ .
- $p_A$  is the pressure at port **A**.
- $p_{env}$  is the environmental pressure, which is selected in the **Environment pressure specification** parameter.

The cylinder diameter,  $d_0$ , is  $d_0 = d_i + 2c$ , where  $c$  is the **Piston-cylinder clearance**, and the piston diameter,  $d_i$ , is  $d_i = \sqrt{\frac{4A_p}{\pi}}$ , where  $A_p$  is the average of the **Piston cross-sectional area in chamber A** and **Piston cross-sectional area in chamber B** parameters.

### Numerically-Smoothed Area and Pressure

You can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smooths the cushion A and B orifice areas and the check valve pressure ranges. The orifice area is smoothly saturated between the cushion A and cushion B **Leakage area between plunger and cushion sleeve** and **Cushion plunger cross-sectional area** parameters while the valve pressure is saturated between the cushion A and cushion B **Check valve cracking pressure differential** and **Check valve maximum pressure differential** parameters. For more information, see "Numerical Smoothing".

### **Block Schematic**

The Double-Acting Actuator (IL) block comprises four Simscape Foundation blocks:

- Laminar Leakage (IL)
- Translational Mechanical Converter (IL)
- Translational Hard Stop
- Ideal Translational Motion Sensor

and two Isothermal Liquid library blocks:

- Cylinder Cushion (IL)
- Cylinder Friction (IL)

**Momentum Balance**

The momentum conservation equation for the actuator is

$$F = \epsilon(S_A p_A - S_B p_B - S_{Rod} p_{env})$$

where:

- $F$  is the force the liquid exerts on the converter interface. This force expression does not account for the force contributions due to the hard stop, cylinder cushions, or cylinder friction subcomponents. To see those force contributions to the converter interface, see the documentation pages for those subcomponents.
- $\varepsilon$  depends on the **Mechanical orientation** of the converter. If **Mechanical orientation** is Pressure at A causes positive displacement of R relative to C,  $\varepsilon = 1$ . If **Mechanical orientation** is Pressure at A causes negative displacement of R relative to C,  $\varepsilon = -1$ .
- $S_{Rod}$  is the rod cross-sectional area where  $S_{Rod} = S_A - S_B$ .
- $S_A$  is the value of the **Piston cross-sectional area in chamber A** parameter.
- $S_B$  is the value of the **Piston cross-sectional area in chamber B** parameter.
- $p_A$  is the pressure inside chamber A.
- $p_B$  is the pressure inside chamber B.
- $p_{env}$  is the environment pressure.

## Ports

### Input

**p** — Piston position input, m  
physical signal

Physical signal input port associated with the piston position that you specify using a Simscape Multibody block.

### Dependencies

To expose this port, set **Piston displacement from chamber A cap** to Provide input signal from Multibody joint.

### Output

**p** — Piston position output, m  
physical signal

Physical signal port associated with the piston position.

### Dependencies

To expose this port, set **Piston displacement from chamber A cap** to Calculate from velocity of port R relative to port C.

### Conserving

**A** — Inlet to chamber A  
isothermal liquid

Isothermal liquid conserving port associated with the inlet to chamber A.

**B** — Inlet to chamber B  
isothermal liquid

Isothermal liquid conserving port associated with the inlet to chamber B.

**C** — Actuator casing  
mechanical translational

Mechanical translational conserving port associated with the case.

**R** — Actuator piston  
mechanical translational

Mechanical translational conserving port associated with the piston.

## Parameters

### Actuator

**Mechanical orientation** — Piston displacement direction

Pressure at A causes positive displacement of R relative to C (default) | Pressure at A causes negative displacement of R relative to C

Sets the piston displacement direction. When you set this parameter to:

- Pressure at A causes positive displacement of R relative to C the piston displacement is positive when the volume of liquid at port **A** is expanding. This corresponds to rod extension.
- Pressure at A causes negative displacement of R relative to C the piston displacement is negative when the volume of liquid at port **A** is expanding. This corresponds to rod contraction.

**Piston cross-sectional area in chamber A** — Chamber A piston area  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the piston rod on the chamber A side.

**Piston cross-sectional area in chamber B** — Chamber B piston area  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the piston rod on the chamber B side.

**Piston stroke** — Maximum piston travel distance  
0.1 m (default) | positive scalar

Maximum piston travel distance.

**Dead volume in chamber A** — Chamber A fluid volume at full piston retraction  
1e-5 m<sup>3</sup> (default) | positive scalar

Volume of liquid when the piston displacement is 0 in chamber A. This is the liquid volume when the piston is up against the actuator end cap.

**Dead volume in chamber B** — Chamber B fluid volume at full piston retraction  
1e-5 m<sup>3</sup> (default) | positive scalar

Volume of liquid when the piston displacement is 0 in chamber B. This is the liquid volume when the piston is up against the actuator end cap.

**Environment pressure specification** — Reference environment pressure  
Atmospheric pressure (default) | Specified pressure

Environment reference pressure. The Atmospheric pressure option sets the environmental pressure to 0.101325 MPa.

**Environment pressure** — User-defined environmental pressure  
0.101325 MPa (default) | positive scalar

User-defined environmental pressure.

#### **Dependencies**

To enable this parameter, set **Environment pressure specification** to Specified pressure.

**Breakaway to Coulomb friction force ratio** — Ratio of breakaway force to Coulomb friction force  
1.2 (default) | positive scalar

Ratio of the breakaway force to the Coulomb friction force.

#### **Dependencies**

To enable this parameter, in the **Friction** tab, select **Cylinder friction effect**.

**Breakaway friction velocity** — Threshold for motion  
0.1 m/s (default) | positive scalar

Threshold velocity for motion against friction force to begin.

#### **Dependencies**

To enable this parameter, in the **Friction** tab, select **Cylinder friction effect**.

### **Hard Stop**

**Hard stop model** — Select the hard stop model  
Stiffness and damping applied smoothly through transition region, damped rebound (default) | Full stiffness and damping applied at bounds, undamped rebound | Full stiffness and damping applied at bounds, damped rebound | Based on coefficient of restitution

Model choice for the force on the piston at full extension or full retraction. See the Translational Hard Stop block for more information.

**Hard-stop stiffness coefficient** — Stiffness coefficient  
1e10 N/m (default) | positive scalar

Piston stiffness coefficient.

#### **Dependencies**

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound
- Full stiffness and damping applied at bounds, undamped rebound

- Full stiffness and damping applied at bounds, damped rebound

**Hard-stop damping coefficient** — Damping coefficient

150 N\*s/m (default) | positive scalar

Piston damping coefficient.

**Dependencies**

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound
- Full stiffness and damping applied at bounds, undamped rebound
- Full stiffness and damping applied at bounds, damped rebound

**Transition region** — Application range of hard stop force model

0.1 mm (default) | positive scalar

Application range of the hard stop force model. Outside of this range of the piston maximum extension and piston maximum retraction, the **Hard stop model** is not applied and there is no additional force on the piston.

**Dependencies**

To enable this parameter, set **Hard stop model** to Stiffness and damping applied smoothly through transition region, damped rebound.

**Coefficient of restitution** — Ratio of final-to-initial relative speed between slider and stop after collision

0.7 (default) | unitless value between 0 and 1

Ratio of the final to the initial relative speed between the slider and the stop after the slider bounces.

**Dependencies**

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Static contact speed threshold** — Threshold relative speed between slider and stop before collision

0.001 m/s (default) | nonnegative scalar

Threshold relative speed between slider and stop before collision. When the slider hits the case with speed less than the value of the **Static contact speed threshold** parameter, they stay in contact. Otherwise, the slider bounces. To avoid modeling static contact between the slider and the case, set this parameter to 0.

**Dependencies**

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Static contact release force threshold** — Threshold force needed to transition from contact mode to free mode

0.001 N (default) | positive scalar

Minimum force needed to release the slider from a static contact mode.

**Dependencies**

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Converter Cushion A**

**Cylinder A end cushioning** — Whether to model piston slow-down at maximum extension  
off (default) | on

Whether to model piston slow-down at maximum extension. See the Cylinder Cushion (IL) block for more information.

**Cushion plunger cross-sectional area** — Cylinder cushion plunger area  
1e-4 m<sup>2</sup> (default) | positive scalar

Area of the plunger inside the actuator cushion element.

**Dependencies**

To enable this parameter, select **Cylinder A end cushioning**.

**Cushion plunger length** — Length of cushion plunger  
1e-3 m (default) | positive scalar

Length of the cushion plunger.

**Dependencies**

To enable this parameter, select **Cylinder A end cushioning**.

**Cushion orifice area** — Area of orifice between cushion chambers  
1e-6 m<sup>2</sup> (default) | positive scalar

Area of the orifice between cushion chambers.

**Dependencies**

To enable this parameter, select **Cylinder A end cushioning**.

**Leakage area between plunger and cushion sleeve** — Gap between cushion plunger and sleeve  
1e-7 m<sup>2</sup> (default) | positive scalar

Gap area between the cushion plunger and sleeve. This value contributes to numerical stability by maintaining continuity in the flow.

**Dependencies**

To enable this parameter, select **Cylinder A end cushioning**.

**Check valve cracking pressure differential** — Cushion threshold pressure  
0.01 MPa (default) | positive scalar

Pressure beyond which the valve operation is triggered. When the pressure difference between port **A** and  $P_{env}$  meets or exceeds the **Check valve cracking pressure differential**, the cushion valve begins to open.

**Dependencies**

To enable this parameter, select **Cylinder A end cushioning**.

**Check valve maximum pressure differential** — Maximum cushion differential pressure  
0.1 MPa (default) | positive scalar

Maximum cushion valve differential pressure. This parameter provides an upper limit to the pressure so that system pressures remain realistic.

**Dependencies**

To enable this parameter, select **Cylinder A end cushioning**.

**Check valve maximum area** — Area of fully opened cushion valve  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the cushion valve in its fully open position.

**Dependencies**

To enable this parameter, select **Cylinder A end cushioning**.

**Check valve leakage area** — Cushion valve gap area when in fully closed position  
 $1e-10 \text{ m}^2$  (default) | positive scalar

Sum of all gaps when the cushion check valve is in a fully closed position. Any area smaller than this value is saturated to the specified leakage area. This value contributes to numerical stability by maintaining continuity in the flow.

**Dependencies**

To enable this parameter, select **Cylinder A end cushioning**.

**Converter Cushion B**

**Cylinder B end cushioning** — Whether to model piston slow-down at maximum extension  
off (default) | on

Whether to model piston slow-down at maximum extension. See the Cylinder Cushion (IL) block for more information.

**Cushion plunger cross-sectional area** — Cylinder cushion plunger area  
 $1e-4 \text{ m}^2$  (default) | positive scalar

Area of the plunger inside the actuator cushion element.

**Dependencies**

To enable this parameter, select **Cylinder B end cushioning**.

**Cushion plunger length** — Length of cushion plunger  
 $1e-3 \text{ m}$  (default) | positive scalar

Length of the cushion plunger.

**Dependencies**

To enable this parameter, select **Cylinder B end cushioning**.

**Cushion orifice area** — Area of orifice between cushion chambers

1e-6 m<sup>2</sup> (default) | positive scalar

Area of the orifice between cushion chambers.

**Dependencies**

To enable this parameter, select **Cylinder B end cushioning**.

**Leakage area between plunger and cushion sleeve** — Gap between cushion plunger and sleeve

1e-7 m<sup>2</sup> (default) | positive scalar

Gap area between the cushion plunger and sleeve. This value contributes to numerical stability by maintaining continuity in the flow.

**Dependencies**

To enable this parameter, select **Cylinder B end cushioning**.

**Check valve cracking pressure differential** — Cushion threshold pressure

0.01 MPa (default) | positive scalar

Pressure beyond which the valve operation is triggered. When the pressure difference between port **A** and  $P_{env}$  meets or exceeds the **Check valve cracking pressure differential**, the cushion valve begins to open.

**Dependencies**

To enable this parameter, select **Cylinder B end cushioning**.

**Check valve maximum pressure differential** — Maximum cushion differential pressure

0.1 MPa (default) | positive scalar

Maximum cushion valve differential pressure. This parameter provides an upper limit to the pressure so that system pressures remain realistic.

**Dependencies**

To enable this parameter, select **Cylinder B end cushioning**.

**Check valve maximum area** — Area of fully opened cushion valve

1e-4 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the cushion valve in its fully open position.

**Dependencies**

To enable this parameter, select **Cylinder B end cushioning**.

**Check valve leakage area** — Cushion valve gap area when in fully closed position

1e-10 m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the cushion check valve is in a fully closed position. Any area smaller than this value is saturated to the specified leakage area. This value contributes to numerical stability by maintaining continuity in the flow.

#### Dependencies

To enable this parameter, select **Cylinder B end cushioning**.

**Smoothing factor** — Numerical smoothing factor

0.01 (default) | positive scalar

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the variable orifice and check valve are in near-open or near-closed positions. Set this value to a nonzero value less than one to increase the stability of your simulation in these regimes.

#### Dependencies

To enable this parameter, select **Cylinder B end cushioning**.

#### Friction

**Cylinder friction effect** — Whether to model friction against piston motion

off (default) | on

Whether to model friction against piston motion. The model accounts for Coulomb, Stribeck, and viscous friction. See the Cylinder Friction block for more information.

**Preload force** — Initial force on cylinder

20 N (default) | scalar

Force on the cylinder when it is in the neutral position.

#### Dependencies

To enable this parameter, select **Cylinder friction effect**.

**Coulomb friction force coefficient** — Coulomb friction force coefficient

1e-6 N/Pa (default) | positive scalar

Coulomb force coefficient of friction.

#### Dependencies

To enable this parameter, select **Cylinder friction effect**.

**Viscous friction coefficient** — Viscous friction coefficient

100 N/(m/s) (default) | positive scalar

Viscous friction coefficient.

#### Dependencies

To enable this parameter, select **Cylinder friction effect**.

#### Leakage

**Internal leakage** — Whether to model annular leakage

off (default) | on

Whether to model annular leakage between the fluid chamber and the piston reservoir at reference environment conditions. The leakage is considered laminar. See the Laminar Leakage (IL) block for more information.

**Piston-cylinder clearance** — Radial clearance

1e-4 m (default) | positive scalar

Radial distance between the piston rod and cylinder casing.

#### **Dependencies**

To enable this parameter, select **Internal leakage**.

**Piston head length** — Annular length of piston mounting

0.01 m (default) | positive scalar

Annular length of the piston mounting, not including the piston rod.

#### **Dependencies**

To enable this parameter, select **Internal leakage**.

#### **Initial Conditions**

**Piston displacement from chamber A cap** — Method for determining piston position

Calculate from velocity of port R relative to port C (default) | Provide input signal from Multibody joint

Method for determining the piston position. The block can receive the position from a Multibody block when set to Provide input signal from Multibody joint, or calculates the position internally and reports the position at port **p**. The position is between 0 and the **Piston stroke** when the mechanical orientation is positive and 0 and **-Piston stroke** when the mechanical orientation is negative.

**Initial piston displacement from chamber A cap** — Piston position measured from chamber A cap at start of simulation

0 m (default) | scalar

Piston position with respect to the chamber A cap at the start of the simulation.

#### **Dependencies**

To enable this parameter, set **Piston displacement from chamber A cap** to Calculate from velocity of port R relative to port C.

**Fluid dynamic compressibility** — Whether to model fluid compressibility

on (default) | off

Whether to model any change in fluid density due to fluid compressibility. When you select **Fluid dynamic compressibility**, changes due to the mass flow rate into the block are calculated in addition to density changes due to changes in pressure. In the Isothermal Liquid Library, all blocks calculate density as a function of pressure.

**Initial liquid pressure in chamber A** — Starting liquid pressure in chamber A

0.101325 MPa (default) | positive scalar

Starting liquid pressure for compressible fluids.

### Dependencies

To enable this parameter, select **Fluid dynamic compressibility**.

**Initial liquid pressure in chamber B** — Starting liquid pressure in chamber B  
0.101325 MPa (default) | positive scalar

Starting liquid pressure for compressible fluids.

## Double-Acting Actuator (TL)

Linear actuator with piston motion controlled by two opposing thermal liquid chambers

### Libraries:

Simscape / Fluids / Thermal Liquid / Actuators

### Description

The Double-Acting Actuator (TL) block represents a linear actuator with piston motion controlled by two opposing thermal liquid chambers. The actuator generates force in the extension and retraction strokes. The force generated depends on the pressure difference between the two chambers.

The figure shows the key components of the actuator model. Ports **A** and **B** represent the thermal liquid chamber inlets. Port **R** represents the translating actuator piston and port **C** the actuator case. Ports **HA** and **HB** represent the thermal interfaces between each chamber and the environment. The moving piston is adiabatic.

### Double-Acting Actuator Schematic

#### Displacement

The piston displacement is measured as the position at port **R** relative to port **C**. The **Mechanical orientation** identifies the direction of piston displacement. The piston displacement is considered neutral, or  $\theta$ , when the chamber A volume is equal to the chamber dead volume. When displacement is received as an input, ensure that the derivative of the position is equal to the piston velocity. This is automatically the case when the input is received from a Translational Multibody Interface block connection to a Simscape Multibody joint.

The direction of the piston motion depends on the mechanical orientation setting in the block dialog box. If the mechanical orientation is positive, then a higher pressure at port **A** yields a positive piston translation relative to the actuator case. The direction of motion reverses for a negative mechanical orientation.

#### Hard Stop

A set of hard stops limit the piston range of motion. The hard stops are treated as spring-damper systems. The spring stiffness coefficient controls the restorative component of the hard-stop contact force and the damping coefficient the dissipative component.

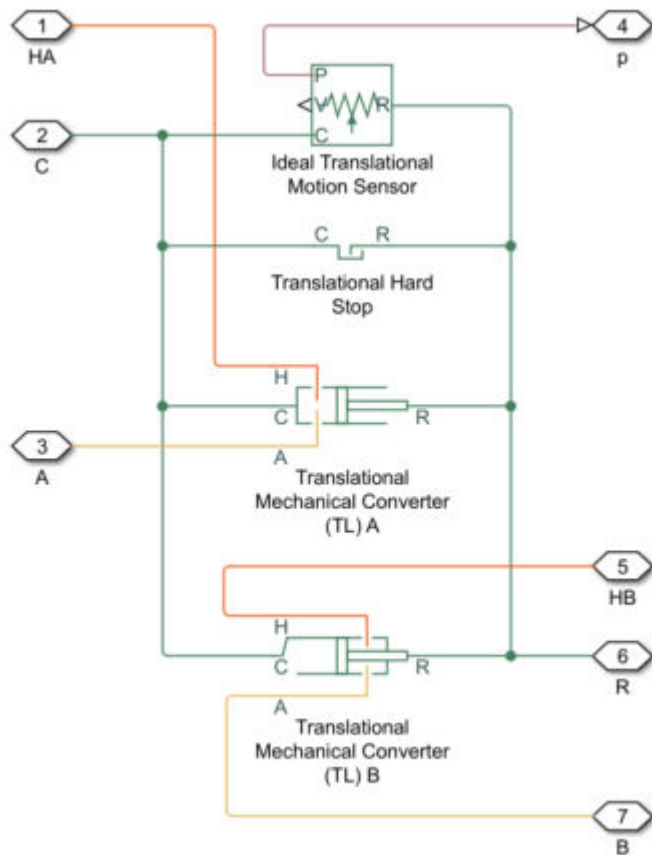

The hard stops are located at the distal ends of the piston stroke. If the mechanical orientation is positive, then the lower hard stop is at  $x = 0$  and the upper hard stop at  $x = +stroke$ . If the

mechanical orientation is negative, then the lower hard stop is at  $x = -stroke$  and the upper hard stop at  $x = 0$ .

### Block Composite

This block is a composite component based on the Simscape Foundation blocks:

- Translational Mechanical Converter (TL)
- Translational Hard Stop
- Ideal Translational Motion Sensor

### Composite Component Diagram

### Ports

#### Input

**p** — Piston position input, m  
physical signal

Physical signal input port associated with the piston position that you specify using a Simscape Multibody block.

**Dependencies**

To expose this port, set **Piston displacement from chamber A cap** to Provide input signal from Multibody joint.

**Output**

**p** — Piston position output, m  
physical signal

Physical signal port associated with the piston position.

**Dependencies**

To expose this port, set **Piston displacement from chamber A cap** to Calculate from velocity of port R relative to port C.

**Conserving**

**A** — Chamber A inlet  
thermal liquid

Thermal liquid conserving port associated with the inlet to chamber A.

**B** — Chamber B inlet  
thermal liquid

Thermal liquid conserving port associated with the inlet to chamber B.

**R** — Actuator piston  
mechanical translational

Mechanical translational conserving port representing the actuator piston.

**C** — Actuator casing  
mechanical translational

Mechanical translational conserving port representing the actuator casing.

**HA** — Chamber A heat flow  
thermal

Thermal conserving port associated chamber A.

**HB** — Chamber B heat flow  
thermal

Thermal conserving port associated with chamber B.

**Parameters****Actuator**

**Mechanical orientation** — Piston displacement direction  
Pressure at A causes positive displacement of R relative to C (default) | Pressure at A causes negative displacement of R relative to C

Sets the piston displacement direction. When you set this parameter to:

- Pressure at A causes positive displacement of R relative to C the piston displacement is positive when the volume of liquid at port A is expanding. This corresponds to rod extension.
- Pressure at A causes negative displacement of R relative to C the piston displacement is negative when the volume of liquid at port A is expanding. This corresponds to rod contraction.

**Piston cross-sectional area in chamber A** — Chamber A piston area

0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the piston rod on the chamber A side.

**Piston cross-sectional area in chamber B** — Chamber B piston area

0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the piston rod on the chamber B side.

**Piston stroke** — Maximum piston travel distance

0.1 m (default) | positive scalar

Maximum piston travel distance.

**Dead volume in chamber A** — Chamber A fluid volume at full piston retraction

1e-5 m<sup>3</sup> (default) | positive scalar

Volume of liquid when the piston displacement is 0 in chamber A. This is the liquid volume when the piston is up against the actuator end cap.

**Dead volume in chamber B** — Chamber B fluid volume at full piston retraction

1e-5 m<sup>3</sup> (default) | positive scalar

Volume of liquid when the piston displacement is 0 in chamber B. This is the liquid volume when the piston is up against the actuator end cap.

**Environment pressure specification** — Reference environment pressure

Atmospheric pressure (default) | Specified pressure

Environment reference pressure. The Atmospheric pressure option sets the environmental pressure to 0.101325 MPa.

**Environment pressure** — User-defined environmental pressure

0.101325 MPa (default) | positive scalar

User-defined environmental pressure.

### Dependencies

To enable this parameter, set **Environment pressure specification** to Specified pressure.

### Hard Stop

**Hard stop model** — Select the hard stop model

Stiffness and damping applied smoothly through transition region, damped rebound (default) | Full stiffness and damping applied at bounds, undamped rebound

| Full stiffness and damping applied at bounds, damped rebound | Based on coefficient of restitution

Model choice for the force on the piston at full extension or full retraction. See the Translational Hard Stop block for more information.

**Hard-stop stiffness coefficient** — Stiffness coefficient  
1e10 N/m (default) | positive scalar

Piston stiffness coefficient.

#### **Dependencies**

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound
- Full stiffness and damping applied at bounds, undamped rebound
- Full stiffness and damping applied at bounds, damped rebound

**Hard-stop damping coefficient** — Damping coefficient  
150 N\*s/m (default) | positive scalar

Piston damping coefficient.

#### **Dependencies**

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound
- Full stiffness and damping applied at bounds, undamped rebound
- Full stiffness and damping applied at bounds, damped rebound

**Transition region** — Application range of hard stop force model  
0.1 mm (default) | positive scalar

Application range of the hard stop force model. Outside of this range of the piston maximum extension and piston maximum retraction, the **Hard stop model** is not applied and there is no additional force on the piston.

#### **Dependencies**

To enable this parameter, set **Hard stop model** to Stiffness and damping applied smoothly through transition region, damped rebound.

**Coefficient of restitution** — Ratio of final-to-initial relative speed between slider and stop after collision  
0.7 (default) | unitless value between 0 and 1

Ratio of the final to the initial relative speed between the slider and the stop after the slider bounces.

#### **Dependencies**

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Static contact speed threshold** — Threshold relative speed between slider and stop before collision  
 0.001 m/s (default) | nonnegative scalar

Threshold relative speed between slider and stop before collision. When the slider hits the case with speed less than the value of the **Static contact speed threshold** parameter, they stay in contact. Otherwise, the slider bounces. To avoid modeling static contact between the slider and the case, set this parameter to 0.

#### Dependencies

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Static contact release force threshold** — Threshold force needed to transition from contact mode to free mode

0.001 N (default) | positive scalar

Minimum force needed to release the slider from a static contact mode.

#### Dependencies

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

#### Initial Conditions

**Piston displacement** — Method for determining piston position

Calculate from velocity of port R relative to port C (default) | Provide input signal from Multibody joint

Method for determining the piston position. The block can receive the position from a Multibody block when set to Provide input signal from Multibody joint, or calculates the position internally and reports the position at port **p**. The position is between 0 and the **Piston stroke** when the mechanical orientation is positive and 0 and **-Piston stroke** when the mechanical orientation is negative.

**Initial piston displacement** — Piston position at start of simulation

0 m (default) | scalar

Piston position at the start of the simulation.

#### Dependencies

To enable this parameter, set **Piston displacement** to Calculate from velocity of port R relative to port C.

**Fluid dynamic compressibility** — Whether to model fluid compressibility

on (default) | off

Whether to model any change in fluid density due to fluid compressibility. When you select **Fluid compressibility**, changes due to the mass flow rate into the block are calculated in addition to density changes due to changes in pressure. In the Isothermal Liquid Library, all blocks calculate density as a function of pressure.

**Initial liquid temperature in chamber A** — Starting liquid temperature in chamber A

293.15 K (default)

Initial temperature of the liquid volume in the actuator.

**Initial liquid temperature in chamber B** — Starting liquid temperature in chamber B  
293.15 K (default)

Initial temperature of the liquid volume in the actuator.

**Initial liquid pressure in chamber A** — Starting liquid pressure in chamber A for compressible fluids  
0.101325 MPa (default) | positive scalar

Starting liquid pressure for compressible fluids.

#### **Dependencies**

To enable this parameter, select **Fluid dynamic compressibility**.

**Initial liquid pressure in chamber B** — Starting liquid pressure in chamber B for compressible fluids  
0.101325 MPa (default) | positive scalar

Starting liquid pressure for compressible fluids.

#### **Dependencies**

To enable this parameter, select **Fluid dynamic compressibility**.

## Double-Acting Actuator (H-G)

(Not recommended) Linear actuator with opposing isothermal liquid and gas chambers

---

**Note** This block has been renamed in Simscape Fluids 3.0 (release 2020a). In Release 2019b and older, this block was named Double-Acting Actuator (IL-G). Older models opened in R2020a currently work with the former version of this block.

---

### Libraries:

Simscape / Fluids / Fluid Network Interfaces / Actuators

### Description

The Double-Acting Actuator (H-G) block represents a linear actuator with opposing chambers of isothermal liquid and gas. The chambers can be individually pressurized to power the actuator in both the extension and retraction strokes. A piston between the chambers converts the pressure difference across them into actuation force.

The figure maps the conserving ports of the block to the actuator parts. Ports **A** and **B** are the inlets of the isothermal liquid and gas chambers. Ports **R** and **C** are the translating piston and case. The gas chamber can exchange heat with the environment and is fitted for this purpose with port **H**. The isothermal liquid, being of constant temperature, exchanges heat neither with the environment nor with the gas across the piston.

The sign of the piston displacement relative to the case depends on the mechanical orientation of the actuator. Use the **Mechanical orientation** parameter to specify this setting. If the mechanical orientation is positive, the piston displacement is positive when the pressure is highest in the isothermal liquid chamber (port **A**). If the mechanical orientation is negative, the piston displacement (under the same pressure conditions) is negative.

Use port **P** to output the instantaneous piston position. The position measurement can be absolute or relative. Configure the **Piston position display** parameter to switch the measurement type if needed:

- From piston initial distance from port A — The measurement is absolute. The first reading is the value specified in the **Piston initial distance from port A**. If that value is 10 in, the first reading is also 10 in.

- **From zero** — The measurement is relative to the initial piston position. The first reading, as it corresponds to the initial piston position, is zero.

Hard stops limit the motion of the piston to the length of the case. The stops are modeled as spring-dampers, with spring and damping coefficients to capture material compliance. One is located at the bottom of the piston stroke and the other at the top:

- If the **Mechanical orientation** setting is **Positive**, the bottom stop is at zero, and the top stop is at a distance equal to the piston stroke.
- If the **Mechanical orientation** setting is **Negative**, the top stop is at zero, and the bottom stop is at a distance equal to the piston stroke.

The block is a composite component built from Simscape Foundation blocks. For more information on how the Double-Acting Actuator (H-G) block works, see the reference pages of the constituent blocks:

- Translational Hydro-Mechanical Converter
- Translational Mechanical Converter (G)
- Translational Hard Stop
- Ideal Translational Motion Sensor

## Ports

### Output

**P** — Piston position, m  
physical signal

Piston position measurement. The measurement can be absolute or relative to the initial piston position. Use the **Piston position display** parameter to specify the measurement type.

### Conserving

**A** — Inlet to chamber A  
hydraulic (isothermal liquid)

Hydraulic (isothermal liquid) conserving port associated with the inlet to chamber A.

**B** — Inlet to chamber B  
gas

Gas conserving port associated with the inlet to chamber B.

**R** — Actuator piston rod  
mechanical translational

Mechanical translational conserving port representing the piston rod. The piston is capable of translational motion relative to the casing.

**C** — Actuator casing  
mechanical translational

Mechanical translational conserving port associated with the case.

**H** — Gas chamber thermal surface  
thermal

Thermal conserving port associated with the surface of the gas chamber through which heat exchange with the surroundings can occur. The thermal processes at this port determine the temperature in the gas chamber and therefore at port **B**.

## Parameters

### Hydraulic Side

**Mechanical orientation** — Direction of motion of the piston relative to the direction of flow of the fluid

Positive | Negative

Orientation of the actuator piston relative to the direction of fluid flow. A positive orientation causes the piston to move in the positive direction relative to the actuator casing in response to a positive flow rate through port A. The mechanical orientation affects the placement of the piston hard stops. See the block description for more information on the hard stop placement.

**Piston cross-sectional area in chamber A** — Cross-sectional area of the fluid volume in the hydraulic chamber

0.01 m<sup>2</sup> (default) | scalar

Area normal to the direction of flow in the body of the hydraulic chamber. The block uses this area to calculate the hydraulic force due to the fluid pressure in the hydraulic chamber. This parameter must be greater than zero.

**Piston stroke** — Distance of travel of piston from hard stop to hard stop

0.1 m (default) | scalar

Total distance of travel available to the piston, from one hard stop to the other. The hard stops limit the piston motion so that the piston is confined to stroke of the piston. See the block description for more information on the locations of the hard stops.

**Piston position display** — Reference against which to output piston position

From piston initial distance from port A (default) | From zero

Reference against which to measure the piston position. This setting reflects in the output of port **P**. Use the default setting, *From piston initial distance from port A*, to output the absolute piston position; the first position reading is then the value of the **Piston initial distance from port A** parameter. Use the alternative setting, *From zero*, to output the piston position relative to the specified initial value; the first position reading is then zero.

**Piston initial distance from port A** — Piston position relative to the hydraulic chamber inlet at the start of simulation

0 m (default) | scalar

Distance of the piston from the hard stop closest to the hydraulic inlet at the start of simulation. Use this parameter to change the starting position of the piston. This parameter affects the placement of the piston hard stops. For more information on the hard stop placement, see the block description.

**Fluid dynamic compressibility** — Choice to model the effects of dynamic compressibility inside the hydraulic chamber

Off (default) | On

Option to model the effects of dynamic compressibility inside the hydraulic chamber. The hydraulic fluid is treated as compressible if this parameter is set to *On* and as incompressible if it is set to *Off*. The block ignores the dependence of the hydraulic fluid density on pressure and temperature if *Off* is selected.

**Dead volume in chamber A** — Fluid volume in the hydraulic chamber in the bottomed-out position

1e-4 m<sup>3</sup> (default) | scalar

Hydraulic fluid volume remaining in the hydraulic chamber when the piston is pressed against the hard stop closest to the hydraulic inlet. The dead volume enables the block to capture the internal states of the hydraulic fluid volume—its pressure and temperature—when this volume is at a minimum. This parameter must be greater than zero.

#### Dependencies

This parameter is enabled when the **Compressibility** parameter is set to *On*.

**Specific heat ratio** — Specific heat ratio of the gas entrained in the hydraulic fluid

1.4 (default) | scalar

Ratio of the specific heat of the gas entrained in the hydraulic fluid at constant pressure to that at constant volume. The block uses this parameter in the calculations of density for the hydraulic fluid.

#### Dependencies

This parameter is enabled when the **Compressibility** parameter is set to *On*.

**Initial liquid pressure (gauge)** — Gauge pressure in the hydraulic chamber relative to the actuator environment

0 Pa (default) | scalar

Pressure inside the hydraulic chamber at simulation time zero relative to absolute zero. This parameter helps set the initial states of the hydraulic fluid volume.

#### Dependencies

This parameter is enabled when the **Compressibility** parameter is set to *On*.

## Gas Side

**Piston cross-sectional area in chamber B** — Cross-sectional area of the fluid volume in the gas chamber

1e-3 m<sup>2</sup> (default) | positive scalar

Area normal to the direction of flow in the body of the gas chamber. The block uses this area to calculate the pneumatic force due to the fluid pressure in the gas chamber. This parameter must be greater than zero.

**Cross-sectional area at port B** — Cross-sectional area of the inlet of the gas chamber

1e-3 m<sup>2</sup> (default) | positive scalar

Area normal to the direction of flow at the entrance to the gas chamber. The cross-sectional area at the entrance can differ from that in the body of the chamber. Set the two cross-sectional areas to different values to model the effects of a sudden area change at the inlet. This parameter must be greater than zero.

**Dead volume in chamber B** — Fluid volume in the gas chamber in the bottomed-out position

1e-4 m<sup>3</sup> (default) | positive scalar

Gas volume remaining in the gas chamber when the piston is pressed against the hard stop closest to the gas inlet. The dead volume enables the block to capture the internal states of the gas volume—its pressure and temperature—when this volume is at a minimum. This parameter must be greater than zero.

**Initial gas pressure (absolute)** — Absolute pressure inside the gas chamber at the start of simulation

0.101325 MPa (default) | scalar

Pressure inside the gas chamber at simulation time zero relative to absolute zero. This parameter helps set the initial state of the gas volume.

**Environment pressure specification** — Choice of atmospheric or custom environment pressure for the gas side

Atmospheric pressure (default) | Specified pressure

Option to set the environment pressure of the gas chamber to the typical value of one earth atmosphere or to a custom value. Selecting **Specified pressure** exposes an additional parameter, **Environment pressure**, that you use to specify a custom pressure.

**Environment pressure** — Absolute pressure of the environment outside the gas chamber

0.101325 MPa (default) | scalar

Pressure outside the gas chamber relative to absolute zero. This pressure acts against the pressure inside the gas chamber. A pressure of zero corresponds to a perfect vacuum.

### Dependencies

This parameter is enabled when the **Environment pressure specification** is set to **Specified pressure**.

### Hard Stop

**Hard stop model** — Select the hard stop model

Stiffness and damping applied smoothly through transition region, damped rebound (default) | Full stiffness and damping applied at bounds, undamped rebound

| Full stiffness and damping applied at bounds, damped rebound | Based on coefficient of restitution

Model choice for the force on the piston at full extension or full retraction. See the Translational Hard Stop block for more information.

**Hard-stop stiffness coefficient** — Stiffness coefficient  
1e6 N/m (default) | positive scalar

Piston stiffness coefficient.

#### Dependencies

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound
- Full stiffness and damping applied at bounds, undamped rebound
- Full stiffness and damping applied at bounds, damped rebound

**Hard-stop damping coefficient** — Damping coefficient  
150 N\*s/m (default) | positive scalar

Piston damping coefficient.

#### Dependencies

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound
- Full stiffness and damping applied at bounds, undamped rebound
- Full stiffness and damping applied at bounds, damped rebound

**Transition region** — Application range of hard stop force model  
0.1 mm (default) | positive scalar

Application range of the hard stop force model. Outside of this range of the piston maximum extension and piston maximum retraction, the **Hard stop model** is not applied and there is no additional force on the piston.

#### Dependencies

To enable this parameter, set **Hard stop model** to Stiffness and damping applied smoothly through transition region, damped rebound.

**Coefficient of restitution** — Ratio of final-to-initial relative speed between slider and stop after collision  
0.7 (default) | unitless value between 0 and 1

Ratio of the final to the initial relative speed between the slider and the stop after the slider bounces.

#### Dependencies

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Static contact speed threshold** — Threshold relative speed between slider and stop before collision  
0.001 m/s (default) | nonnegative scalar

Threshold relative speed between slider and stop before collision. When the slider hits the case with speed less than the value of the **Static contact speed threshold** parameter, they stay in contact. Otherwise, the slider bounces. To avoid modeling static contact between the slider and the case, set this parameter to 0.

#### **Dependencies**

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Static contact release force threshold** — Threshold force needed to transition from contact mode to free mode

0.001 N (default) | positive scalar

Minimum force needed to release the slider from a static contact mode.

#### **Dependencies**

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

## **Version History**

# Double-Acting Actuator (G-IL)

Linear actuator with isothermal liquid and gas chambers

## Libraries:

Simscape / Fluids / Fluid Network Interfaces / Actuators

## Description

The Double-Acting Actuator (G-IL) block represents an isothermal liquid chamber and a gas chamber separated by a piston plate. The piston actuation is controlled by the pressure differential between the chambers. The motion of the piston when it is near full extension or full retraction is limited by one of four hard stop models.

Port **A** is the isothermal liquid inlet and port **B** is the gas inlet. Connect elements for heat transfer between the gas chamber and the environment to port **H**. Port **C** acts as a mechanical translational reference for the actuator casing. Port **R** is associated with the actuator piston. The piston position is reported at port **P**.

## Displacement

The piston displacement is measured as the position at port **R** relative to port **C**. The **Mechanical orientation** identifies the direction of piston displacement. The piston displacement is neutral, or  $\theta$ , when the chamber volume is equal to the chamber dead volume. When displacement is received as an input, ensure that the derivative of the position is equal to the piston velocity. This is automatically the case when the input is received from a Translational Multibody Interface block connection to a Simscape Multibody joint.

## Hard Stop Model

To avoid mechanical damage to the piston when it is fully extended or fully retracted, an actuator typically displays nonlinear behavior when the piston approaches these limits. The Double-Acting Actuator (G-IL) block models this behavior with a choice of four hard stop models, which model the material compliance through a spring-damper system. The hard stop models are:

- Stiffness and damping applied smoothly through transition region, damped rebound.

- Full stiffness and damping applied at bounds, undamped rebound.
- Full stiffness and damping applied at bounds, damped rebound.
- Based on coefficient of restitution

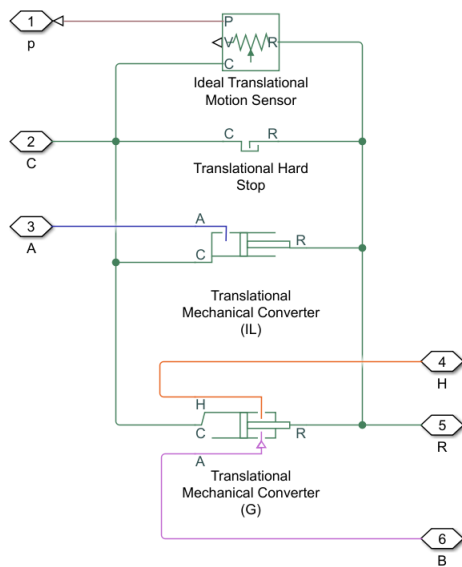

The hard stop force is modeled when the piston is at its upper or lower bound. The boundary region is within the **Transition region** of the **Piston stroke** or piston initial displacement. Outside of this region,  $F_{HardStop} = 0$ .

For more information about these settings, see the Translational Hard Stop block page.

### Block Schematic

The Double-Acting Actuator (G-IL) block is a composite of four Simscape Foundation blocks:

- Translational Mechanical Converter (G)
- Translational Mechanical Converter (IL)
- Translational Hard Stop
- Ideal Translational Motion Sensor

### Ports

#### Output

**p** — Piston position, m  
physical signal

Physical signal port associated with the piston position.

#### Conserving

**A** — Inlet to chamber A  
isothermal liquid

Isothermal liquid conserving port associated with the inlet to chamber A.

**B** — Inlet to chamber B  
gas

Gas conserving port associated with the inlet to chamber B.

**C** — Actuator casing  
mechanical translational

Mechanical translational conserving port associated with the case.

**R** — Actuator piston rod  
mechanical translational

Mechanical translational conserving port associated with the piston rod.

**H** — Heat flow  
thermal

Thermal conserving port associated with heat transfer to or from the gas chamber.

## Parameters

### Configuration

**Mechanical orientation** — Piston displacement direction

Pressure at A causes positive displacement of R relative to C (default) | Pressure at A causes negative displacement of R relative to C

Piston displacement direction. Pressure at A causes positive displacement of R relative to C corresponds to piston extension when the pressure difference between chambers A and B is positive. Pressure at A causes negative displacement of R relative to C corresponds to piston retraction when the pressure difference between chambers A and B is positive.

**Piston stroke** — Maximum piston travel distance

0.1 m (default) | positive scalar

Maximum piston travel distance.

**Initial piston displacement from chamber A cap** — Piston position at start of simulation

0 m (default) | scalar

Piston position at the start of the simulation.

**Hard stop model** — Select the hard stop model

Stiffness and damping applied smoothly through transition region, damped rebound (default) | Full stiffness and damping applied at bounds, undamped rebound | Full stiffness and damping applied at bounds, damped rebound | Based on coefficient of restitution

Model choice for the force on the piston at full extension or full retraction. See the Translational Hard Stop block for more information.

**Hard-stop stiffness coefficient** — Stiffness coefficient  
1e10 N/m (default) | positive scalar

Piston stiffness coefficient.

**Dependencies**

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound
- Full stiffness and damping applied at bounds, undamped rebound
- Full stiffness and damping applied at bounds, damped rebound

**Hard-stop damping coefficient** — Damping coefficient  
150 N\*s/m (default) | positive scalar

Piston damping coefficient.

**Dependencies**

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound
- Full stiffness and damping applied at bounds, undamped rebound
- Full stiffness and damping applied at bounds, damped rebound

**Transition region** — Application range of hard stop force model  
0.1 mm (default) | positive scalar

Application range of the hard stop force model. Outside of this range of the piston maximum extension and piston maximum retraction, the **Hard stop model** is not applied and there is no additional force on the piston.

**Dependencies**

To enable this parameter, set **Hard stop model** to Stiffness and damping applied smoothly through transition region, damped rebound.

**Coefficient of restitution** — Ratio of final-to-initial relative speed between slider and stop after collision  
0.7 (default) | unitless value between 0 and 1

Ratio of the final to the initial relative speed between the slider and the stop after the slider bounces.

**Dependencies**

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Static contact speed threshold** — Threshold relative speed between slider and stop before collision  
0.001 m/s (default) | nonnegative scalar

Threshold relative speed between slider and stop before collision. When the slider hits the case with speed less than the value of the **Static contact speed threshold** parameter, they stay in contact.

Otherwise, the slider bounces. To avoid modeling static contact between the slider and the case, set this parameter to 0.

#### Dependencies

To enable this parameter, set **Hard stop model** to `Based on coefficient of restitution`.

**Static contact release force threshold** — Threshold force needed to transition from contact mode to free mode

0.001 N (default) | positive scalar

Minimum force needed to release the slider from a static contact mode.

#### Dependencies

To enable this parameter, set **Hard stop model** to `Based on coefficient of restitution`.

### Isothermal Liquid Side

**Piston cross-sectional area in chamber A** — Cross-sectional area of piston rod

0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the piston rod in chamber A.

**Dead volume in chamber A** — Chamber volume at full piston retraction

1e-5 m<sup>3</sup> (default) | positive scalar

Open volume in the fluid chamber when the piston is fully retracted.

**Fluid dynamic compressibility** — Whether to model fluid compressibility

On (default) | Off

Whether to model any change in fluid density due to fluid compressibility. When **Fluid compressibility** is set to On, changes due to the mass flow rate into the block are calculated in addition to density changes due to changes in pressure. In the Isothermal Liquid Library, all blocks calculate density as a function of pressure.

**Initial liquid pressure in chamber A** — Initial liquid pressure for compressible fluids

0.101325 MPa (default) | positive scalar

Initial liquid pressure for compressible fluids.

#### Dependencies

To enable this parameter, set **Fluid dynamic compressibility** to On.

**Environment pressure specification** — Reference environment pressure

Atmospheric pressure (default) | Specified pressure

Environment reference pressure. The `Atmospheric pressure` option sets the environmental pressure to 0.101325 MPa.

**Environment pressure** — User-defined environmental pressure

0.101325 MPa (default) | positive scalar

User-defined environmental pressure.

**Dependencies**

To enable this parameter, set **Environment pressure specification** to Specified pressure.

**Gas Side**

**Piston cross-sectional area in chamber B** — Cross-sectional area of piston rod  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the piston rod in chamber B.

**Cross-sectional area at port B** — Port cross-sectional area  
1e-3 m<sup>2</sup> (default) | positive scalar

Cross-sectional area at port B.

**Dead volume in chamber B** — Chamber volume at full piston retraction  
1e-5 m<sup>3</sup> (default) | positive scalar

Open volume in the gas chamber when the piston is fully retracted.

**Initial gas pressure in chamber B** — Starting gas chamber pressure  
0.101325 MPa (default) | positive scalar

Initial pressure in the gas chamber.

**Initial gas temperature in chamber B** — Starting gas chamber temperature  
293.15 K (default) | positive scalar

Initial temperature in the gas chamber.

**Environment pressure specification** — Reference environment pressure  
Atmospheric pressure (default) | Specified pressure

Environment reference pressure. The Atmospheric pressure option sets the environmental pressure to 0.101325 MPa.

**Environment pressure** — User-defined environmental pressure  
0.101325 MPa (default) | positive scalar

User-defined environmental pressure.

**Dependencies**

To enable this parameter, set **Environment pressure specification** to Specified pressure.

## Double-Acting Actuator (TL-G)

Linear actuator with opposing thermal liquid and gas chambers

### Libraries:

Simscape / Fluids / Fluid Network Interfaces / Actuators

### Description

The Double-Acting Actuator (TL-G) block models a linear actuator with opposing chambers of thermal liquid and gas. The chambers can be individually pressurized to power the actuator in both extension and retraction strokes. A piston between the chambers converts the pressure difference across them into actuation force.

The figure maps the conserving ports of the block to the actuator parts. Ports **A** and **B** are the inlets of the thermal liquid and gas chambers. Ports **R** and **C** are the translating piston and case. The chambers can exchange heat with the environment and are fitted for this purpose with ports **HA** and **HB**. The piston is perfectly insulating. The thermal liquid and gas chambers do not exchange heat with each other.

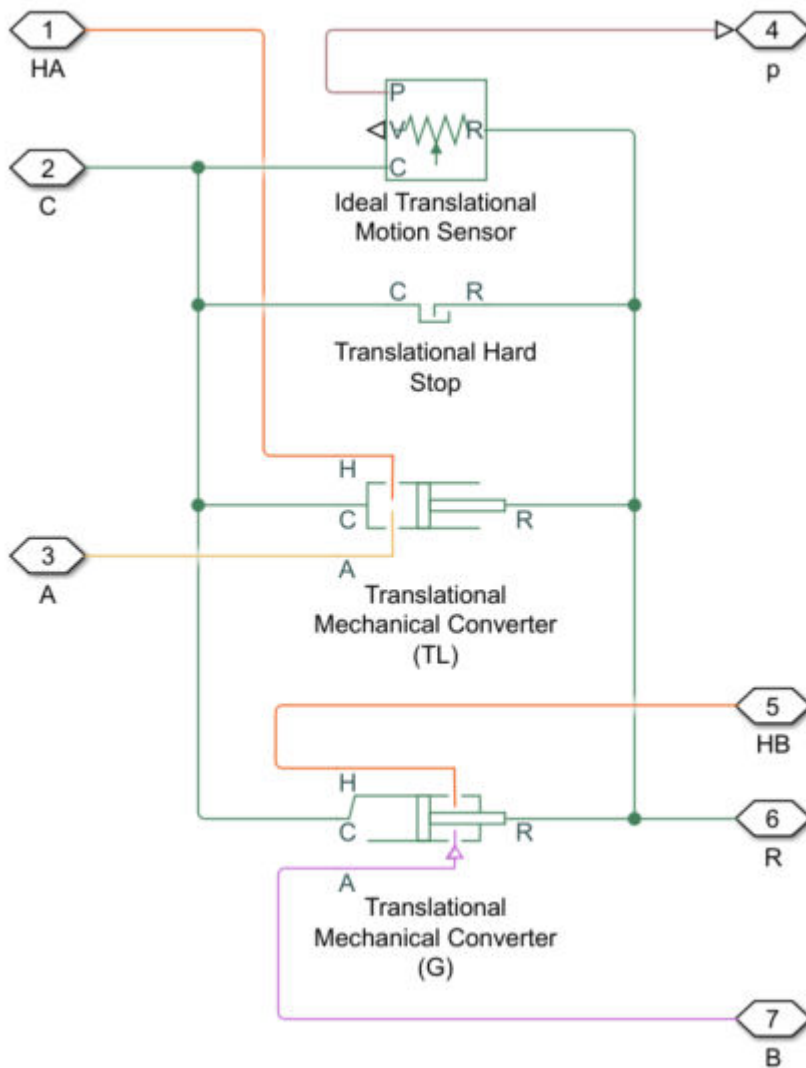

The sign of the piston displacement relative to the case depends on the mechanical orientation of the actuator. Use the **Mechanical orientation** parameter to specify this setting. If the mechanical orientation is positive, the piston displacement is positive when the pressure is highest in the thermal liquid chamber (port **A**). If the mechanical orientation is negative, the piston displacement (under the same pressure conditions) is negative.

Use port **P** to output the instantaneous piston position. The measurement is absolute (relative to zero). Hard stops limit the motion of the piston to the length of the case. The stops are modeled as spring-dampers, with spring and damping coefficients to capture material compliance. One is located at the bottom of the piston stroke and the other at the top:

- If the **Mechanical orientation** setting is **Positive**, the bottom stop is at zero, and the top stop is at a distance equal to the piston stroke.
- If the **Mechanical orientation** setting is **Negative**, the top stop is at zero, and the bottom stop is at a distance equal to the piston stroke.

The block is a composite component built from Simscape Foundation blocks. For more information on how the Double-Acting Actuator (TL-G) block works, see the reference pages of the constituent blocks:

- Translational Mechanical Converter (TL)
- Translational Mechanical Converter (G)
- Translational Hard Stop
- Ideal Translational Motion Sensor

## Ports

### Output

**P** — Piston position, m  
physical signal

Physical signal output port associated with the piston position. The measurement is absolute. The first reading is the value of the **Piston initial displacement** parameter.

## Conserving

**A** — Inlet to chamber A  
thermal liquid

Thermal liquid conserving port associated with the inlet to chamber A.

**B** — Inlet to chamber B  
gas

Gas conserving port representing the inlet to chamber B.

**R** — Actuator piston  
mechanical translational

Mechanical translational conserving port representing the actuator piston.

**C** — Actuator casing  
mechanical translational

Mechanical translational conserving port representing the actuator casing.

**HA** — Chamber A heat flow  
thermal

Thermal conserving port associated with the surface through which heat exchange can occur between the thermal liquid volume and the actuator surroundings. The thermal processes at this port influence the temperature in the thermal liquid chamber and therefore at port **A**.

**HB** — Chamber B heat flow  
thermal

Thermal conserving port associated with the surface through which heat exchange can occur between the gas volume and the actuator surroundings. The thermal processes at this port influence the temperature in the gas chamber and therefore at port **A**.

## Parameters

### Thermal Liquid Side

**Mechanical orientation** — Direction of motion of the piston relative to the direction of flow of the fluid  
Positive | Negative

Orientation of the actuator piston relative to the direction of fluid flow. A positive orientation causes the piston to move in the positive direction relative to the actuator casing in response to a positive flow rate through port A. The mechanical orientation affects the placement of the piston hard stops. See the block description for more information on the hard stop placement.

**Piston cross-sectional area in chamber A** — Cross-sectional area of the fluid volume in the thermal liquid chamber  
0.01 m<sup>2</sup> (default) | scalar in units of area

Area normal to the direction of flow in the body of the thermal liquid chamber. The block uses this area to calculate the hydraulic force due to the fluid pressure in the thermal liquid chamber. This parameter must be greater than zero.

**Piston stroke** — Distance of travel of the piston from hard stop to hard stop

0.2 m (default) | scalar in units of length

Total distance of travel available to the piston, from one hard stop to the other. The hard stops limit the piston motion so that the piston is confined to stroke of the piston. See the block description for more information on the locations of the hard stops.

**Piston initial displacement** — Position of the piston at the start of simulation

0 m (default) | scalar in units of length

Absolute position of the piston at the start of simulation. The zero position coincides with the lower hard stop if the mechanical orientation is positive and with the upper hard stop if the mechanical orientation is negative.

**Dead volume in chamber A** — Fluid volume in the thermal liquid chamber in the bottomed-out position

1e-4 m<sup>3</sup> (default) | scalar in units of volume

Thermal liquid volume remaining in the thermal liquid chamber when the piston is pressed against the hard stop closest to the thermal liquid inlet. The dead volume enables the block to capture the internal states of the thermal liquid volume—its pressure and temperature—when this volume is at a minimum. This parameter must be greater than zero.

**Fluid dynamic compressibility** — Choice to model the effects of dynamic compressibility inside the thermal liquid chamber

On (default) | Off

Option to model the effects of dynamic compressibility inside the thermal liquid chamber. The thermal liquid is treated as compressible if this parameter is set to On and as incompressible if it is set to Off. The block ignores the dependence of the thermal liquid density on pressure and temperature if Off is selected.

**Initial liquid pressure in chamber A** — Absolute pressure in the thermal liquid chamber

0.101325 Pa (default) | scalar in units of pressure

Pressure inside the thermal liquid chamber at simulation time zero relative to absolute zero. This parameter helps set the initial states of the thermal liquid volume.

#### Dependencies

This parameter is enabled when the **Compressibility** parameter is set to On.

**Initial liquid temperature in chamber A** — Temperature in the thermal liquid chamber at the start of simulation

293.15 K (default) | scalar in units of temperature

Average temperature inside the thermal liquid chamber at the start of simulation. This parameter helps set the initial states of the thermal liquid volume.

**Environment pressure specification** — Choice of atmospheric or custom environment pressure for the thermal liquid side

Atmospheric pressure (default) | Specified pressure

Option to set the environment pressure of the thermal liquid chamber to the typical value of one earth atmosphere or to a custom value. Selecting **Specified pressure** exposes an additional parameter, **Environment pressure**, that you use to specify a custom pressure.

**Environment pressure** — Absolute pressure of the environment outside the thermal liquid chamber  
0.101325 MPa (default) | scalar in units of pressure

Pressure outside the thermal liquid chamber relative to absolute zero. This pressure acts against the pressure inside the thermal liquid chamber. A pressure of zero corresponds to a perfect vacuum.

#### Dependencies

This parameter is enabled when the **Environment pressure specification** is set to **Specified pressure**.

#### Gas Side

**Piston cross-sectional area in chamber B** — Cross-sectional area of the fluid volume in the gas chamber

1e-3 m<sup>2</sup> (default) | positive scalar in units of area

Area normal to the direction of flow in the body of the gas chamber. The block uses this area to calculate the pneumatic force due to the fluid pressure in the gas chamber. This parameter must be greater than zero.

**Cross-sectional area at port B** — Cross-sectional area of the inlet of the gas chamber

1e-3 m<sup>2</sup> (default) | positive scalar in units of area

Area normal to the direction of flow at the entrance to the gas chamber. The cross-sectional area at the entrance can differ from that in the body of the chamber. Set the two cross-sectional areas to different values to model the effects of a sudden area change at the inlet. This parameter must be greater than zero.

**Dead volume in chamber B** — Fluid volume in the gas chamber in the bottomed-out state

1e-4 m<sup>3</sup> (default) | positive scalar in units of volume

Gas volume remaining in the gas chamber when the piston is pressed against the hard stop closest to the gas inlet. The dead volume enables the block to capture the internal states of the gas volume—its pressure and temperature—when this volume is at a minimum. This parameter must be greater than zero.

**Initial gas pressure (absolute)** — Absolute pressure inside the gas chamber at the start of simulation

0.101325 MPa (default) | scalar in units of pressure

Pressure inside the gas chamber at simulation time zero relative to absolute zero. This pressure helps set the initial state of the gas volume.

**Environment pressure specification** — Choice of atmospheric or custom environment pressure for the gas side

Atmospheric pressure (default) | Specified pressure

Option to set the environment pressure of the gas chamber to the typical value of one earth atmosphere or to a custom value. Selecting **Specified pressure** exposes an additional parameter, **Environment pressure**, that you use to specify a custom pressure.

**Environment pressure** — Absolute pressure of the environment outside the gas chamber  
 0.101325 MPa (default) | scalar in units of pressure

Pressure outside the gas chamber relative to absolute zero. This pressure acts against the pressure inside the gas chamber. A pressure of zero corresponds to a perfect vacuum.

#### Dependencies

This parameter is enabled when the **Environment pressure specification** is set to Specified pressure.

#### Hard Stop

**Hard stop model** — Select the hard stop model  
 Stiffness and damping applied smoothly through transition region, damped rebound (default) | Full stiffness and damping applied at bounds, undamped rebound | Full stiffness and damping applied at bounds, damped rebound | Based on coefficient of restitution

Model choice for the force on the piston at full extension or full retraction. See the Translational Hard Stop block for more information.

**Hard-stop stiffness coefficient** — Stiffness coefficient  
 1e6 N/m (default) | positive scalar

Piston stiffness coefficient.

#### Dependencies

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound
- Full stiffness and damping applied at bounds, undamped rebound
- Full stiffness and damping applied at bounds, damped rebound

**Hard-stop damping coefficient** — Damping coefficient  
 150 N\*s/m (default) | positive scalar

Piston damping coefficient.

#### Dependencies

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound
- Full stiffness and damping applied at bounds, undamped rebound
- Full stiffness and damping applied at bounds, damped rebound

**Transition region** — Application range of hard stop force model  
 0.1 mm (default) | positive scalar

Application range of the hard stop force model. Outside of this range of the piston maximum extension and piston maximum retraction, the **Hard stop model** is not applied and there is no additional force on the piston.

**Dependencies**

To enable this parameter, set **Hard stop model** to `Stiffness and damping applied smoothly through transition region, damped rebound`.

**Coefficient of restitution** — Ratio of final-to-initial relative speed between slider and stop after collision

0.7 (default) | unitless value between 0 and 1

Ratio of the final to the initial relative speed between the slider and the stop after the slider bounces.

**Dependencies**

To enable this parameter, set **Hard stop model** to `Based on coefficient of restitution`.

**Static contact speed threshold** — Threshold relative speed between slider and stop before collision

0.001 m/s (default) | nonnegative scalar

Threshold relative speed between slider and stop before collision. When the slider hits the case with speed less than the value of the **Static contact speed threshold** parameter, they stay in contact. Otherwise, the slider bounces. To avoid modeling static contact between the slider and the case, set this parameter to 0.

**Dependencies**

To enable this parameter, set **Hard stop model** to `Based on coefficient of restitution`.

**Static contact release force threshold** — Threshold force needed to transition from contact mode to free mode

0.001 N (default) | positive scalar

Minimum force needed to release the slider from a static contact mode.

**Dependencies**

To enable this parameter, set **Hard stop model** to `Based on coefficient of restitution`.

## Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Hydraulic Cylinders

## Description

The Double-Acting Hydraulic Cylinder block models a device that converts hydraulic energy into mechanical energy in the form of translational motion. Hydraulic fluid pumped under pressure into one of the two cylinder chambers forces the piston to move and exert force on the cylinder rod. Double-acting cylinders transfer force and motion in both directions.

Connections **R** and **C** are mechanical translational conserving ports corresponding to the cylinder rod and cylinder clamping structure, respectively. Connections **A** and **B** are hydraulic conserving ports. Port **A** is connected to converter **A** and port **B** is connected to converter **B**.

The energy through hydraulic port **A** or **B** is directed to the appropriate Translational Hydro-Mechanical Converter block. The converter transforms hydraulic energy into mechanical energy and accounts for the fluid compressibility in the cylinder chamber. The rod motion is limited with the mechanical Translational Hard Stop block in such a way that the rod can travel only between cylinder caps.

## Displacement

The piston displacement is measured as the position at port **R** relative to port **C**. The **Cylinder orientation** identifies the direction of piston displacement. The piston displacement is neutral, or  $\theta$ , when the chamber A volume is equal to the chamber dead volume. When displacement is received as an input, ensure that the derivative of the position is equal to the piston velocity. This is automatically the case when the input is received from a Translational Multibody Interface block connection to a Simscape Multibody joint.

## Composite Structure

The model of the cylinder is built of Simscape Foundation library blocks. The schematic diagram of the model is shown below.

## Assumptions and Limitations

- No leakage, internal or external, is taken into account.
- No loading on piston rod, such as inertia, friction, spring, and so on, is taken into account. If necessary, you can easily add them by connecting an appropriate building block to cylinder port R.

## Ports

### Input

**p** — Piston position, m  
physical signal

Piston displacement from cap A, received as a physical signal from a Simscape Multibody block.

### Dependencies

To enable this port, set the **Piston displacement from cap A** parameter to Provide input signal from Multibody joint.

### Conserving

**A** — Hydraulic conserving port associated with the cylinder chamber A  
hydraulic

Hydraulic conserving port associated with the cylinder chamber A.

**B** — Hydraulic conserving port associated with the cylinder chamber B  
hydraulic

Hydraulic conserving port associated with the cylinder chamber B.

**R** — Mechanical translational conserving port associated with the cylinder rod  
mechanical translational

Mechanical translational conserving port associated with the cylinder rod.

**C** — Mechanical translational conserving port associated with the cylinder clamping structure  
mechanical translational

Mechanical translational conserving port associated with the cylinder clamping structure.

## Parameters

### Basic Parameters

**Piston area B** — Chamber B effective piston area

0.5e-3 m<sup>2</sup> (default) | positive scalar

Chamber B effective piston area.

**Piston stroke** — Piston maximum travel between caps

0.1 m (default) | positive scalar

Piston maximum travel between caps.

**Dead volume A** — Fluid volume in chamber A that remains in the chamber after the rod is fully retracted

1e-4 m<sup>3</sup> (default) | positive scalar

Fluid volume in chamber A that remains in the chamber after the rod is fully retracted.

**Dead volume B** — Fluid volume in chamber B that remains in the chamber after the rod is fully extended

1e-4 m<sup>3</sup> (default) | positive scalar

Fluid volume in chamber B that remains in the chamber after the rod is fully extended.

**Specific heat ratio** — Specific heat ratio used in compressibility calculations

1.4 (default) | positive scalar greater than 1

Specific heat ratio used in compressibility calculations. This parameter is equivalent to the **Specific heat ratio** parameter of the Translational Hydro-Mechanical Converter block.

**Cylinder orientation** — Specifies cylinder orientation with respect to the globally assigned positive direction

Pressure at A causes positive displacement of R relative to C (default) | Pressure at A causes negative displacement of R relative to C

Specifies cylinder orientation with respect to the globally assigned positive direction. The cylinder can be installed in two different ways, depending upon whether it exerts force in the positive or in the negative direction when pressure is applied at its inlet. If pressure applied at port **A** exerts force in negative direction, set the parameter to Pressure at A causes negative displacement of R relative to C

### Hard Stop Properties

**Contact stiffness** — Elasticity of collision

1e6 N/m (default) | positive scalar

Specifies the elastic property of colliding bodies for the Translational Hard Stop block. The greater the value of the parameter, the less the bodies penetrate into each other, the more rigid the impact becomes. Lesser value of the parameter makes contact softer, but generally improves convergence and computational efficiency.

**Contact damping** — Dissipating property of collision

150 N\*s/m (default) | nonnegative scalar

Specifies dissipating property of colliding bodies for the Translational Hard Stop block. At zero damping, the impact is close to an absolutely elastic one. The greater the value of the parameter, the more energy dissipates during an interaction. Keep in mind that damping affects slider motion as long as the slider is in contact with the stop, including the period when slider is pulled back from the contact. For computational efficiency and convergence reasons, it is recommended that you assign a nonzero value to this parameter.

**Hard stop model** — Select the hard stop model

Stiffness and damping applied smoothly through transition region, damped rebound (default) | Full stiffness and damping applied at bounds, undamped rebound | Full stiffness and damping applied at bounds, damped rebound

Modeling approach for hard stops. Options include:

- **Stiffness and damping applied smoothly through transition region (default)** — Scale the magnitude of the contact force from zero to its full value over a specified transition length. The scaling is polynomial in nature. The polynomial scaling function is numerically smooth and it produces no zero crossings of any kind.
- **Full stiffness and damping applied at bounds, undamped rebound** — Apply the full value of the calculated contact force when the hard-stop location is breached. The contact force is a mix of spring and damping forces during penetration and a spring force—without a damping component—during rebound. No smoothing is applied.
- **Full stiffness and damping applied at bounds, damped rebound** — Apply the full value of the calculated contact force when the hard-stop location is breached. The contact force is a mix of spring and damping forces during both penetration and rebound. No smoothing is applied.

**Transition region** — Region where force is ramped up

0.1 mm (default) | positive scalar

Region where the force is ramped up from zero to the full value. At the end of the transition region, the full stiffness and damping are applied.

#### Dependencies

To enable this parameter, set **Hard stop model** to Stiffness and damping applied smoothly through transition region, damped rebound.

#### Initial Conditions

**Piston displacement from cap A** — Method for determining the piston position

Calculate from velocity of port R relative to port C (default) | Provide input signal from Multibody joint

Method for determining the piston position. Setting this parameter to Provide input signal from Multibody joint exposes the physical signal port **p**, which lets the block receive the piston position from a Simscape Multibody block.

**Initial piston displacement from cap A** — The distance that the piston is extended at the beginning of simulation

0 m (default) | nonnegative scalar

The distance that the piston is extended at the beginning of simulation. You can set the piston position to any point within its stroke. The default value corresponds to the fully retracted position.

### Dependencies

To enable this parameter, set **Piston displacement from cap A** to Calculate from velocity of port R relative to port C.

**Chamber A initial pressure** — Pressure in the cylinder chamber A at the beginning of simulation  
0 Pa (default) | nonnegative scalar

Pressure in the cylinder chamber A at the beginning of simulation.

**Chamber B initial pressure** — Pressure in the cylinder chamber B at the beginning of simulation  
0 Pa (default) | nonnegative scalar

Pressure in the cylinder chamber B at the beginning of simulation.

## Library

Hydraulic Cylinders

## Description

The Double-Acting Hydraulic Cylinder (Simple) block represents a simplified version of a double-acting hydraulic cylinder, developed for applications where only the basic cylinder functionality must be reproduced, in exchange for better numerical efficiency. For these reasons, such factors as fluid compressibility, friction, and leakages are assumed to be negligible. The hard stops are assumed to be fully inelastic, to eliminate any possible oscillations at the end of the stroke. The model is especially suitable for real-time and HIL (hardware-in-the-loop) simulation, if such simplifications are acceptable.

The model is described with the following equations:

$$F = A_A \cdot p_A - A_B \cdot p_B - F_c$$

$$q_A = A_A \cdot v$$

$$q_B = A_B \cdot v$$

$$\frac{dx}{dt} = v$$

$$v = v_R - v_C$$

$$F_c = \begin{cases} (x - x_E) \cdot K_p \cdot v & \text{if } x > x_E, v > 0 \\ (x - x_R) \cdot K_p \cdot v & \text{if } x < x_R, v < 0 \\ 0 & \text{otherwise} \end{cases}$$

$$x_E = S - x_0$$

$$x_R = -x_0$$

where

$F$	Force developed by the cylinder
$v$	Cylinder rod velocity
$v_R, v_C$	Absolute velocities of cylinder rod and cylinder case, respectively
$A_A$	Piston area at port A side
$A_B$	Piston area at port B side
$p_A$	Pressure at the cylinder port A
$p_B$	Pressure at the cylinder port B
$q_A$	Flow rate through port A into the cylinder
$q_B$	Flow rate through port B from the cylinder
$x$	Piston position
$x_0$	Initial distance between piston and cap A
$F_c$	Hard stop force
$x_E$	Distance the piston can travel to fully extend from initial position
$x_R$	Distance the piston can travel to fully retract from initial position
$K_p$	Penetration coefficient
$S$	Piston stroke

The main difference between this block and the Double-Acting Hydraulic Cylinder block is the representation of the hard stop:

- The Double-Acting Hydraulic Cylinder block utilizes the elastic model of the stop, which is essentially a combination of a spring and a damper, connected in parallel. The stiffness of the spring, which represents contact stiffness of colliding bodies, is very high, resulting in high-frequency, low-magnitude oscillations at the moment the bodies collide. These oscillations can hardly be noticed experimentally, but they are difficult to process by a numerical simulation and generally decrease numerical efficiency.
- The hard stop in the Double-Acting Hydraulic Cylinder (Simple) block is represented with the inelastic model, which is essentially a viscous damper with the penetration-dependent damping coefficient. This coefficient is referred to as the penetration coefficient. With inelastic model, no oscillation is generated during an impact, resulting in improved numerical robustness and efficiency. But inelastic stop model has a feature that you must consider while selecting the model: colliding bodies continue slowly moving into each other as long as the contact is loaded with the compressing force. In real life, this phenomenon is similar to collision of two bodies separated by a sizable layer of viscous liquid. It takes some time to squeeze the liquid before bodies themselves come into contact.

Connections R and C are mechanical translational conserving ports corresponding to the cylinder rod and cylinder clamping structure, respectively. Connections A and B are hydraulic conserving ports. Port A is connected to chamber A and port B is connected to chamber B.

You can adjust the block directionality with the **Cylinder orientation** parameter.

## Basic Assumptions and Limitations

- Friction between moving parts is not taken into account.
- Inertia effects are not taken into account.
- Fluid compressibility is not taken into account.
- Leakage flows are assumed to be negligible.
- The hard stops are assumed to be fully inelastic, as explained above.

## Parameters

### Piston area A

Chamber A effective piston area. The default value is  $0.001 \text{ m}^2$ .

### Piston area B

Chamber B effective piston area. The default value is  $5e-4 \text{ m}^2$ .

### Piston stroke

Piston maximum travel between caps. The default value is  $0.1 \text{ m}$ .

### Piston initial distance from cap A

The distance between the piston and cap A at the beginning of simulation. This value cannot exceed the piston stroke. The default value is  $0$ .

### Penetration coefficient

Specifies the penetration property of colliding bodies. The higher the value of the coefficient, the less the bodies penetrate into each other, but the sharper the increase of the impact force. To find out the value of the coefficient for a particular application, it is recommended to run the same model with different hard stop models (or with different cylinder models) until they show close results. The default value of the coefficient is  $1e12 \text{ N/m/(m/s)}$ .

### Cylinder orientation

Specifies cylinder orientation with respect to the globally assigned positive direction. The cylinder can be installed in two different ways, depending upon whether it exerts force in the positive or in the negative direction when pressure is applied at its inlet. If pressure applied at port A exerts force in negative direction, set the parameter to `Acts in negative direction`. The default value is `Acts in positive direction`.

## Restricted Parameters

When your model is in Restricted editing mode, you cannot modify the following parameter:

- **Cylinder orientation**

All other block parameters are available for modification.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the cylinder chamber A.

**B**

Hydraulic conserving port associated with the cylinder chamber B.

**R**

Mechanical translational conserving port associated with the cylinder rod.

**C**

Mechanical translational conserving port associated with the cylinder clamping structure.

## Examples

The “Closed-Loop Hydraulic Actuator Model for Real-Time Simulation” example shows how to use this cylinder along with other blocks optimized for real-time and HIL simulation.

## Version History

# Double-Acting Rotary Actuator (IL)

Double-acting rotary actuator in an isothermal liquid system

## Libraries:

Simscape / Fluids / Isothermal Liquid / Actuators

## Description

The Double-Acting Rotary Actuator (IL) block models a rotary actuator in an isothermal liquid network. The actuator converts the pressure differential between two chambers into mechanical torque. The motion of the piston when it is near full extension or full retraction is limited by one of four hard stop models.

Ports **A** and **B** are the isothermal liquid conserving ports associated with inlets of chamber A and chamber B, respectively. Port **R** is associated with the actuator shaft and port **C** is associated with the reference actuator casing. If **Mechanical orientation** is set to **Pressure at A causes positive rotation of R relative to C**, the pressure in chamber A causes a positive rotation of the shaft at port **R** relative to port **C**. When the shaft angle is calculated internally, the physical signal port **q** reports the shaft angle. When the angle is set by a connection to a Simscape Multibody joint, it is received as a physical signal at port **q**.

## Displacement

The piston displacement is measured as the position at port **R** relative to port **C**. The **Mechanical orientation** identifies the direction of piston displacement. The piston displacement is neutral, or  $\theta$ , when the chamber volume is equal to the chamber dead volume. When displacement is received as an input, ensure that the derivative of the position is equal to the piston velocity. This is automatically the case when the input is received from a Rotational Multibody Interface block connection to a Simscape Multibody joint.

## Hard Stop Model

To avoid mechanical damage to an actuator when it is fully extended or fully retracted, an actuator typically displays nonlinear behavior when the piston approaches these limits. The Single-Acting Rotary Actuator (IL) block models this behavior with a choice of four hard stop models, which model the material compliance through a spring-damper system. The hard stop models are:

- Stiffness and damping applied smoothly through transition region, damped rebound.
- Full stiffness and damping applied at bounds, undamped rebound.
- Full stiffness and damping applied at bounds, damped rebound.
- Based on coefficient of restitution

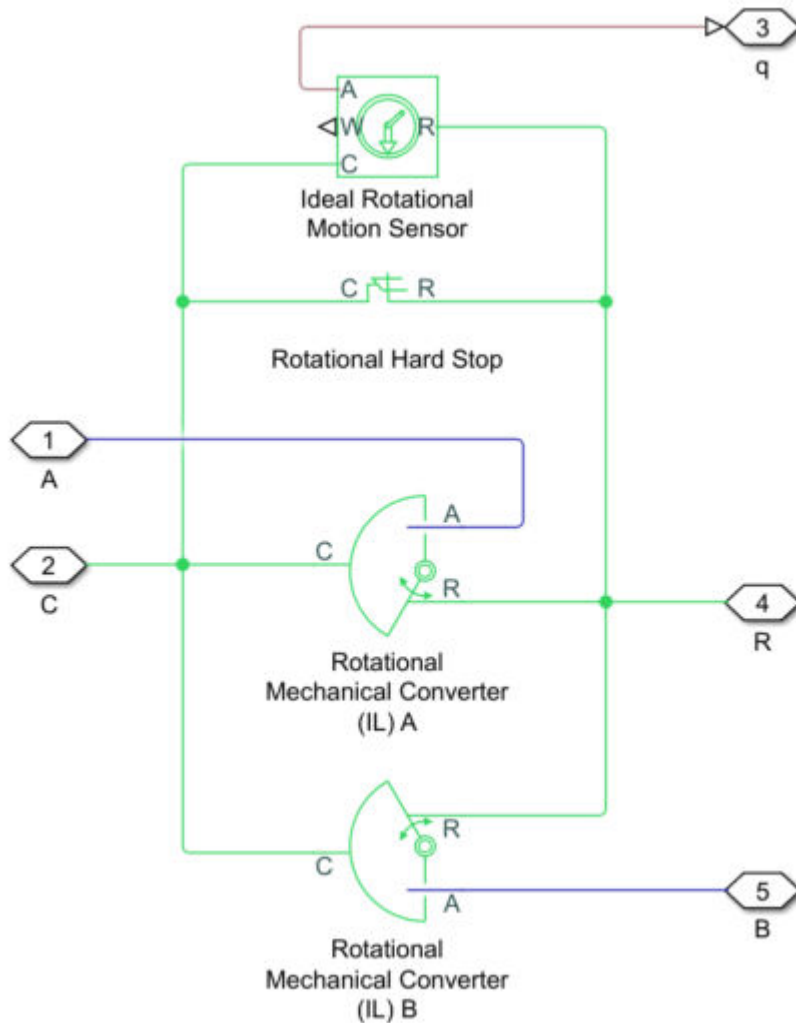

The hard stop force is modeled when the piston is at its upper or lower bound. The boundary region is within the **Transition region** of the **Stroke** or piston initial displacement. Outside of this region,  $F_{HardStop} = 0$ .

For more information about these settings, see the Rotational Hard Stop block page.

## Block Schematics

The Double-Acting Rotary Actuator (IL) block comprises three Foundation Library blocks:

- Ideal Rotational Motion Sensor
- Rotational Hard Stop
- Rotational Mechanical Converter (IL)

## Underlying Block Components

### Leakage

Laminar leakage is not accounted for in the Double-Acting Rotary Actuator (IL) block. To include leakage in your simulation, set the **Cross-sectional geometry** parameter to **Custom** and connect ports **A** and **B** to ports **A** and **B** of a Laminar Leakage (IL) block.

## Adding Leakage to the Simulation

### Ports

#### Input

**q** — Shaft angle  
physical signal

Shaft angle, received as a physical signal from a Simscape Multibody block.

#### Dependencies

To expose this port, set **Shaft rotation from chamber A** to Provide input signal from Multibody joint.

#### Output

**q** — Actuator angle  
physical signal

Physical signal output port associated with the shaft angular position.

#### Dependencies

To expose this port, set **Shaft rotation from chamber A** to Calculate from angular velocity of port R relative to port C.

### Conserving

**A** — Chamber A inlet  
isothermal liquid

Isothermal liquid conserving port associated with the actuator chamber A.

**B** — Chamber B inlet  
isothermal liquid

Isothermal liquid conserving port associated with the actuator chamber B.

**R** — Actuator shaft  
mechanical rotational

Mechanical rotational conserving port associated with the shaft.

**C** — Actuator casing  
mechanical rotational

Mechanical rotational conserving port associated with the cylinder case.

## Parameters

### Actuator

**Mechanical orientation** — Piston displacement direction  
Pressure at A causes positive displacement of R relative to C (default) | Pressure at A causes negative displacement of R relative to C

Sets the piston displacement direction. When you set this parameter to:

- Pressure at A causes positive displacement of R relative to C the piston displacement is positive when the volume of liquid at port **A** is expanding. This corresponds to rod extension.
- Pressure at A causes negative displacement of R relative to C the piston displacement is negative when the volume of liquid at port **A** is expanding. This corresponds to rod contraction.

**Volume displacement in chamber A** — Volume displacement  
 $1e-4 \text{ m}^3/\text{rad}$  (default) | positive scalar

Effective displacement of the actuator in chamber A.

**Volume displacement in chamber B** — Volume displacement  
 $1e-4 \text{ m}^3/\text{rad}$  (default) | positive scalar

Effective displacement of the actuator in chamber B.

**Stroke** — Angle  
 $5.0 \text{ rad}$  (default) | positive scalar

Shaft maximum travel between stops.

**Dead volume in chamber A** — Fluid volume  
 $1e-5 \text{ m}^3$  (default) | positive scalar

Volume of liquid when the piston displacement is  $\theta$  in chamber A. This is the liquid volume when the piston is up against the actuator end cap.

**Dead volume in chamber B** — Fluid volume  
 $1e-5 \text{ m}^3$  (default) | positive scalar

Volume of liquid when the piston displacement is  $\theta$  in chamber B. This is the liquid volume when the piston is up against the actuator end cap.

**Environment pressure specification** — Pressure reference source  
 Atmospheric pressure (default) | Specified pressure

Choice of environment pressure. Options include Atmospheric pressure and Specified pressure.

**Environment pressure** — User-defined pressure reference  
 0.101325 MPa (default) | positive scalar

Pressure outside the actuator casing. This pressure acts against the pressures inside the actuator chambers. A value of zero corresponds to a vacuum.

#### Dependencies

To enable this parameter, set **Environment pressure specification** to Specified pressure.

#### Hard Stop

**Hard stop model** — Select the hard stop model  
 Stiffness and damping applied smoothly through transition region, damped rebound (default) | Full stiffness and damping applied at bounds, undamped rebound | Full stiffness and damping applied at bounds, damped rebound | Based on coefficient of restitution

Model choice for the force on the piston at full extension or full retraction. See the Rotational Hard Stop block for more information.

**Hard stop stiffness coefficient** — Stiffness coefficient  
 1e6 N\*m/rad (default) | positive scalar

Specifies the elastic property of colliding bodies for the Rotational Hard Stop block. The greater the value of the parameter, the more rigid the impact between the piston and the stop becomes. Lower values make contact softer and generally improve convergence and computational efficiency.

#### Dependencies

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound
- Full stiffness and damping applied at bounds, undamped rebound
- Full stiffness and damping applied at bounds, damped rebound

**Hard stop damping coefficient** — Damping coefficient  
 150 N\*m(rad/s) (default) | positive scalar

Specifies the dissipating property of colliding bodies for the Rotational Hard Stop block. At zero damping, the impact is elastic. The greater the value of the parameter, the greater the energy dissipation during piston-stop interaction. Damping affects slider motion as long as the slider is in contact with the stop, including the period when slider is pulled back from the contact. Set this parameter to a nonzero value to improve the efficiency and convergence of your simulation.

#### Dependencies

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound
- Full stiffness and damping applied at bounds, undamped rebound
- Full stiffness and damping applied at bounds, damped rebound

**Transition region** — Transition region

0.001 rad (default) | positive scalar

Distance below which scaling is applied to the hard-stop force. The contact force is zero when the distance to the hard stop is equal to the value of this parameter. The contact force is at its full value when the distance to the hard stop is zero.

**Dependencies**

To enable this parameter, set **Hard stop model** to Stiffness and damping applied smoothly through transition region, damped rebound.

**Coefficient of restitution** — Ratio of final-to-initial relative speed between slider and stop after collision

0.7 (default) | unitless value between 0 and 1

Ratio of the final to the initial relative speed between the slider and the stop after the slider bounces.

**Dependencies**

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Static contact speed threshold** — Threshold relative speed between slider and stop before collision

0.1 rad/s (default) | nonnegative scalar

Threshold relative speed between the slider and stop before collision. When the slider hits the case with speed less than the value of the **Static contact speed threshold** parameter, they stay in contact. Otherwise, the slider bounces. To avoid modeling static contact between the slider and the case, set this parameter to 0.

**Dependencies**

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Static contact release torque threshold** — Threshold torque needed to transition from contact mode to free mode

0.001 N\*m (default) | positive scalar

Minimum torque needed to release the slider from a static contact mode.

**Dependencies**

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Initial Conditions****Shaft rotation from chamber A** — Method for determining shaft angle

Calculate from velocity of port R relative to port C (default) | Provide input signal from Multibody joint

Method for determining the shaft angle. The block can receive the angle from a Multibody block when set to **Provide input signal from Multibody joint**, or calculates the angle internally, which is reported at port **q**.

**Initial shaft rotation from chamber A** — Initial rotation

0 rad (default) | scalar

The position of the actuator at the beginning of simulation. This value falls between 0 and the value of the **Stroke** in the positive orientation, and 0 and the negative value of the **Stroke** in the negative orientation.

**Dependencies**

To enable this parameter, set **Shaft rotation from chamber A** to **Calculate from velocity of port R relative to port C**.

**Fluid dynamic compressibility** — Fluid compressibility

On (default) | Off

Whether to model any change in fluid density due to fluid compressibility. When **Fluid compressibility** is set to **On**, changes due to the mass flow rate into the block are calculated in addition to density changes due to changes in pressure. In the Isothermal Liquid Library, all blocks calculate density as a function of pressure.

**Initial liquid pressure in chamber A** — Liquid pressure

0.101325 MPa (default) | positive scalar

Pressure in actuator chamber A at the start of simulation.

**Dependencies**

To enable this parameter, set **Fluid dynamic compressibility** to **On**.

**Initial liquid pressure in chamber B** — Liquid pressure

0.101325 MPa (default) | positive scalar

Pressure in actuator chamber B at the start of simulation.

**Dependencies**

To enable this parameter, set **Fluid dynamic compressibility** to **On**.

## Version History

Introduced in R2020a

### R2023a: New hard stop parameterization option

The block has a new option for the **Hard stop model** parameter. This option, called **Based on coefficient of restitution**, models the hard stop by using a mode chart.

## Library

Hydraulic Cylinders

## Description

The Double-Acting Rotary Actuator block models a double-acting hydraulic rotary actuator, which directly converts hydraulic energy into mechanical rotational energy without employing intermediary transmissions such as rack-and-pinion, sliding spline, chain, and so on. Hydraulic fluid pumped under pressure into one of the two actuator chambers forces the shaft to rotate and generate torque. Double-acting actuators generate torque and motion in both directions.

The model of the actuator is built of Simscape Foundation library blocks. The schematic diagram of the model is shown below.

The blocks in the diagram perform the following functions:

Rotational Hydro-Mechanical Converter A	Converts hydraulics energy into mechanical rotational energy when fluid is pumped into actuator chamber A, while accounting for fluid compressibility.
Rotational Hydro-Mechanical Converter B	Converts hydraulics energy into mechanical rotational energy when fluid is pumped into actuator chamber B, while accounting for fluid compressibility.
Rotational Hard Stop	Imposes limits on shaft rotation.
Linear Hydraulic Resistance	Accounts for leakages.

Connections A and B are hydraulic conserving ports. Port A is connected to chamber A and port B is connected to chamber B. Connection S is a mechanical rotational conserving port associated with the actuator shaft.

The block directionality is adjustable and can be controlled with the **Actuator orientation** parameter.

## Basic Assumptions and Limitations

No loading, such as inertia, friction, spring, and so on, is taken into account. If necessary, you can easily add them by connecting an appropriate building block to port S.

## Parameters

### Actuator displacement

Effective displacement of the actuator. The default value is  $4.5e-5 \text{ m}^3/\text{rad}$ .

**Shaft stroke**

Shaft maximum travel between stops. The default value is 5.1 rad.

**Shaft initial angle**

The position of the shaft at the beginning of simulation. You can set the shaft position to any angle within its stroke. The default value is 0, which corresponds to the shaft position at the very beginning of the stroke.

**Dead volume A**

Fluid volume in chamber A that remains in the chamber when the shaft is positioned at the very beginning of the stroke. The default value is  $1e-4 \text{ m}^3$ .

**Dead volume B**

Fluid volume in chamber B that remains in the chamber when the shaft is positioned at the end of the stroke. The default value is  $1e-4 \text{ m}^3$ .

**Leak coefficient**

Leak coefficient for the Linear Hydraulic Resistance block. The default value is  $1e-14 \text{ (m}^3/\text{s)/Pa}$ .

**Specific heat ratio**

Gas-specific heat ratio for the Hydraulic Piston Chamber block. The default value is 1.4.

**Contact stiffness**

Specifies the elastic property of colliding bodies for the Rotational Hard Stop block. The greater the value of the parameter, the less the bodies penetrate into each other, the more rigid the impact becomes. Lesser value of the parameter makes contact softer, but generally improves convergence and computational efficiency. The default value is  $1e6 \text{ N}^*\text{m/rad}$ .

**Contact damping**

Specifies dissipating property of colliding bodies for the Rotational Hard Stop block. At zero damping, the impact is close to an absolutely elastic one. The greater the value of the parameter, the more energy dissipates during an interaction. Keep in mind that damping affects slider motion as long as the slider is in contact with the stop, including the period when slider is pulled back from the contact. For computational efficiency and convergence reasons, MathWorks recommends that you assign a nonzero value to this parameter. The default value is  $150 \text{ N}^*\text{m/ (rad/s)}$ .

**Hard stop model**

Modeling approach for hard stops. Options include:

- **Stiffness and damping applied smoothly through transition region (default)** — Scale the magnitude of the contact force from zero to its full value over a specified transition length. The scaling is polynomial in nature. The polynomial scaling function is numerically smooth and it produces no zero crossings of any kind.
- **Full stiffness and damping applied at bounds, undamped rebound** — Apply the full value of the calculated contact force when the hard-stop location is breached. The contact force is a mix of spring and damping forces during penetration and a spring force—without a damping component—during rebound. No smoothing is applied.
- **Full stiffness and damping applied at bounds, damped rebound** — Apply the full value of the calculated contact force when the hard-stop location is breached. The contact force is a mix of spring and damping forces during both penetration and rebound. No smoothing is applied. This is the hard-stop model used in previous releases.

**Transition region**

Distance below which scaling is applied to the hard-stop force. The contact force is zero when the distance to the hard stop is equal to the value specified here. It is at its full value when the distance to the hard stop is zero. The default value is 1 mm..

**Actuator orientation**

Specifies actuator orientation with respect to the globally assigned positive direction. The actuator can be installed in two different ways, depending upon whether it generates torque in the positive or in the negative direction when pressure is applied at its inlet. If pressure applied at port A generates torque in the negative direction, set the parameter to `Acts in negative direction`. The default value is `Acts in positive direction`.

**Restricted Parameters**

When your model is in Restricted editing mode, you cannot modify the following parameter:

- **Actuator orientation**

All other block parameters are available for modification.

**Global Parameters**

Parameter determined by the type of working fluid:

- **Fluid bulk modulus**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

**Ports**

The block has the following ports:

A

Hydraulic conserving port associated with the actuator chamber A.

B

Hydraulic conserving port associated with the actuator chamber B.

S

Mechanical rotational conserving port associated with the actuator shaft.

**Version History**

**Introduced in R2007a**

## Double-Acting Servo Valve Actuator (IL)

Double-acting servo cylinder with spring-centered spool in an isothermal liquid system

### Libraries:

Simscape / Fluids / Valve Actuators & Forces

### Description

The Double-Acting Servo Valve Actuator (IL) block models a double-acting servo cylinder arranged as a spring-centered spool. The spring neutral position is where the spool is located at the middle of the stroke. The motion of the piston when it is near full extension or full retraction is limited by one of four hard stop models. Fluid compressibility is optionally modeled in both piston chambers.

The physical signal output **S** reports the spool position.

### Hard Stop Model

To avoid mechanical damage to an actuator when it is fully extended or fully retracted, an actuator typically displays nonlinear behavior when the piston approaches these limits. The Double-Acting Servo Valve Actuator (IL) block models this behavior with a choice of four hard stop models, which model the material compliance through a spring-damper system. The hard stop models are:

- Stiffness and damping applied smoothly through transition region, damped rebound.
- Full stiffness and damping applied at bounds, undamped rebound.
- Full stiffness and damping applied at bounds, damped rebound.
- Based on coefficient of restitution

The hard stop force is modeled when the piston is at its upper or lower bound. The boundary region is within the **Transition region** of the **Spool stroke** or piston initial displacement. Outside of this region,  $F_{HardStop} = 0$ .

For more information about these settings, see the Translational Hard Stop block page.

### Block Schematic

The Double-Acting Servo Actuator block comprises an Isothermal Liquid library block and two Simscape Foundation blocks:

- Double-Acting Actuator (IL)
- Translational Spring
- Translational Damper

## Ports

### Conserving

**A** — Liquid port for chamber A  
isothermal liquid

Isothermal liquid conserving port associated with the liquid inlet of chamber A.

**B** — Liquid port for chamber B  
isothermal liquid

Isothermal liquid conserving port associated with the liquid inlet of chamber B.

### Output

**S** — Spool position, m  
physical signal

Physical signal associated with the spool position, in m. A position of zero indicates that the spool is at a neutral position in the middle of a stroke.

## Parameters

### Cylinder

**Spool cross-sectional area** — Area measurement  
1e-4 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of the spool

**Spool stroke** — Distance  
5e-3 m (default) | positive scalar

Distance the spool travels in a stroke.

**Spring stiffness** — Rate of force for the spring  
1e3 N/m (default) | scalar

Spring rate of the centering springs.

**Damping coefficient** — Damping coefficient  
150 N/(m/s) (default) | positive scalar

Damping coefficient in the contact between the piston and the case.

### Hard Stop

**Hard stop model** — Select the hard stop model  
Stiffness and damping applied smoothly through transition region, damped rebound (default) | Full stiffness and damping applied at bounds, undamped rebound | Full stiffness and damping applied at bounds, damped rebound | Based on coefficient of restitution

Model choice for the force on the piston at full extension or full retraction. See the Translational Hard Stop block for more information.

**Hard-stop stiffness coefficient** — Stiffness coefficient  
1e10 N/m (default) | positive scalar

Piston stiffness coefficient.

### Dependencies

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound
- Full stiffness and damping applied at bounds, undamped rebound
- Full stiffness and damping applied at bounds, damped rebound

**Hard-stop damping coefficient** — Damping coefficient  
150 N\*s/m (default) | positive scalar

Piston damping coefficient.

**Dependencies**

To enable this parameter, set **Hard stop model** to

- Stiffness and damping applied smoothly through transition region, damped rebound
- Full stiffness and damping applied at bounds, undamped rebound
- Full stiffness and damping applied at bounds, damped rebound

**Transition region** — Application range of hard stop force model

0.1 mm (default) | positive scalar

Application range of the hard stop force model. Outside of this range of the piston maximum extension and piston maximum retraction, the **Hard stop model** is not applied and there is no additional force on the piston.

**Dependencies**

To enable this parameter, set **Hard stop model** to Stiffness and damping applied smoothly through transition region, damped rebound.

**Coefficient of restitution** — Ratio of final-to-initial relative speed between slider and stop after collision

0.7 (default) | unitless value between 0 and 1

Ratio of the final to the initial relative speed between the slider and the stop after the slider bounces.

**Dependencies**

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Static contact speed threshold** — Threshold relative speed between slider and stop before collision

0.001 m/s (default) | nonnegative scalar

Threshold relative speed between slider and stop before collision. When the slider hits the case with speed less than the value of the **Static contact speed threshold** parameter, they stay in contact. Otherwise, the slider bounces. To avoid modeling static contact between the slider and the case, set this parameter to 0.

**Dependencies**

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Static contact release force threshold** — Threshold force needed to transition from contact mode to free mode

0.001 N (default) | positive scalar

Minimum force needed to release the slider from a static contact mode.

**Dependencies**

To enable this parameter, set **Hard stop model** to Based on coefficient of restitution.

**Effects and Initial Conditions**

**Spool initial displacement** — Initial location of the spool

0 m (default) | scalar

When the initial displacement of the spool is set to 0, the spool begins directly between chamber A and chamber B. A positive distance moves the spool away from chamber A, while a negative amount moves the spool toward chamber A.

**Fluid dynamic compressibility** — Fluid compressibility

On (default) | Off

Whether to model any change in fluid density due to fluid compressibility. When **Fluid compressibility** is set to On, changes due to the mass flow rate into the block are calculated in addition to density changes due to changes in pressure. In the Isothermal Liquid Library, all blocks calculate density as a function of pressure.

**Initial liquid pressure in chamber A** — Liquid pressure

0.101325 MPa (default) | positive scalar

Pressure in actuator chamber A at the start of simulation.

**Dependencies**

To enable this parameter, set **Fluid dynamic compressibility** to On.

**Initial liquid pressure in chamber B** — Liquid pressure

0.101325 MPa (default) | positive scalar

Pressure in actuator chamber B at the start of simulation.

**Dependencies**

To enable this parameter, set **Fluid dynamic compressibility** to On.

## Version History

Introduced in R2020a

**R2023a: New hard stop parameterization option**

The block has a new option for the **Hard stop model** parameter. This option, called **Based on coefficient of restitution**, models the hard stop by using a mode chart.

# Double-Acting Servo Cylinder

(To be removed) Hydraulic double-acting servo cylinder with spring-centered plunger

---

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

---

## Library

Valve Actuators

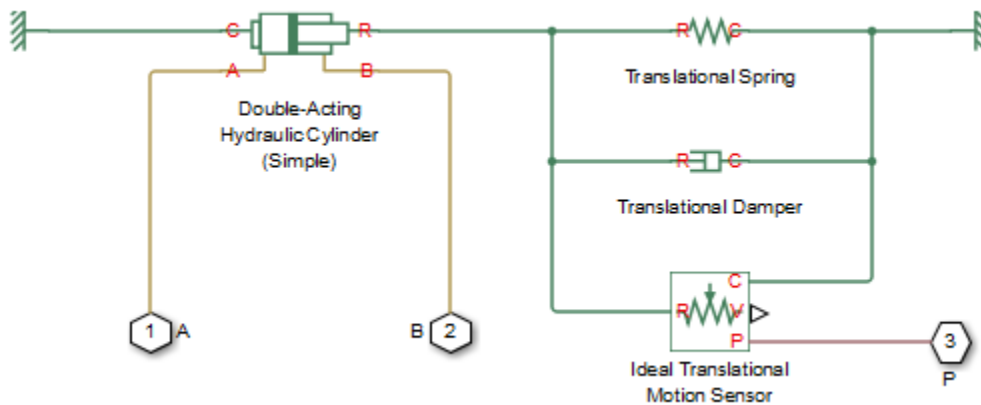

## Description

The Double-Acting Servo Cylinder block models a hydraulic double-acting servo cylinder implemented as a spring-centered plunger.

Changing pressure at ports A and B shifts the spool from the neutral position in proportion to the pressure differential. Use the servo cylinder for control purposes.

The model of the cylinder uses the Double-Acting Hydraulic Cylinder (Simple), Translational Spring, Translational Damper, and Ideal Translational Motion Sensor blocks. The following figure shows the schematic diagram of the model.

The plunger is located initially in the middle of the stroke. The plunger displacement is computed with the following equations:

$$A(p_A - p_B) = k \cdot x + B \cdot v + F_{HS}$$

$$F_{HS} = \begin{cases} (x - S/2) \cdot K_p \cdot v & \text{if } x > S/2, v > 0 \\ (x + S/2) \cdot K_p \cdot \text{abs}(v) & \text{if } x < -S/2, v < 0 \\ 0 & \text{otherwise} \end{cases}$$

where

$p_A, p_B$	Pressures at port A and B, respectively
A	Spool face area
k	Spring rate
B	Damping coefficient
$F_{HS}$	Hard stop force
$K_p$	Stop penetration coefficient
S	Piston stroke
v	Piston velocity
x	Piston displacement

Connection P is a physical signal output port that outputs the plunger displacement from the central position. Connections A and B are hydraulic conserving ports. Pressure at port A moves the plunger in the positive direction.

### Basic Assumptions and Limitations

- Friction between moving parts is not taken into account.
- Inertia effects are not taken into account.
- Fluid compressibility is not taken into account.
- Leakage flows are assumed to be negligible.

- The hard stops are assumed to be fully inelastic. For details, see the Double-Acting Hydraulic Cylinder (Simple) block reference page.

## Parameters

### Piston area

The face area of the piston. The default value is  $1e-4 \text{ m}^2$ .

### Piston stroke

The full piston stroke, from one hard stop to another. The piston is located initially in the middle of the stroke and can travel half a stroke in the positive and negative direction. The default value is  $0.005 \text{ m}$ .

### Spring rate

The spring rate of the centering springs. The default value is  $1000 \text{ N/m}$ .

### Damping coefficient

The damping coefficient in the contact between the piston and the case. The default value is  $150 \text{ N/(m/s)}$ .

### Stop penetration coefficient

The penetration property of the piston hard stop. The hard stop is represented as absolutely inelastic, and the property is characterized by the penetration coefficient. The default value of the coefficient is  $1e12 \text{ N/m/(m/s)}$ .

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the cylinder chamber A.

B

Hydraulic conserving port associated with the cylinder chamber B.

P

Physical signal output port that outputs the piston displacement.

# Ejector (G)

Ejector in a gas network

## Libraries:

Simscape / Fluids / Gas / Turbomachinery

## Description

The Ejector (G) block models an ejector in a gas network. The ejector forces the high-pressure primary flow through a nozzle with a specific throat area, which creates a low-pressure jet that draws in the secondary flow. The expansion of the primary jet creates a throat for the secondary flow. The block assumes that the two flows mix under uniform pressure and the combined flow exits through a diffuser to recover pressure. The primary and secondary flows must be the same gas.

You can use an ejector as a pump or compressor to drive a secondary fluid. Unlike a pump or compressor, there is no external source of mechanical energy, and rather the high pressure primary fluid is the energy source that drives the secondary fluid.

## Ejector Geometry

The high-pressure primary flow enters the ejector at location p and flows through a convergent-divergent nozzle with throat area  $S_{pt}$ , which is the value of the **Primary nozzle throat area** parameter. The ejector chokes the primary flow at the throat (location pt) and accelerates the flow to a low-pressure supersonic jet at the primary nozzle exit (location pn). The low pressure of the supersonic primary flow jet draws in the secondary flow at location s around the nozzle.

The supersonic primary flow jet continues to expand and decrease in pressure beyond the nozzle exit until it reaches its largest area at the expanded primary flow jet (location pe). The expansion of the supersonic primary flow jet creates a fictitious aerodynamic throat for the secondary flow at location st, which is at the same location as pe. The secondary flow also chokes at the aerodynamic throat. After passing the aerodynamic throat, the primary and secondary flow mix under uniform pressure (location m). If the mixed flow is still supersonic, the flow causes a shock in the mixing chamber at location s and the diffuser (location d) decelerates the mixed flow to raise the outlet pressure.

This schematic describes the ejector where:

- Location p is the primary inlet.
- Location s is the secondary inlet.
- Location pt is the primary nozzle throat.
- Location pn is the primary nozzle exit.
- Location pe is the expanded primary flow jet.
- Location st is the secondary aerodynamic throat.
- Location m is the mixed flow.
- Location ms is the shock in the mixing chamber.
- Location d is the diffuser outlet.

### Mass Flow Rate

The ejector accelerates the primary gas flow through the nozzle. The mass flow rate of the primary flow is

$$\dot{m}_p = S_{pt} \sqrt{\left(\frac{2\gamma}{\gamma-1}\right) \eta_p \rho_p \left[ \left(\frac{p_m}{p_p}\right)^{\frac{2}{\gamma}} - \left(\frac{p_m}{p_p}\right)^{\frac{\gamma+1}{\gamma}} \right]}$$

where:

- $S_{pt}$  is the value of the **Primary nozzle throat area** parameter.
- $\gamma = \frac{c_p}{c_v}$  is the ratio of heat capacities where  $c_p$  is the specific heat at constant pressure and  $c_v$  is the specific heat at constant volume.
- $\eta_p$  is the value of the **Efficiency for primary flow through nozzle** parameter.
- $p_p$  is the pressure at the primary flow inlet.
- $p_m$  is the pressure after the primary and secondary flow mix.
- $\rho_p$  is the density at the primary flow inlet.

The primary flow draws the secondary gas flow into the suction chamber and accelerates it towards the fictitious aerodynamic throat created by the expanding primary jet. The mass flow rate of the secondary flow is

$$\dot{m}_s = S_{st} \sqrt{\left(\frac{2\gamma}{\gamma-1}\right) \eta_s \rho_s \left[ \left(\frac{p_m}{p_s}\right)^{\frac{2}{\gamma}} - \left(\frac{p_m}{p_s}\right)^{\frac{\gamma+1}{\gamma}} \right]}$$

where:

- $S_{st}$  is the area of the fictitious aerodynamic throat. The block calculates the value based on the expansion of the primary flow jet.

- $\eta_s$  is the value of the **Efficiency for secondary suction flow** parameter.
- $p_s$  is the pressure at the secondary flow inlet.
- $\rho_s$  is the density at the secondary flow inlet.

When  $\frac{p_m}{p_p} < B_{crit}$ , where  $B_{crit} = \left(\frac{2}{\gamma+1}\right)^{\frac{\gamma}{\gamma-1}}$ , the primary flow becomes choked and the mass flow rate reaches the maximum value

$$\dot{m}_p^* = S_{pt} \sqrt{\eta_p p_p \rho_p \gamma \left(\frac{2}{\gamma+1}\right)^{\frac{\gamma+1}{\gamma-1}}}.$$

When  $\frac{p_m}{p_s} < B_{crit}$ , the secondary flow becomes choked and the mass flow rate reaches the maximum value

$$\dot{m}_s^* = S_{st} \sqrt{\eta_s p_s \rho_s \gamma \left(\frac{2}{\gamma+1}\right)^{\frac{\gamma+1}{\gamma-1}}}.$$

### Primary and Secondary Flow Relations

The flow area expansion of the supersonic primary flow jet comes from the relation

$$\frac{S_{pe}}{S_{pt}} = \psi_{pe} \sqrt{\frac{\left(\frac{\gamma-1}{2}\right) \left(\frac{2}{\gamma+1}\right)^{\frac{\gamma+1}{\gamma-1}}}{\left(\frac{p_m}{p_p}\right)^{\frac{2}{\gamma}} - \left(\frac{p_m}{p_p}\right)^{\frac{\gamma+1}{\gamma}}}},$$

where  $\psi_{pe}$  is the value of the **Efficiency for primary flow expansion** parameter.

The block uses the area of the expanded supersonic primary flow jet,  $S_{pe}$ , to calculate the flow area of the fictitious secondary flow aerodynamic throat,  $S_{st}$

$$\frac{S_{st}}{S_{pt}} = \frac{S_m}{S_{pt}} - \max\left\{\frac{S_{pe}}{S_{pt}}, \frac{S_{pn}}{S_{pt}}\right\},$$

where:

- $\frac{S_m}{S_{pt}}$  is the value of the **Area ratio of mixing chamber to throat** parameter.
- $\frac{S_{pn}}{S_{pt}}$  is the value of the **Area ratio of nozzle exit to throat** parameter.

The primary flow velocity of the expanded jet is

$$v_{pe} = \sqrt{\frac{2\gamma}{\gamma-1} \left(\frac{p_p}{\rho_p}\right) \left[1 - \left(\frac{p_m}{p_p}\right)^{\frac{\gamma-1}{\gamma}}\right]}.$$

The secondary flow velocity at the aerodynamic throat is

$$v_{st} = \sqrt{\frac{2\gamma}{\gamma-1} \left(\frac{p_s}{\rho_s}\right) \left[1 - \left(\frac{p_m}{p_s}\right)^{\frac{\gamma-1}{\gamma}}\right]}.$$

The secondary flow velocity is limited to the choked value. When  $\frac{p_m}{p_s} < B_{crit}$ , the secondary flow reaches the maximum value of

$$v_{st}^* = \sqrt{\frac{2\gamma}{\gamma+1} \left(\frac{p_s}{\rho_s}\right)}.$$

### Mixing Model

After the fictitious aerodynamic throat, the primary and secondary flows mix under uniform pressure. The mixed flow temperature is

$$T_m = \frac{\dot{m}_p T_p + \dot{m}_s T_s}{\dot{m}_m} - \frac{\gamma-1}{2\gamma R} v_m^2,$$

where:

- $T_p$  is the primary flow inlet temperature. The block assumes that this value is equal to the primary flow stagnation temperature because kinetic energy at the inlet is negligible relative to the inside of the ejector.
- $T_m$  is the mixed flow temperature.
- $T_s$  is the secondary flow inlet temperature. The block assumes that this value is equal to the secondary flow stagnation temperature because kinetic energy at the inlet is negligible relative to the inside of the ejector.
- $R$  is the specific gas constant.
- $v_m$  is the flow velocity after the primary and secondary flow mix.
- $\dot{m}_m$  is the mass flow rate after the primary and secondary flow mix, meaning  $\dot{m}_m = \dot{m}_p + \dot{m}_s$ .

The momentum balance in the mixing region is

$$p_m S_m + \dot{m}_m v_m = p_m S_{pe} + \dot{m}_p v_{pe} + p_m S_{st} + \dot{m}_s v_{st},$$

where  $S_m$  is the cross-sectional area after the primary and secondary flow mix.

The pressure terms drop out due to the uniform pressure mixing assumption, and the mixed flow velocity is

$$v_m = \frac{\dot{m}_p v_{pe} + \dot{m}_s v_{st}}{\dot{m}_m}.$$

The mixed flow Mach number is

$$M_m = \frac{v_m}{\sqrt{\gamma R T_m}}.$$

### Mixed Diffuser Flow Relations

If the flow is supersonic after mixing, meaning  $M_M > 1$ , a shock wave occurs. The pressure rise after the shock is

$$\frac{p_{ms}}{p_m} = 1 + \frac{2\gamma}{\gamma+1}(M_m^2 - 1),$$

where  $M_m$  is the Mach number after the primary and secondary flow mix.

The Mach number after the shock is

$$M_{ms}^2 = \frac{\frac{\gamma-1}{\gamma+1}(M_m^2 - 1) + 1}{\frac{2\gamma}{\gamma+1}(M_m^2 - 1) + 1}.$$

After the shock, the diffuser decelerates the flow to raise the pressure. The block assumes that the kinetic energy at the diffuser outlet is negligible and decelerates the flow to stagnation pressure at  $p_d$ :

$$\frac{p_d}{p_{ms}} = \left(1 + \frac{\gamma-1}{2}M_{ms}^2\right)^{\frac{\gamma}{\gamma-1}}.$$

If  $M_M \leq 1$ , there is no shock and

$$\begin{aligned} \frac{p_{ms}}{p_m} &= 1 \\ M_{ms}^2 &= M_m^2. \end{aligned}$$

The relationship between the mixing pressure,  $p_m$ , and the diffuser outlet pressure,  $p_d$ , is

$$\frac{p_d}{p_m} = \begin{cases} \frac{\left[\frac{\gamma+1}{2}M_m^2\right]^{\frac{\gamma}{\gamma-1}}}{\left[\frac{2\gamma}{\gamma+1}(M_m^2 - 1) + 1\right]^{\frac{1}{\gamma-1}}}, & M_m > 1 \\ \left(1 + \frac{\gamma-1}{2}M_m^2\right)^{\frac{\gamma}{\gamma-1}}, & M_m \leq 1 \end{cases}$$

### Critical Mode Operation

In normal operation, the primary flow is high pressure and is choked during operation. The block can also operate if the secondary flow is choked. If both the primary and secondary flows are choked, the block operates in critical mode.

The critical mixing pressure,  $p_m^*$ , is a low pressure threshold that causes choking in both primary and secondary flow:

$$p_m^* = \min\{p_p, p_s\} \left(\frac{2}{\gamma+1}\right)^{\frac{\gamma}{\gamma-1}}.$$

The block uses the same equations as above, with  $p_m$  replaced by  $p_m^*$ , to calculate the critical diffuser outlet pressure,  $p_d^*$ . If the actual outlet pressure is greater than the critical diffuser outlet pressure,

then the ejector is subcritical and the block relates the mixing pressure to diffuser outlet pressure. If the actual outlet pressure is less than the critical diffuser outlet pressure, then the ejector is critical and the block limits the mixing pressure to the critical mixing pressure. This means that:

$$p_m = \begin{cases} \frac{p_d}{\left(\frac{p_d}{p_m}\right)} & p_d \geq p_d^* \\ p_m^* & p_d < p_d^* \end{cases}$$

### Assumptions and Limitations

- The block uses isentropic ideal gas relations to derive the model equations.
- The block accounts for losses due to friction, mixing, and expansion waves and shocks at the nozzle exit using empirical loss coefficients.
- After the primary flow exits the nozzle, the flows do not mix until the primary flow has fully expanded.
- After expansion, the flows mix under uniform pressure.
- Kinetic energy at the primary flow inlet, secondary flow inlet, and diffuser outlet are negligible compared to the kinetic energy of the flow inside the ejector.
- The flow is steady and one-dimensional.
- The flow is adiabatic.
- Model results with reversed flow may not be accurate.

### Ports

#### Conserving

**A** — Primary inlet  
gas

Gas conserving port associated with associated with the primary nozzle inlet.

**B** — Outlet  
gas

Gas conserving port associated with the diffuser outlet.

**S** — Secondary inlet  
gas

Gas conserving port associated with the secondary inlet.

### Parameters

**Primary nozzle throat area** — Area of primary nozzle throat  
1e-4 m<sup>2</sup> (default) | positive scalar

Area of the throat for the primary flow nozzle.

**Area ratio of nozzle exit to throat** — Ratio of areas of nozzle exit to nozzle throat  
3 (default) | positive scalar

Ratio of the area of the nozzle exit to the area of the nozzle throat. This parameter limits how big the secondary aerodynamic throat can be.

**Area ratio of mixing chamber to throat** — Ratio of areas of mixing chamber to throat  
8 (default) | positive scalar

Ratio of the area of the mixing chamber to the area of the throat. The difference between the mixing chamber area and the expanded jet area of the primary flow creates a fictitious aerodynamic throat for the secondary flow.

**Minimum area ratio of secondary throat to primary throat** — Limit on ratio of aerodynamic areas of secondary throat to primary throat  
0.1 (default) | positive scalar

Minimum aerodynamic area ratio for the secondary throat to the primary throat. The block does not allow the area of the fictitious aerodynamic throat to go below this value. To avoid hitting this minimum, increase the value of the **Area ratio of mixing chamber to throat** parameter.

**Report when secondary throat area falls below minimum** — Notification when secondary throat area is below minimum  
Warning (default) | None | Error

Whether the block does nothing, generates a warning, or generates an error when the secondary throat area falls below the minimum, specified by the **Minimum area ratio of secondary throat to primary throat** parameter.

**Efficiency for primary flow through nozzle** — Efficiency factor of primary flow through nozzle  
0.95 (default) | positive scalar

Empirical factor that accounts for reduction in primary mass flow rate due to losses in the primary nozzle.

**Efficiency for secondary suction flow** — Efficiency factor of secondary suction flow  
0.85 (default) | positive scalar

Empirical factor that accounts for reduction in secondary mass flow rate due to losses in the suction of the secondary flow.

**Efficiency for primary flow expansion** — Efficiency factor of primary flow expansion  
0.88 (default) | positive scalar

Empirical factor that accounts for reduction in the expansion of the primary flow jet due to mixing losses.

**Efficiency for mixing** — Efficiency factor for mixed flow velocity due to mixing  
0.84 (default) | positive scalar

Empirical factor that accounts for reduction in the mixed flow velocity due to losses in the mixing chamber.

**Cross-sectional area at port A** — Cross-sectional area of port A  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of port A.

**Cross-sectional area at port B** — Cross-sectional area of port B  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of port **B**.

**Cross-sectional area at port S** — Cross-sectional area of port S  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of port **S**.

Ejector in a moist air network

## Libraries:

Simscape / Fluids / Moist Air / Turbomachinery

## Description

The Ejector (MA) block models an ejector in a moist air network. The ejector forces the high-pressure primary flow through a nozzle with a specific throat area, which creates a low-pressure jet that draws in the secondary flow. The expansion of the primary jet creates a throat for the secondary flow. The block assumes that the two flows mix under uniform pressure and the combined flow exits through a diffuser to recover pressure. The primary and secondary flows must contain the same moist air species but may have different compositions.

You can use an ejector as a pump or compressor to drive a secondary fluid. Unlike a pump or compressor, there is no external source of mechanical energy, and the high pressure primary fluid is the energy source that drives the secondary fluid.

## Ejector Geometry

The high-pressure primary flow enters the ejector at location p and flows through a convergent-divergent nozzle with throat area  $S_{pt}$ , which is the value of the **Primary nozzle throat area** parameter. The ejector chokes the primary flow at the throat (location pt) and accelerates the flow to a low-pressure supersonic jet at the primary nozzle exit (location pn). The low pressure of the supersonic primary flow jet draws in the secondary flow at location s around the nozzle.

The supersonic primary flow jet continues to expand and decrease in pressure beyond the nozzle exit until it reaches its largest area at the expanded primary flow jet (location pe). The expansion of the supersonic primary flow jet creates a fictitious aerodynamic throat for the secondary flow at location st, which is at the same location as pe. The secondary flow also chokes at the aerodynamic throat. After passing the aerodynamic throat, the primary and secondary flow mix under uniform pressure (location m). If the mixed flow is still supersonic, the flow causes a shock in the mixing chamber at location s and the diffuser (location d) decelerates the mixed flow to raise the outlet pressure.

This schematic describes the ejector where:

- Location p is the primary inlet.
- Location s is the secondary inlet.
- Location pt is the primary nozzle throat.
- Location pn is the primary nozzle exit.
- Location pe is the expanded primary flow jet.
- Location st is the secondary aerodynamic throat.
- Location m is the mixed flow.
- Location ms is the shock in the mixing chamber.
- Location d is the diffuser outlet.

### Mass Flow Rate

The ejector accelerates the primary moist air flow through the nozzle. The mass flow rate of the primary flow is

$$\dot{m}_p = S_{pt} \sqrt{\left(\frac{2\gamma}{\gamma-1}\right) \eta_p p_p \rho_p \left[ \left(\frac{p_m}{p_p}\right)^{\frac{2}{\gamma}} - \left(\frac{p_m}{p_p}\right)^{\frac{\gamma+1}{\gamma}} \right]}$$

where:

- $S_{pt}$  is the value of the **Primary nozzle throat area** parameter.
- $\gamma = \frac{c_p}{c_v}$  is the ratio of heat capacities where  $c_p$  is the specific heat at constant pressure and  $c_v$  is the specific heat at constant volume.
- $\eta_p$  is the value of the **Efficiency for primary flow through nozzle** parameter.
- $p_p$  is the pressure at the primary flow inlet.
- $p_m$  is the pressure after the primary and secondary flow mix.
- $\rho_p$  is the density at the primary flow inlet.

The primary flow draws the secondary moist air flow into the suction chamber and accelerates it towards the fictitious aerodynamic throat created by the expanding primary jet. The mass flow rate of the secondary flow is

$$\dot{m}_s = S_{st} \sqrt{\left(\frac{2\gamma}{\gamma-1}\right) \eta_s p_s \rho_s \left[ \left(\frac{p_m}{p_s}\right)^{\frac{2}{\gamma}} - \left(\frac{p_m}{p_s}\right)^{\frac{\gamma+1}{\gamma}} \right]}$$

where:

- $S_{st}$  is the area of the fictitious aerodynamic throat. The block calculates the value based on the expansion of the primary flow jet.

- $\eta_s$  is the value of the **Efficiency for secondary suction flow** parameter.
- $p_s$  is the pressure at the secondary flow inlet.
- $\rho_s$  is the density at the secondary flow inlet.

When  $\frac{p_m}{p_p} < B_{crit}$ , where  $B_{crit} = \left(\frac{2}{\gamma+1}\right)^{\frac{\gamma}{\gamma-1}}$ , the primary flow becomes choked and the mass flow rate reaches the maximum value

$$\dot{m}_p^* = S_{pt} \sqrt{\eta_p p_p \rho_p \gamma \left(\frac{2}{\gamma+1}\right)^{\frac{\gamma+1}{\gamma-1}}}.$$

When  $\frac{p_m}{p_s} < B_{crit}$ , the secondary flow becomes choked and the mass flow rate reaches the maximum value

$$\dot{m}_s^* = S_{st} \sqrt{\eta_s p_s \rho_s \gamma \left(\frac{2}{\gamma+1}\right)^{\frac{\gamma+1}{\gamma-1}}}.$$

### Primary and Secondary Flow Relations

The flow area expansion of the supersonic primary flow jet comes from the relation

$$\frac{S_{pe}}{S_{pt}} = \psi_{pe} \sqrt{\frac{\left(\frac{\gamma-1}{2}\right) \left(\frac{2}{\gamma+1}\right)^{\frac{\gamma+1}{\gamma-1}}}{\left(\frac{p_m}{p_p}\right)^{\frac{2}{\gamma}} - \left(\frac{p_m}{p_p}\right)^{\frac{\gamma+1}{\gamma}}}},$$

where  $\psi_{pe}$  is the value of the **Efficiency for primary flow expansion** parameter.

The block uses the area of the expanded supersonic primary flow jet,  $S_{pe}$ , to calculate the flow area of the fictitious secondary flow aerodynamic throat,  $S_{st}$

$$\frac{S_{st}}{S_{pt}} = \frac{S_m}{S_{pt}} - \max\left\{\frac{S_{pe}}{S_{pt}}, \frac{S_{pn}}{S_{pt}}\right\},$$

where:

- $\frac{S_m}{S_{pt}}$  is the value of the **Area ratio of mixing chamber to throat** parameter.
- $\frac{S_{pn}}{S_{pt}}$  is the value of the **Area ratio of nozzle exit to throat** parameter.

The primary flow velocity of the expanded jet is

$$v_{pe} = \sqrt{\frac{2\gamma}{\gamma-1} \left(\frac{p_p}{\rho_p}\right) \left[1 - \left(\frac{p_m}{p_p}\right)^{\frac{\gamma-1}{\gamma}}\right]}.$$

The secondary flow velocity at the aerodynamic throat is

$$v_{st} = \sqrt{\frac{2\gamma}{\gamma-1} \left(\frac{p_s}{\rho_s}\right) \left[1 - \left(\frac{p_m}{p_s}\right)^{\frac{\gamma-1}{\gamma}}\right]}.$$

The secondary flow velocity is limited to the choked value. When  $\frac{p_m}{p_s} < B_{crit}$ , the secondary flow reaches the maximum value of

$$v_{st}^* = \sqrt{\frac{2\gamma}{\gamma+1} \left(\frac{p_s}{\rho_s}\right)}.$$

### Mixing Model

After the fictitious aerodynamic throat, the primary and secondary flows mix under uniform pressure. The mixed flow temperature is

$$T_m = \frac{\dot{m}_p T_p + \dot{m}_s T_s}{\dot{m}_m} - \frac{\gamma-1}{2\gamma R} v_m^2,$$

where:

- $T_p$  is the primary flow inlet temperature. The block assumes that this value is equal to the primary flow stagnation temperature because kinetic energy at the inlet is negligible relative to the inside of the ejector.
- $T_m$  is the mixed flow temperature.
- $T_s$  is the secondary flow inlet temperature. The block assumes that this value is equal to the secondary flow stagnation temperature because kinetic energy at the inlet is negligible relative to the inside of the ejector.
- $R$  is the specific gas constant.
- $v_m$  is the flow velocity after the primary and secondary flow mix.
- $\dot{m}_m$  is the mass flow rate after the primary and secondary flow mix, meaning  $\dot{m}_m = \dot{m}_p + \dot{m}_s$ .

The momentum balance in the mixing region is

$$p_m S_m + \dot{m}_m v_m = p_m S_{pe} + \dot{m}_p v_{pe} + p_m S_{st} + \dot{m}_s v_{st},$$

where  $S_m$  is the cross-sectional area after the primary and secondary flow mix.

The pressure terms drop out due to the uniform pressure mixing assumption, and the mixed flow velocity is

$$v_m = \frac{\dot{m}_p v_{pe} + \dot{m}_s v_{st}}{\dot{m}_m}.$$

The mixed flow Mach number is

$$M_m = \frac{v_m}{\sqrt{\gamma R T_m}}.$$

### Mixed Diffuser Flow Relations

If the flow is supersonic after mixing, meaning  $M_M > 1$ , a shock wave occurs. The pressure rise after the shock is

$$\frac{p_{ms}}{p_m} = 1 + \frac{2\gamma}{\gamma+1}(M_m^2 - 1),$$

where  $M_m$  is the Mach number after the primary and secondary flow mix.

The Mach number after the shock is

$$M_{ms}^2 = \frac{\frac{\gamma-1}{\gamma+1}(M_m^2 - 1) + 1}{\frac{2\gamma}{\gamma+1}(M_m^2 - 1) + 1}.$$

After the shock, the diffuser decelerates the flow to raise the pressure. The block assumes that the kinetic energy at the diffuser outlet is negligible and decelerates the flow to stagnation pressure at  $p_d$ :

$$\frac{p_d}{p_{ms}} = \left(1 + \frac{\gamma-1}{2}M_{ms}^2\right)^{\frac{\gamma}{\gamma-1}}.$$

If  $M_M \leq 1$ , there is no shock and

$$\begin{aligned} \frac{p_{ms}}{p_m} &= 1 \\ M_{ms}^2 &= M_m^2. \end{aligned}$$

The relationship between the mixing pressure,  $p_m$ , and the diffuser outlet pressure,  $p_d$ , is

$$\frac{p_d}{p_m} = \begin{cases} \frac{\left[\frac{\gamma+1}{2}M_m^2\right]^{\frac{\gamma}{\gamma-1}}}{\left[\frac{2\gamma}{\gamma+1}(M_m^2 - 1) + 1\right]^{\frac{1}{\gamma-1}}}, & M_m > 1 \\ \left(1 + \frac{\gamma-1}{2}M_m^2\right)^{\frac{\gamma}{\gamma-1}}, & M_m \leq 1 \end{cases}$$

### Critical Mode Operation

In normal operation, the primary flow is high pressure and is choked during operation. The block can also operate if the secondary flow is choked. If both the primary and secondary flows are choked, the block operates in critical mode.

The critical mixing pressure,  $p_m^*$ , is a low pressure threshold that causes choking in both primary and secondary flow:

$$p_m^* = \min\{p_p, p_s\} \left(\frac{2}{\gamma+1}\right)^{\frac{\gamma}{\gamma-1}}.$$

The block uses the same equations as above, with  $p_m$  replaced by  $p_m^*$ , to calculate the critical diffuser outlet pressure,  $p_d^*$ . If the actual outlet pressure is greater than the critical diffuser outlet pressure,

then the ejector is subcritical and the block relates the mixing pressure to diffuser outlet pressure. If the actual outlet pressure is less than the critical diffuser outlet pressure, then the ejector is critical and the block limits the mixing pressure to the critical mixing pressure. This means that:

$$p_m = \begin{cases} \frac{p_d}{\left(\frac{p_d}{p_m}\right)} & p_d \geq p_d^* \\ p_m^* & p_d < p_d^* \end{cases}$$

### Assumptions and Limitations

- The block uses isentropic ideal gas relations to derive the model equations.
- The block accounts for losses due to friction, mixing, and expansion waves and shocks at the nozzle exit using empirical loss coefficients.
- After the primary flow exits the nozzle, the flows do not mix until the primary flow has fully expanded.
- After expansion, the flows mix under uniform pressure.
- Kinetic energy at the primary flow inlet, secondary flow inlet, and diffuser outlet are negligible compared to the kinetic energy of the flow inside the ejector.
- The flow is steady and one-dimensional.
- The flow is adiabatic.
- Model results with reversed flow may not be accurate.

## Ports

### Conserving

**A** — Primary inlet

moist air

Moist air conserving port associated with the primary nozzle inlet.

**B** — Outlet

moist air

Moist air conserving port associated with the diffuser outlet.

**S** — Secondary inlet

moist air

Moist air conserving port associated with the secondary inlet.

## Parameters

**Primary nozzle throat area** — Area of primary nozzle throat

1e-4 m<sup>2</sup> (default) | positive scalar

Area of the throat for the primary flow nozzle.

**Area ratio of nozzle exit to throat** — Ratio of areas of nozzle exit to nozzle throat

3 (default) | positive scalar

Ratio of the area of the nozzle exit to the area of the nozzle throat. This parameter limits how big the secondary aerodynamic throat can be.

**Area ratio of mixing chamber to throat** — Ratio of areas of mixing chamber to throat  
8 (default) | positive scalar

Ratio of the area of the mixing chamber to the area of the throat. The difference between the mixing chamber area and the expanded jet area of the primary flow creates a fictitious aerodynamic throat for the secondary flow.

**Minimum area ratio of secondary throat to primary throat** — Limit on ratio of aerodynamic areas of secondary throat to primary throat  
0.1 (default) | positive scalar

Minimum aerodynamic area ratio for the secondary throat to the primary throat. The block does not allow the area of the fictitious aerodynamic throat to go below this value. To avoid hitting this minimum, increase the value of the **Area ratio of mixing chamber to throat** parameter.

**Report when secondary throat area falls below minimum** — Notification when secondary throat area is below minimum  
Warning (default) | None | Error

Whether the block does nothing, generates a warning, or generates an error when the secondary throat area falls below the minimum, specified by the **Minimum area ratio of secondary throat to primary throat** parameter.

**Efficiency for primary flow through nozzle** — Efficiency factor of primary flow through nozzle  
0.95 (default) | positive scalar

Empirical factor that accounts for reduction in primary mass flow rate due to losses in the primary nozzle.

**Efficiency for secondary suction flow** — Efficiency factor of secondary suction flow  
0.85 (default) | positive scalar

Empirical factor that accounts for reduction in secondary mass flow rate due to losses in the suction of the secondary flow

**Efficiency for primary flow expansion** — Efficiency factor of primary flow expansion  
0.88 (default) | positive scalar

Empirical factor that accounts for reduction in the expansion of the primary flow jet due to mixing losses.

**Efficiency for mixing** — Efficiency factor for mixed flow velocity due to mixing  
0.84 (default) | positive scalar

Empirical factor that accounts for reduction in the mixed flow velocity due to losses in the mixing chamber.

**Cross-sectional area at port A** — Cross-sectional area of port A  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of port A.

**Cross-sectional area at port B** — Cross-sectional area of port B  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of port **B**.

**Cross-sectional area at port S** — Cross-sectional area of port S  
0.01 m<sup>2</sup> (default) | positive scalar

Cross-sectional area of port **S**.

## Library

Local Hydraulic Resistances

### Description

The Elbow block represents an elbow as a local hydraulic resistance. The pressure loss is computed with the semi-empirical formula based on pressure loss coefficient, which is determined in accordance with the Crane Co. recommendations (see [1] on page 1-786, p. A-29). Two types of elbow are considered: smoothly curved (standard) and sharp-edged (miter). The block covers elbows in the 5-100 mm and 0-90 degrees range.

The block is based on the Local Resistance block. It computes the pressure loss coefficient and passes its value, as well as the critical Reynolds number value, to the Local Resistance block, which computes the pressure loss according to the formulas explained in the reference documentation for that block.

The pressure loss for turbulent flow regime is determined according to the following formula:

$$p = K \frac{\rho}{2A^2} q |q|$$

where

$q$	Flow rate
$p$	Pressure loss
$K$	Pressure loss coefficient
$A$	Elbow cross-sectional area
$\rho$	Fluid density

The flow regime is checked in the underlying Local Resistance block by comparing the Reynolds number to the specified critical Reynolds number value. For laminar flow regime, the formula for

pressure loss computation is modified, as described in the reference documentation for the Local Resistance block.

The core data for the pressure loss coefficient computation is the table-specified relationship between the friction factor  $f_T$  and the internal diameter for clean commercial steel pipes, with flow in the zone of complete turbulence (see [1] on page 1-786, p. A-26). For smoothly curved, standard 90° elbows, the pressure loss coefficient is determined with the formula

$$K = 30f_T$$

For elbows with different angles, the coefficient is corrected with the relationship presented in [2] on page 1-786, Fig.4.6:

$$K_{corr} = \alpha(0.0142 - 3.703 \cdot 10^{-5}\alpha)$$

where  $\alpha$  is the elbow angle in degrees ( $0 \leq \alpha \leq 90$ ).

Therefore, the pressure loss coefficient for smoothly curved, standard elbows is determined with the formula

$$K_{SCE} = 30f_T \cdot \alpha(0.0142 - 3.703 \cdot 10^{-5}\alpha)$$

For sharp-edged, miter bends the pressure loss coefficient is determined according to the table provided in [1] on page 1-786, p. A-29, as a function of the elbow diameter and angle

$$K_{ME} = f(d, \alpha)$$

where  $5 \leq d \leq 100$  mm and  $0 \leq \alpha \leq 90$  degrees.

Connections A and B are conserving hydraulic ports associated with the block inlet and outlet, respectively.

The block positive direction is from port A to port B. This means that the flow rate is positive if fluid flows from A to B, and the pressure differential is determined as  $p = p_A - p_B$ .

---

**Warning** The formulas used in the Elbow block are very approximate, especially in the laminar and transient flow regions. For more accurate results, use the Local Resistance block with a table-specified  $K=f(Re)$  relationship.

---

## Basic Assumptions and Limitations

- Fluid inertia is not taken into account.
- The elbow is assumed to be made of a clean commercial steel pipe.

## Parameters

### Elbow type

The parameter can have one of two values: `Smoothly curved` or `Sharp-edged (miter)`. The default value is `Smoothly curved`.

### Elbow internal diameter

The internal diameter of the pipe. The value must be in the range between 5 and 100 mm. The default value is 0.01 m.

### Elbow angle

The angle of the bend. The value must be in the range between 0 and 90 degrees. The default value is 90 deg.

### Laminar transition specification

Select how the block transitions between the laminar and turbulent regimes:

- `Pressure ratio` — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- `Reynolds number` — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

### Laminar flow pressure ratio

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to `Pressure ratio`.

### Critical Reynolds number

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 80. This parameter is visible only if the **Laminar transition specification** parameter is set to `Reynolds number`.

## Restricted Parameters

When your model is in Restricted editing mode, you cannot modify the following parameter:

- **Elbow type**
- **Laminar transition specification**

All other block parameters are available for modification.

## Global Parameters

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the elbow inlet.

B

Hydraulic conserving port associated with the elbow outlet.

## Elbow (G)

Pipe turn in a gas network

### Libraries:

Simscape / Fluids / Gas / Pipes & Fittings

## Description

The Elbow (G) block models flow in a pipe turn in a gas network. The block calculates pressure losses due to pipe turns, but omits the effect of viscous friction.

You can model a smoothly curved or sharp-edged pipe elbow by setting the **Elbow type** parameter to `Smoothly curved` or `Sharp-edged (Miter)`, respectively. To model a smooth pipe with a 90° bend that models losses due to friction, you can also use the Pipe Bend (G) block.

## Loss Coefficients

When the **Elbow type** parameter is `Smoothly curved`, the block calculates the loss coefficient as:

$$K = 30f_T C_{angle}.$$

The block calculates  $C_{angle}$ , the angle correction factor, from Keller [2] as

$$C_{angle} = 0.0148\theta - 3.9716 \cdot 10^{-5}\theta^2,$$

where  $\theta$  is the value of the **Bend angle** parameter in degrees. The block defines the friction factor,  $f_T$ , as the value for clean commercial steel. The block then interpolates the values from tabular data based on the internal elbow diameter for  $f_T$  provided by Crane [1]. This table contains the pipe friction data for clean commercial steel pipe with flow in the zone of complete turbulence.

Nominal size	1/2"	3/4"	1"	1 1/4"	1 1/2"	2"	2 1/2, 3"	4"	5"	6"	8-10"	12-16"	18-24"
Friction factor, $f_T$	.027	.025	.023	.022	.021	.019	.018	.017	.016	.015	.014	.013	.012

The values provided by Crane are valid for diameters up to 600 millimeters. The friction factor for larger diameters or for wall roughness beyond this range is calculated by nearest-neighbor extrapolation.

When the **Elbow type** parameter is `Sharp-edged (Miter)`, the block calculates the loss coefficient  $K$  for the bend angle,  $\alpha$ , according to Crane [1]:

## MITRE BENDS

**Mass Flow Rate**

Mass is conserved through the pipe segment

$$\dot{m}_A + \dot{m}_B = 0.$$

The mass flow rate through the elbow is

$$\dot{m} = A \sqrt{\frac{2\bar{\rho}}{K}} \frac{\Delta p}{[\Delta p^2 + \Delta p_{crit}^2]^{1/4}},$$

where:

- $A$  is the flow area.
- $\bar{\rho}$  is the average fluid density.
- $\Delta p$  is the pipe segment pressure difference,  $p_A - p_B$ .

The critical pressure difference,  $\Delta p_{threshold}$ , is the threshold for transition between laminar and turbulent flow

$$\Delta p_{threshold} = \frac{p_A + p_B}{2} (1 - B_{lam}),$$

where:

- $p_A$  is the pressure at port **A**.
- $p_B$  is the pressure at port **B**.
- $B_{lam}$  is the value of the **Laminar flow pressure ratio** parameter.

**Energy Balance**

The block balances energy such that

$$\Phi_A + \Phi_B = 0,$$

where:

- $\phi_A$  is the energy flow rate at port **A**.
- $\phi_B$  is the energy flow rate at port **B**.

## Ports

### Conserving

**A** — Inlet or outlet  
gas

Gas conserving port associated with the inlet or outlet of the pipe. This block has no intrinsic directionality.

**B** — Inlet or outlet  
gas

Gas conserving port associated with the inlet or outlet of the pipe. This block has no intrinsic directionality.

## Parameters

**Elbow type** — Bend geometry  
Smoothly curved (default) | Sharp-edged (Miter)

Bend specification of the pipe segment. When you set this parameter to Sharp-edged (Miter), the block introduces a sharp change in flow direction, such as at a pipe joint, and models the flow losses using a separate set of empirical data from gradually turning pipe segments.

**Elbow internal diameter** — Pipe internal diameter  
0.01 m (default) | positive scalar

Internal diameter of the pipe elbow segment.

**Elbow angle** — Pipe curve angle  
90 deg (default) | positive scalar

Angle of the swept pipe curve.

**Laminar flow pressure ratio** — Pressure ratio at which flow transitions between laminar and turbulent regimes  
0.999 (default) | positive scalar

Pressure ratio at which the gas flow transitions between the laminar and turbulent regimes.

## Elbow (IL)

Pipe turn in an isothermal liquid network

### Libraries:

Simscape / Fluids / Isothermal Liquid / Pipes & Fittings

## Description

The Elbow (IL) block models flow in a pipe turn in an isothermal liquid network. Pressure losses due to pipe turns are calculated, but the effect of viscous friction is omitted.

Two **Elbow type** settings are available: **Smoothly-curved** and **Sharp-edged (Miter)**. For a smooth pipe with a 90° bend and modeled losses due to friction, you can also use the Pipe Bend (IL) block.

### Loss Coefficients

When the **Elbow type** parameter is **Smoothly curved**, the block calculates the loss coefficient as:

$$K = 30f_T C_{angle}.$$

The block calculates  $C_{angle}$ , the angle correction factor, from Keller [2] as

$$C_{angle} = 0.0148\theta - 3.9716 \cdot 10^{-5}\theta^2,$$

where  $\theta$  is the value of the **Bend angle** parameter in degrees. The block defines the friction factor,  $f_T$ , as the value for clean commercial steel. The block then interpolates the values from tabular data based on the internal elbow diameter for  $f_T$  provided by Crane [1]. This table contains the pipe friction data for clean commercial steel pipe with flow in the zone of complete turbulence.

Nominal size	½"	¾"	1"	1 ¼"	1 ½"	2"	2 ½, 3"	4"	5"	6"	8-10"	12-1 6"	18-2 4"
Friction factor, $f_T$	.027	.025	.023	.022	.021	.019	.018	.017	.016	.015	.014	.013	.012

The values provided by Crane are valid for diameters up to 600 millimeters. The friction factor for larger diameters or for wall roughness beyond this range is calculated by nearest-neighbor extrapolation.

When the **Elbow type** parameter is **Sharp-edged (Miter)**, the block calculates the loss coefficient  $K$  for the bend angle,  $\alpha$ , according to Crane [1]:

## MITRE BENDS

$\alpha$	$K$
$0^\circ$	$2 f_r$
$15^\circ$	$4 f_r$
$30^\circ$	$8 f_r$
$45^\circ$	$15 f_r$
$60^\circ$	$25 f_r$
$75^\circ$	$40 f_r$
$90^\circ$	$60 f_r$

**Mass Flow Rate**

Mass is conserved through the pipe segment:

$$\dot{m}_A + \dot{m}_B = 0.$$

The mass flow rate through the elbow is calculated as:

$$\dot{m} = A \sqrt{\frac{2\bar{\rho}}{K}} \frac{\Delta p}{[\Delta p^2 + \Delta p_{crit}^2]^{1/4}},$$

where:

- $A$  is the flow area.
- $\bar{\rho}$  is the average fluid density.
- $\Delta p$  is the pipe segment pressure difference,  $p_A - p_B$ .

The critical pressure difference,  $\Delta p_{crit}$ , is the pressure differential associated with the **Critical Reynolds number**,  $Re_{crit}$ , the flow regime transition point between laminar and turbulent flow:

$$\Delta p_{crit} = \frac{\bar{\rho}}{2} K \left( \frac{\nu Re_{crit}}{D} \right)^2,$$

where

- $\nu$  is the fluid kinematic viscosity.
- $D$  is the elbow internal diameter.

**Energy Balance**

The block balances energy such that

$$\Phi_A + \Phi_B = 0,$$

where:

- $\phi_A$  is the energy flow rate at port **A**.
- $\phi_B$  is the energy flow rate at port **B**.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Liquid entry or exit port to the pipe segment.

**B** — Liquid port  
isothermal liquid

Liquid entry or exit port to the pipe segment.

## Parameters

**Elbow type** — Bend geometry  
Smoothly curved (default) | Sharp-edged (Miter)

Bend specification of the pipe segment. A sharp-edged, or mitre, bend introduces a sharp change in flow direction, such as at a pipe joint, and the flow losses are modeled by a separate set of empirical data from gradually-turning pipe segments.

**Elbow internal diameter** — Pipe internal diameter  
0.01 m (default) | positive scalar

Internal diameter of the pipe elbow segment.

**Elbow angle** — Pipe curve angle  
90 deg (default) | positive scalar

Angle of the swept pipe curve.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the pipe segment.

## Elbow (MA)

Pipe turn in an moist air network

### Libraries:

Simscape / Fluids / Moist Air / Pipes & Fittings

## Description

The Elbow (MA) block models flow in a pipe turn in a moist air network. The block calculates pressure losses due to pipe turns, but omits the effect of viscous friction.

You can model a smoothly curved or sharp-edged pipe elbow by setting the **Elbow type** parameter to *Smoothly curved* or *Sharp-edged (Miter)*, respectively. To model a smooth pipe with a 90° bend that models losses due to friction, you can also use the Pipe Bend (MA) block.

### Loss Coefficients

When the **Elbow type** parameter is *Smoothly curved*, the block calculates the loss coefficient as:

$$K = 30f_T C_{angle}.$$

The block calculates  $C_{angle}$ , the angle correction factor, from Keller [2] as

$$C_{angle} = 0.0148\theta - 3.9716 \cdot 10^{-5}\theta^2,$$

where  $\theta$  is the value of the **Bend angle** parameter in degrees. The block defines the friction factor,  $f_T$ , as the value for clean commercial steel. The block then interpolates the values from tabular data based on the internal elbow diameter for  $f_T$  provided by Crane [1]. This table contains the pipe friction data for clean commercial steel pipe with flow in the zone of complete turbulence.

Nominal size	1/2"	3/4"	1"	1 1/4"	1 1/2"	2"	2 1/2, 3"	4"	5"	6"	8-10"	12-16"	18-24"
Friction factor, $f_T$	.027	.025	.023	.022	.021	.019	.018	.017	.016	.015	.014	.013	.012

The values provided by Crane are valid for diameters up to 600 millimeters. The friction factor for larger diameters or for wall roughness beyond this range is calculated by nearest-neighbor extrapolation.

When the **Elbow type** parameter is *Sharp-edged (Miter)*, the block calculates the loss coefficient  $K$  for the bend angle,  $\alpha$ , according to Crane [1]:

## MITRE BENDS

$\alpha$	$K$
$0^\circ$	$2 f_r$
$15^\circ$	$4 f_r$
$30^\circ$	$8 f_r$
$45^\circ$	$15 f_r$
$60^\circ$	$25 f_r$
$75^\circ$	$40 f_r$
$90^\circ$	$60 f_r$

**Mass Flow Rate**

The block conserves mass through the pipe segment

$$\dot{m}_A + \dot{m}_B = 0$$

$$\dot{m}_{wA} + \dot{m}_{wB} = 0$$

$$\dot{m}_{gA} + \dot{m}_{gB} = 0$$

where the subscript  $w$  denotes water vapor and the subscript  $g$  denotes trace gas.

The mass flow rate through the elbow is

$$\dot{m} = A \sqrt{\frac{2\bar{\rho}}{K}} \frac{\Delta p}{[\Delta p^2 + \Delta p_{crit}^2]^{1/4}},$$

where:

- $A$  is the flow area.
- $\bar{\rho}$  is the average fluid density.
- $\Delta p$  is the pipe segment pressure difference,  $p_A - p_B$ .

The critical pressure difference,  $\Delta p_{threshold}$ , is the threshold for transition between laminar and turbulent flow

$$\Delta p_{threshold} = \frac{p_A + p_B}{2} (1 - B_{lam}),$$

where:

- $p_A$  is the pressure at port **A**.
- $p_B$  is the pressure at port **B**.
- $B_{lam}$  is the value of the **Laminar flow pressure ratio** parameter.

**Energy Balance**

The block balances energy such that

$$\Phi_A + \Phi_B = 0,$$

where:

- $\phi_A$  is the energy flow rate at port **A**.
- $\phi_B$  is the energy flow rate at port **B**.

## Ports

### Conserving

**A** — Inlet or outlet  
moist air

Moist air conserving port associated with the inlet or outlet of the pipe. This block has no intrinsic directionality.

**B** — Inlet or outlet  
moist air

Moist air conserving port associated with the inlet or outlet of the pipe. This block has no intrinsic directionality.

## Parameters

**Elbow type** — Bend geometry  
Smoothly curved (default) | Sharp-edged (Miter)

Bend specification of the pipe segment. When you set this parameter to **Sharp-edged (Miter)**, the block introduces a sharp change in flow direction, such as at a pipe joint, and models the flow losses using a separate set of empirical data from gradually turning pipe segments.

**Elbow internal diameter** — Pipe internal diameter  
0.01 m (default) | positive scalar

Internal diameter of the pipe elbow segment.

**Elbow angle** — Pipe curve angle  
90 deg (default) | positive scalar

Angle of the swept pipe curve.

**Laminar flow pressure ratio** — Pressure ratio at which flow transitions between laminar and turbulent regimes  
0.999 (default) | positive scalar

Pressure ratio at which the moist air flow transitions between the laminar and turbulent regimes.

## E-NTU Heat Transfer

Detailed heat transfer model between two general fluids

### Libraries:

Simscape / Fluids / Fluid Network Interfaces / Heat Exchangers / Fundamental Components

### Description

The E-NTU Heat Transfer block models the heat exchange between two general fluids based on the standard Effectiveness-NTU method. The fluid thermal properties are specified explicitly through Simscape physical signals. Combine with the Heat Exchanger Interface (TL) block to model the pressure drop and temperature change between the inlet and outlet of a heat exchanger.

The block dialog box provides a choice of common heat exchanger configurations. These include concentric-pipe with parallel and counter flows, shell-and-tube with one or more shell passes, and cross-flow with mixed and unmixed flows. A generic configuration lets you model other heat exchangers based on tabular effectiveness data.

### Heat Exchanger Configurations

#### Heat Transfer Rate

The E-NTU model defines the heat transfer rate between fluids 1 and 2 in terms of an effectiveness parameter  $\varepsilon$ :

$$Q_1 = -Q_2 = \varepsilon Q_{Max}, \quad 0 < \varepsilon < 1,$$

where:

- $Q_1$  and  $Q_2$  are the heat transfer rates into fluid 1 and fluid 2.
- $Q_{Max}$  is the maximum possible heat transfer rate between fluid 1 and fluid 2 at a given set of operating conditions.
- $\varepsilon$  is the effectiveness parameter.

The maximum possible heat transfer rate between the two fluids is

$$Q_{Max} = C_{Min}(T_{1,In} - T_{2,In}),$$

where:

- $C_{Min}$  is the minimum value of the thermal capacity rate:

$$C_{Min} = \min(\dot{m}_1 c_{p,1}, \dot{m}_2 c_{p,2})$$

- $T_{1,In}$  and  $T_{2,In}$  are the inlet temperatures of fluid 1 and fluid 2.
- $\dot{m}_1$  and  $\dot{m}_2$  are the mass flow rates of fluid 1 and fluid 2 into the heat exchanger volume through the inlet.
- $c_{p,1}$  and  $c_{p,2}$  are the specific heat coefficients at constant pressure of fluid 1 and fluid 2. The **Minimum fluid-wall heat transfer coefficient** parameter in the block dialog box sets a lower bound on the allowed values of the heat transfer coefficients.

### Heat Exchanger Effectiveness

The heat exchanger effectiveness calculations depend on the flow arrangement type selected in the block dialog box. For all but `Generic – effectiveness table`, the block computes the thermal exchange effectiveness through analytical expressions written in terms of the number of transfer units (NTU) and thermal capacity ratio. The number of transfer units is defined as

$$NTU = \frac{U_{Overall} A_{Heat}}{C_{Min}} = \frac{1}{C_{Min} R_{Overall}},$$

where:

- $NTU$  is the number of transfer units.
- $U_{Overall}$  is the overall heat transfer coefficient between fluid 1 and fluid 2.
- $R_{Overall}$  is the overall thermal resistance between fluid 1 and fluid 2.
- $A_{Heat}$  is aggregate area of the primary and secondary, or finned, heat transfer surfaces.

The thermal capacity ratio is defined as

$$C_{rel} = \frac{C_{Min}}{C_{Max}}$$

where:

- $C_{rel}$  is the thermal capacity ratio.

The overall heat transfer coefficient and thermal resistance used in the NTU calculation are functions of the heat transfer mechanisms at work. These mechanisms include convective heat transfer between the fluids and the heat exchanger interface and conduction through the interface wall [2]:

$$R_{Overall} = \frac{1}{U_{Overall} A_{Heat}} = \frac{1}{h_1 A_{Heat,1}} + R_{Foul,1} + R_{Wall} + R_{Foul,2} + \frac{1}{h_2 A_{Heat,2}},$$

where:

- $h_1$  and  $h_2$  are the heat transfer coefficients between fluid 1 and the interface wall and between fluid 2 and the interface wall.
- $A_{Heat,1}$  and  $A_{Heat,2}$  are the heat transfer surface areas on the fluid-1 and fluid-2 sides.

- $R_{Foul,1}$  and  $R_{Foul,2}$  are the fouling resistances on the fluid-1 and fluid-2 sides.
- $R_{Wall}$  is the interface wall thermal resistance.

### Heat Transfer From Fluid 1 to Fluid 2

The tables show some of the analytical expressions used to compute the heat exchange effectiveness [1]. The parameter  $N$  refers to the number of shell passes and the parameter  $\epsilon_1$  to the effectiveness for a single shell pass.

<b>Concentric Tubes</b>	
Counter Flow	$\epsilon = \begin{cases} \frac{1 - \exp[-NTU(1 - C_{rel})]}{1 - C_{rel}\exp[-NTU(1 - C_{rel})]}, & \text{if } C_{rel} < 1 \\ \frac{NTU}{1 + NTU}, & \text{if } C_{rel} = 1 \end{cases}$
Parallel Flow	$\epsilon = \frac{1 - \exp[-NTU(1 + C_{rel})]}{1 + C_{rel}}$
<b>Shell and Tube</b>	
One shell pass and two, four, or six tube passes	$\epsilon_1 = \frac{2}{1 + C_{rel} + \sqrt{1 + C_{rel}^2} \frac{1 + \exp(-NTU\sqrt{1 + C_{rel}^2})}{1 - \exp(-NTU\sqrt{1 + C_{rel}^2})}}$
$N$ Shell Passes and $2N$ , $4N$ , or $6N$ Tube Passes	$\epsilon = \frac{[(1 - \epsilon_1 C_{rel}) / (1 - \epsilon_1)]^N - 1}{[(1 - \epsilon_1 C_{rel}) / (1 - \epsilon_1)]^N - C_{rel}}$
<b>Cross Flow (Single Pass)</b>	
Both Fluids Unmixed	$\epsilon = 1 - \exp\left(\frac{\exp(-C_{rel}NTU^{0.78}) - 1}{C_{rel}NTU^{-0.22}}\right)$
Both Fluids Mixed	$\epsilon = \frac{1}{\frac{1}{1 - \exp(-NTU)} + \frac{C_{rel}}{1 - \exp(-C_{rel}NTU)} - \frac{1}{NTU}}$
$C_{Max}$ mixed, $C_{Min}$ unmixed	$\epsilon = \frac{1}{C_{rel}}(1 - \exp(-C_{rel}(1 - \exp(-NTU))))$
$C_{Max}$ unmixed, $C_{Min}$ mixed	$\epsilon = 1 - \exp\left(-\frac{1}{C_{rel}}(1 - \exp(-C_{rel}NTU))\right)$

## Assumptions and Limitations

The flows are single-phase. The heat transfer is strictly one of sensible heat. The transfer is limited to interior of the exchanger, with the environment neither gaining heat from nor providing heat to the flows—the heat exchanger is an adiabatic component.

## Ports

### Input

**C1** — Fluid 1 thermal capacity  
physical signal

Physical signal input port for the thermal capacity rate of fluid 1.

**C2** — Fluid 2 thermal capacity  
physical signal

Physical signal input port for the thermal capacity rate of fluid 2.

**HC1** — Fluid 1 heat transfer coefficient  
physical signal

Physical signal input port for the heat transfer coefficient between fluid 1 and the interface wall.

**HC2** — Fluid 2 heat transfer coefficient  
physical signal

Physical signal input port for the heat transfer coefficient between fluid 2 and the interface wall.

### Conserving

**H1** — Fluid 1 thermal inlet temperature  
thermal

Thermal conserving port associated with the inlet temperature of fluid 1.

**H2** — Fluid 2 thermal inlet temperature  
thermal

Thermal conserving port associated with the inlet temperature of fluid.

## Parameters

**Flow arrangement** — Manner in which the flows align in the heat exchanger  
Parallel or counter flow (default) | Shell and tube | Cross flow | Generic – effectiveness table

Heat exchanger geometry. Select `Generic – effectiveness table` to model other heat exchanger geometries based on tabular effectiveness data.

In the `Parallel or counter flow` configuration, the relative flow directions of fluids 1 and 2 determine whether the heat exchanger is based on parallel or counter flows. The flow directions depend on the remainder of the Simscape Fluids model.

**Wall thermal resistance** — Resistance of the wall to heat flow by thermal conduction

1.6e-4 K/W (default) | positive scalar

Thermal resistance of the interface wall separating the two heat exchanger fluids. The block uses this parameter to compute the rate of heat transfer between the fluids.

**Number of shell passes** — Number of times the flow traverses the shell before exiting

1 (default) | positive scalar

Number of times the flow traverses the shell before exiting.

#### Dependencies

To enable this parameter, set **Flow arrangement** to Shell and tube.

**Cross flow type** — Mixing condition in each of the flow channels

Both fluids mixed (default) | Both fluids unmixed | Controlled Fluid 1 mixed & Controlled Fluid 2 unmixed | Controlled Fluid 1 unmixed & Controlled Fluid 2 mixed

Fluid mixing configuration. The fluids can be mixed or unmixed. The block uses the mixing configuration to determine which empirical heat transfer correlations to use.

#### Dependencies

To enable this parameter, set **Flow arrangement** to Cross flow.

**Number of heat transfer units vector, NTU** — Number of transfer units at each breakpoint in lookup table for heat exchanger effectiveness

[.5, 1, 2, 3, 4, 5] (default) | vector of positive scalars

$M$ -element vector of NTU values at which to specify the effectiveness tabular data. The number of transfer units (NTU) is a dimensionless parameter defined as

$$NTU = \frac{A_s U}{C_{min}}$$

where:

- $A_s$  is the heat transfer surface area.
- $U$  is the overall heat transfer coefficient.
- $C_{min}$  is the smallest of the thermal capacity rates for the hot and cold fluids.

#### Dependencies

To enable this parameter, set **Flow arrangement** to Generic – effectiveness table.

**Thermal capacity ratio vector, CR** — Thermal capacity ratio at each breakpoint in lookup table for heat exchanger effectiveness

[0, .25, .5, .75, 1] (default) | vector of positive scalars

$N$ -element vector of thermal capacity ratios at which to specify the effectiveness tabular data. The thermal capacity ratio is the fraction

$$C_r = \frac{C_{min}}{C_{max}}$$

where  $C_{\min}$  and  $C_{\max}$  are the minimum and maximum thermal capacity rates.

#### Dependencies

To enable this parameter, set **Flow arrangement** to Generic – effectiveness table.

**Effectiveness table, E(NTU,CR)** — Heat exchanger effectiveness at each breakpoint in lookup table over the number of transfer units and thermal capacity ratio

[.3, .3, .3, .3, .3; .6, .55, .5, .47, .43; .85, .76, .68, .61, .55; .94, .83, .72, .65, .58; .98, .86, .75, .66, .58; .99, .86, .75, .66, .58] (default) | table of positive scalars

$M$ -by- $N$  matrix with the heat exchanger effectiveness values. The matrix rows correspond to the different values specified in the **Number of heat transfer units vector, NTU** parameter. The matrix columns correspond to the values specified in the **Thermal capacity ratio vector, CR** parameter.

#### Dependencies

To enable this parameter, set **Flow arrangement** to Generic – effectiveness table.

#### Controlled Fluid 1

**Heat transfer surface area** — Aggregate heat transfer surface area on the controlled fluid 1 side  
0.01 m<sup>2</sup> (default) | positive scalar

Aggregate surface area for heat transfer between the cold and hot fluids.

**Fouling factor** — Measure of thermal resistance due to fouling deposits  
1e-4 K\*m<sup>2</sup>/W (default) | positive scalar

Empirical parameter used to quantify the increased thermal resistance due to dirt deposits on the heat transfer surface.

**Minimum fluid-wall heat transfer coefficient** — Lower bound for the heat transfer coefficient  
5 W/(m<sup>2</sup> \* K) (default) | positive scalar

Smallest allowed value of the heat transfer coefficient. The heat transfer coefficient specified through physical signal ports HC1 saturates at this value. The block uses the heat transfer coefficient to calculate the heat transfer rate between fluids 1 and 2 as described in “Heat Transfer Rate” on page 1-802.

#### Controlled Fluid 2

**Heat transfer surface area** — Aggregate heat transfer surface area on the controlled fluid 2 side  
0.01 m<sup>2</sup> (default) | positive scalar

Aggregate surface area for heat transfer between the cold and hot fluids.

**Fouling factor** — Measure of thermal resistance due to fouling deposits  
1e-4 K\*m<sup>2</sup>/W (default) | positive scalar

Empirical parameter used to quantify the increased thermal resistance due to dirt deposits on the heat transfer surface.

**Minimum fluid-wall heat transfer coefficient** — Lower bound for the heat transfer coefficient  
5 W/(m<sup>2</sup> \* K) (default) | positive scalar

Smallest allowed value of the heat transfer coefficient. The heat transfer coefficient specified through physical signal ports HC2 saturates at this value. The block uses the heat transfer coefficient to calculate the heat transfer rate between fluids 1 and 2 as described in “Heat Transfer Rate” on page 1-802.

Simscape / Fluids / Gas / Turbomachinery

## Description

The Fan (G) block represents a fan in a gas network. You can model the torque and pressure gain over the fan as a function of static pressure and flow rate or by using 1D or 2D tabulated reference pressure, shaft speed, and flow rate data.

By default, flow and pressure gain are from port **A** to port **B**. Port **C** represents the fan casing, and port **R** represents the fan shaft. You can specify the normal operating shaft direction in the **Mechanical orientation** parameter. If the shaft begins to spin in the opposite direction, the pressure difference across the fan drops to zero.

### Parameterization by Nominal Pressure, Flow Rate, and Shaft Speed

When you set the **Fan parameterization** parameter to **Static pressure and flow rate at reference shaft speed**, the block uses the analytical fan affinity laws and reference pressure differential to calculate the pressure gain from port **A** to port **B**:

$$p_B - p_A = \Delta p_{ref} \left( \frac{\omega}{\omega_{ref}} \right)^2 \left( \frac{D}{D_{ref}} \right)^2,$$

where:

- $\Delta p_{ref}$  is the reference pressure differential. The block uses a quadratic fit of the fan pressure differential values at the **Maximum static pressure gain at zero flow**, **Nominal static pressure gain**, and **Maximum volumetric flow rate at zero pressure** parameters.
- $\omega$  is the shaft angular velocity,  $\omega_R - \omega_C$ .
- $\omega_{ref}$  is the **Reference shaft speed** parameter.
- $\frac{D}{D_{ref}}$  is the **Fan diameter scale factor** parameter.

The block calculates the shaft torque from the reference mechanical power and the fan affinity laws:

$$\tau = \Phi_{ref} \frac{\omega^2}{\omega_{ref}^3} \left( \frac{D}{D_{ref}} \right)^5.$$

Where  $\Phi_{ref}$  is the proportion of the pressure gain to the fan efficiency:

$$\Phi_{ref} = \frac{q_{ref} \Delta p_{ref}}{\eta_{ref}}.$$

When you set the **Shaft power specification** parameter to **Fan efficiency**, the block uses a quadratic fit of efficiency between the fan peak performance,  $\eta_{nom}$ , and 0.  $\eta_{nom}$  is equivalent to the **Nominal efficiency** parameter, which the block interprets as the peak efficiency. If you set the **Shaft power specification** parameter to **Brake power**, the block derives the nominal fan efficiency from the nominal brake power,  $\Phi_{nom}$ , at peak or nominal conditions:

$$\eta_{nom} = \frac{q_{nom} \Delta p_{nom}}{\Phi_{nom}}.$$

The block assumes the efficiency is zero when there is no flow or when the flow reaches the maximum volumetric flow rate at zero pressure. The block uses the current flow  $q$  to compute the reference flow rate as:

$$q_{ref} = q \frac{\omega_{ref} \left( \frac{D_{ref}}{D} \right)^3}{\omega}.$$

### 1-D Tabulated Data Parameterization: Pressure as a Function of Flow Rate at Reference Shaft Speed

When you set the **Fan parameterization** parameter to **1D tabulated data - static pressure vs. flow rate at reference shaft speed**, you can model fan performance as a function of volumetric flow rate. The block interpolates the pressure gain from port **A** to port **B** from the 1-D **Static pressure gain vector** parameter,  $\Delta p_{ref}(q_{ref})$ :

$$p_B - p_A = \Delta p_{ref}(q_{ref}) \left( \frac{\rho}{\rho_{ref}} \right) \left( \frac{\omega}{\omega_{ref}} \right)^2 \left( \frac{D}{D_{ref}} \right)^2.$$

Here,  $\rho$  is the moist air density, and  $\rho_{ref}$  is the reference density, which is equivalent to the **Reference density** parameter. The block calculates the shaft torque from the reference mechanical power and the fan affinity laws:

$$\tau = \Phi_{ref}(q_{ref}) \frac{\omega^2}{\omega_{ref}^3} \left( \frac{\rho}{\rho_{ref}} \right) \left( \frac{D}{D_{ref}} \right)^5,$$

where  $\rho_{ref}$  is the **Reference density**.

The block uses the current flow  $q$  to compute the reference flow rate:

$$q_{ref} = q \frac{\omega_{ref} \left( \frac{D_{ref}}{D} \right)^3}{\omega}.$$

When the simulation is outside the range of the provided tables, the block extrapolates pressure based on the average slope of the fan curves and the reference torque to the nearest point.

### 2-D Tabulated Data Parameterization: Pressure as a Function of Shaft Speed and Flow Rate

When you set the **Fan parameterization** parameter to **2D tabulated data - static pressure vs. shaft speed and flow rate**, you can model fan performance as a 2-D function of volumetric flow rate and angular velocity. The block interpolates the pressure gain from port **A** to port **B** from the 2-D **Static pressure gain table, dp(w,q)** parameter. The block defines the reference pressure gain,  $\Delta p_{ref}(q_{ref}, \omega)$ , as

$$p_B - p_A = \Delta p_{ref}(q_{ref}, \omega) \left( \frac{\rho}{\rho_{ref}} \right) \left( \frac{D}{D_{ref}} \right)^2.$$

The block calculates shaft torque from the reference mechanical power and the fan affinity laws:

$$\tau = \frac{\Phi_{ref}(q_{ref}, \omega) \left( \frac{\rho}{\rho_{ref}} \right) \left( \frac{D}{D_{ref}} \right)^5}{\omega},$$

where the reference mechanical power is a function of the reference flow rate and the current shaft speed.

The block uses the current flow  $q$  to compute the reference flow rate:

$$q_{ref} = q \left( \frac{D_{ref}}{D} \right)^3.$$

When the simulation is outside the range of the provided tables, the block extrapolates pressure based on the average slope of the fan curves and the reference torque to the nearest point.

### Missing Data

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the fan curves. Do not use artificial numerical values because these values distort fan behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Static pressure gain table, dp(w,q)**, **Efficiency table, eta(w,q)**, and **Mechanical power table, W(w,q)** parameters must match each other.
- NaN elements must be located in the upper-right portion of the table, which corresponds to the highest volumetric flow rate and lowest shaft speed.

### 2-D Tabulated Data Parameterization: Flow Rate as a Function of Shaft Speed and Pressure

When you set the **Fan parameterization** parameter to 2D tabulated data - flow rate vs. shaft speed and static pressure, you can model the flow rate through the fan as a 2-D function of pressure and angular velocity. The volumetric flow rate is interpolated from the 2-D **Volumetric flow rate table, q(w,dp)** parameter,  $q_{ref}$ . The reference flow rate is a function of the reference pressure gain,  $\Delta p_{ref}$ , and the current shaft speed,  $\omega$ :

$$q = q_{ref}(\Delta p_{ref}, \omega) \left( \frac{D}{D_{ref}} \right)^3,$$

where the reference pressure gain derives from the pressure differential over the fan:

$$\Delta p_{ref} = (p_B - p_A) \left( \frac{\rho_{ref}}{\rho} \right) \left( \frac{D_{ref}}{D} \right)^2.$$

The shaft torque derives from the reference mechanical power and the fan affinity laws:

$$\tau = \frac{\Phi_{ref}(\Delta p_{ref}, \omega) \left( \frac{\rho}{\rho_{ref}} \right) \left( \frac{D}{D_{ref}} \right)^5}{\omega},$$

where the reference mechanical power is a function of the reference flow rate and the current shaft speed.

When the simulation is outside the range of the provided tables, the block extrapolates pressure based on the average slope of the fan curves and the reference torque to the nearest point.

### Missing Data

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the fan curves. Do not use artificial numerical values because these values distort fan behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Volumetric flow rate table,  $q(w,dp)$ , Efficiency table,  $\eta(w,dp)$ , and Mechanical power table,  $W(w,dp)$**  parameters must match each other.
- NaN elements must be located in the upper-right portion of the table, which corresponds to the highest volumetric flow rate and lowest shaft speed.

### Power and Efficiency

You can specify shaft power as either fan efficiency or brake power.

The block calculates efficiency as

$$\eta = \frac{\Phi_{fluid}}{\Phi_{brake}},$$

where the *brake power*, or mechanical power measured at the shaft, is

$$\Phi_{brake} = \tau\omega.$$

The block calculates fluid power as

$$\Phi_{fluid} = q(p_B - p_A).$$

The block calculates torque as

$$\tau = \frac{\Phi_{brake}}{\omega}.$$

### Visualizing the Fan Curve

You can check the parameterized fan performance by plotting the pressure, power, efficiency, and torque as a function of the flow. To generate a plot of the current fan settings, right-click on the block and select **Fluids > Plot Fan Characteristics**. If you change settings or data, click **Apply** on the block parameters and click **Reload Data** on the fan curve figure.

The default block parameterization results in these plots:

### Assumptions and Limitations

- If the shaft rotates opposite to the specified mechanical orientation, pressure difference across the block drops to zero and the results may not be accurate.
- The block assumes that the fan is quasi-steady.
- The block simulates fan performance in terms of static pressure rise, and not total fan pressure.

### Ports

#### Conserving

**A** — Fluid entry  
gas

Gas conserving port associated with the fluid.

**B** — Fluid exit  
gas

Gas conserving port associated with the fluid.

**R** — Shaft  
mechanical rotational

Mechanical rotational conserving port associated with the shaft.

**C** — Casing

mechanical rotational

Mechanical rotational conserving port associated with the casing.

## Parameters

**Fan parameterization** — Fan performance model

Static pressure and flow rate at reference shaft speed (default) | 1D tabulated data - static pressure vs. flow rate at reference shaft speed | 2D tabulated data - static pressure vs. shaft speed and flow rate | 2D tabulated data - flow rate vs. shaft speed and static pressure

Fan performance model, specified as:

- **Static pressure and flow rate at reference shaft speed:** Specify fan performance based on typical, nominal, or rated pressure gain and volumetric flow rate.
- **1D tabulated data – static pressure vs flow rate at reference shaft speed:** Specify fan performance based on interpolation of pressure gain data as a function of volumetric flow rate.
- **2D tabulated data – static pressure vs shaft speed and flow rate:** Specify fan performance based on the interpolation of pressure gain data as a function of shaft speed and volumetric flow rate.
- **2D tabulated data – flow rate vs shaft speed and static pressure:** Specify fan performance based on the interpolation of volumetric flow rate data as a function of shaft speed and pressure gain.

**Shaft power specification** — Power definition

Fan efficiency (default) | Brake power

Fan power specification, specified as:

- **Fan efficiency:** Derive the mechanical power from the fan efficiency.
- **Mechanical power:** Specify the mechanical power directly.

**Nominal volumetric flow rate** — Flow rate at reference shaft speed

$0.12 \text{ m}^3/\text{s}$  (default) | positive scalar

Volumetric flow rate through the fan at the reference shaft speed under nominal, typical, or rated operating conditions.

**Dependencies**

To enable this parameter, set **Fan parameterization** to Static pressure and flow rate at reference shaft speed.

**Nominal static pressure gain** — Pressure gain at reference shaft speed

5400 Pa (default) | positive scalar

Pressure increase from port **A** to port **B** at the reference shaft speed under nominal, typical, or rated operating conditions.

**Dependencies**

To enable this parameter, set **Fan parameterization** to Static pressure and flow rate at reference shaft speed.

**Nominal efficiency** — Efficiency at reference shaft speed

0.40 (default) | positive scalar

Efficiency of converting the shaft power to fluid power at the reference shaft speed under nominal, typical, or rated operating conditions.

**Dependencies**

To enable this parameter, set:

- **Fan parameterization** to Static pressure and flow rate at reference shaft speed.
- **Shaft power specification** to Fan efficiency.

**Nominal mechanical power** — Power at nominal efficiency

1620 W (default) | positive scalar

Mechanical power driving moist air flow at the reference shaft speed under nominal, typical, or rated operating conditions.

**Dependencies**

To enable this parameter, set:

- **Fan parameterization** to Static pressure and flow rate at reference shaft speed.
- **Shaft power specification** to Brake power.

**Maximum static pressure gain at zero flow** — Maximum pressure at reference shaft speed

6400 Pa (default) | positive scalar

Pressure increase from port **A** to port **B** at the reference shaft speed when there is no flow through the fan.

**Dependencies**

To enable this parameter, set **Fan parameterization** to Static pressure and flow rate at reference shaft speed.

**Maximum volumetric flow rate at zero pressure** — Maximum flow rate at reference shaft speed

0.24 m<sup>3</sup>/s (default) | positive scalar

Free-delivery volumetric flow rate at the reference shaft speed and constant pressure.

**Dependencies**

To enable this parameter, set **Fan parameterization** to Static pressure and flow rate at reference shaft speed.

**Reference shaft speed** — Fan curve reference speed

3000 rpm (default) | positive scalar

Reference shaft angular velocity corresponding to the fan characteristic curve data.

**Dependencies**

To enable this parameter, set **Fan parameterization** to Static pressure and flow rate at reference shaft speed or 1D tabulated data - static pressure vs. flow rate at reference shaft speed.

**Minimum shaft speed threshold as fraction of reference** — Threshold for minimum shaft speed  
1e-2 (default) | positive scalar

Threshold for the minimum shaft speed as a fraction of the reference shaft speed. The block uses this value to prevent the shaft speed from becoming zero and causing a division by zero error in the expression for  $q_{ref}$ .

**Dependencies**

To enable this parameter, set **Fan parameterization** to Static pressure and flow rate at reference shaft speed or 1D tabulated data - static pressure vs. flow rate at reference shaft speed.

**Volumetric flow rate vector** — Fan curve flow rate vector  
[.0278, .0556, .0833, .111, .139, .167] m<sup>3</sup>/s (default) | vector

Vector of volumetric flow rate grid points for the 1-D interpolation of the fan characteristic curve. When **Shaft power specification** is Brake power, the fan data can extend beyond the normal operating region, and these values can be negative.

**Dependencies**

To enable this parameter, set **Fan parameterization** to 1D tabulated data - static pressure vs. flow rate at reference shaft speed.

**Static pressure gain vector** — Pressure gain for given volumetric flow rate  
[6410, 6375, 6018, 5366, 4501, 3609] Pa (default) | vector

Vector of pressure gain data points. Each element in the vector corresponds to an element in the **Volumetric flow rate vector** parameter. The pressure gain is the increase in pressure from port **A** to port **B** at the reference shaft speed. When **Shaft power specification** is Brake power, the fan data can extend beyond the normal operating region, and these values can be negative.

**Dependencies**

To enable this parameter, set **Fan parameterization** to 1D tabulated data - static pressure vs. flow rate at reference shaft speed.

**Efficiency vector** — Efficiency for given volumetric flow rate  
[.257, .394, .453, .47, .459, .415] (default) | vector

Vector of fan efficiency data points. Each element in the vector corresponds to an element in the **Volumetric flow rate vector** parameter. The efficiency is the ratio of fluid power to shaft mechanical power at the reference shaft speed.

**Dependencies**

To enable this parameter, set **Fan parameterization** to 1D tabulated data - static pressure vs. flow rate at reference shaft speed and **Shaft power specification** to Fan efficiency.

**Mechanical power vector** — Power for parameterization of torque  
[693, 900, 1107, 1267, 1363, 1452] W (default) | 1-by- $n$  vector

Vector of shaft mechanical power data points. Each element in the vector corresponds to an element in the **Volumetric flow rate vector** parameter. The mechanical power is the power that drives the fan at the reference shaft speed. These values can be negative if the fan data extends beyond the normal operating region.

#### Dependencies

To enable this parameter, set **Fan parameterization** to 1D tabulated data - static pressure vs. flow rate at reference shaft speed and **Shaft power specification** to Brake power.

**Reference density** — Density associated with fan curve data  
1.2 kg/m<sup>3</sup> (default) | positive scalar

Moist air density for a given characteristic fan curve.

#### Dependencies

To enable this parameter, set **Fan parameterization** to 1D tabulated data - static pressure vs. flow rate at reference shaft speed, 2D tabulated data - static pressure vs. shaft speed and flow rate or 2D tabulated data - flow rate vs. shaft speed and static pressure.

**Shaft speed vector,  $w$**  — Shaft angular velocity for given  
[2400; 3000; 3600] rpm (default) | vector

Vector of shaft angular velocity grid points for the 2-D interpolation of the fan characteristic curves.

#### Dependencies

To enable this parameter, set **Fan parameterization** to 2D tabulated data - static pressure vs. shaft speed and flow rate or 2D tabulated data - flow rate vs. shaft speed and static pressure.

**Volumetric flow rate vector,  $q$**  — Flow rate for parameterization of pressure gain  
[.0278, .0556, .0833, .111, .139, .167] m<sup>3</sup>/s (default) | 1-by- $n$  vector

Vector of volumetric flow rate grid points for the 2-D interpolation of the fan characteristic curves. When **Shaft power specification** is Brake power, the fan data can extend beyond the normal operating region, and these values can be negative.

#### Dependencies

To enable this parameter, set **Fan parameterization** to 2D tabulated data - static pressure vs. shaft speed and flow rate.

**Static pressure gain table,  $dp(w,q)$**  — Pressure for parameterization of pressure  
[4111, 4010, 3551, 2881, 2167, 1453; 6410, 6375, 6018, 5366, 4501, 3609; 9217, 9285, 9022, 8428, 7552, 6482] Pa (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of pressure gain data points for the 2-D interpolation of the pressure gain. The pressure gain is the increase in pressure from port **A** to port **B**. When **Shaft power specification** is Brake power, the fan data can extend beyond the normal operating region, and these values can be negative.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of elements in the **Shaft speed vector,  $w$**  parameter. The elements corresponding to zero flow rate must be in strictly ascending order.
- $N$  is the number of elements in the **Volumetric flow rate vector,  $q$**  parameter.

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the fan curves. Do not use artificial numerical values because these values distort fan behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Static pressure gain table,  $dp(w,q)$** , **Efficiency table,  $\eta(w,q)$** , and **Mechanical power table,  $W(w,q)$**  parameters must match each other.
- NaN elements must be located in the upper-right portion of the table, which corresponds to the highest volumetric flow rate and lowest shaft speed.

### Dependencies

To enable this parameter, set **Fan parameterization** to 2D tabulated data - static pressure vs. shaft speed and flow rate.

**Efficiency table,  $\eta(w,q)$**  — Efficiency for parameterization of torque

[.3, .434, .468, .459, .4, .3; .257, .394, .453, .47, .459, .415; .225, .359, .434, .461, .47, .459] 1 (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of efficiency data points for the 2-D interpolation of torque. The efficiency is the ratio of fluid power to shaft mechanical power.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of elements in the **Shaft speed vector,  $w$**  parameter.
- $N$  is the number of elements in the **Volumetric flow rate vector,  $q$**  parameter.

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the fan curves. Do not use artificial numerical values because these values distort fan behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Static pressure gain table,  $dp(w,q)$** , **Efficiency table,  $\eta(w,q)$** , and **Mechanical power table,  $W(w,q)$**  parameters must match each other.
- NaN elements must be located in the upper-right portion of the table, which corresponds to the highest volumetric flow rate and lowest shaft speed.

### Dependencies

To enable this parameter, set **Fan parameterization** to 2D tabulated data - static pressure vs. shaft speed and flow rate and **Shaft power specification** to Fan efficiency.

**Mechanical power table,  $W(w,q)$**  — Mechanical power for parameterization of torque

[381, 514, 632, 697, 753, 809; 693, 900, 1107, 1267, 1363, 1452; 1139, 1438, 1732, 2029, 2233, 2358]  $W$  (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  table of mechanical power data points for the 2-D interpolation of torque. These values can be negative if the fan data extends beyond the normal operating region. The mechanical power is the power that drives the fan.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of elements in the **Shaft speed vector,  $w$**  parameter. The elements corresponding to zero flow rate must be in strictly ascending order.
- $N$  is the number of elements in the **Volumetric flow rate vector,  $q$**  parameter.

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the fan curves. Do not use artificial numerical values because these values distort fan behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Static pressure gain table,  $dp(w,q)$** , **Efficiency table,  $\eta(w,q)$** , and **Mechanical power table,  $W(w,q)$**  parameters must match each other.
- NaN elements must be located in the upper-right portion of the table, which corresponds to the highest volumetric flow rate and lowest shaft speed.

#### Dependencies

To enable this parameter, set **Fan parameterization** to 2D tabulated data - static pressure vs. shaft speed and flow rate and **Shaft power specification** to Brake power.

**Static pressure gain vector,  $dp$**  — Pressure for parameterization of flow rate  
[31, 62, 93, 124] Pa (default) | 1-by- $N$  vector

Vector of pressure gain grid points for the 2-D interpolation of the fan characteristic curves. When **Shaft power specification** is Brake power, the fan data can extend beyond the normal operating region, and these values can be negative.

#### Dependencies

To enable this parameter, set **Fan parameterization** to 2D tabulated data - flow rate vs. shaft speed and static pressure.

**Volumetric flow rate table,  $q(w,dp)$**  — Flow rate for parameterization of flow rate  
[.802, .759, .703, .611; .936, .902, .862, .81; 1.056, 1.027, .994, .956]  
 $m^3/s$  (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of volumetric flow rate data points for the 2-D interpolation of volumetric flow rate. When **Shaft power specification** is Brake power, the fan data can extend beyond the normal operating region, and these values can be negative.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of elements in the **Shaft speed vector,  $w$**  parameter. The elements corresponding to zero flow rate must be in strictly ascending order.
- $N$  is the number of elements in the **Static pressure gain vector,  $Dp$**  parameter.

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the fan curves. Do not use artificial numerical values because these values distort fan behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Volumetric flow rate table,  $q(w,dp)$** , **Efficiency table,  $\eta(w,dp)$** , and **Mechanical power table,  $W(w,dp)$**  parameters must match each other.
- NaN elements must be located in the upper-right portion of the table, which corresponds to the highest volumetric flow rate and lowest shaft speed.

#### Dependencies

To enable this parameter, set **Fan parameterization** to 2D tabulated data - flow rate vs. shaft speed and static pressure.

**Efficiency table,  $\eta(w,dp)$**  — Efficiency for parameterization of torque

[.088, .162, .22, .261; .068, .128, .18, .222; .055, .105, .148, .188] (default)  
|  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of efficiency data points for the 2-D interpolation of torque. The efficiency is the ratio of fluid power to shaft mechanical power.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of elements in the **Shaft speed vector,  $w$**  parameter.
- $N$  is the number of elements in the **Static pressure gain vector,  $Dp$**  parameter.

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the fan curves. Do not use artificial numerical values because these values distort fan behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Volumetric flow rate table,  $q(w,dp)$** , **Efficiency table,  $\eta(w,dp)$** , and **Mechanical power table,  $W(w,dp)$**  parameters must match each other.
- NaN elements must be located in the upper-right portion of the table, which corresponds to the highest volumetric flow rate and lowest shaft speed.

#### Dependencies

To enable this parameter, set **Fan parameterization** to 2D tabulated data - flow rate vs. shaft speed and static pressure and **Shaft power specification** to Fan efficiency.

**Mechanical power table,  $W(w,dp)$**  — Mechanical power for parameterization of torque

[283, 290, 297, 290; 427, 437, 445, 452; 595, 606, 625, 631] W (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of mechanical power data points for the 2-D interpolation of torque. These values can be negative if the fan data extends beyond the normal operating region. The mechanical power is the power that drives the fan.  $M$  and  $N$  are the sizes of the corresponding vectors:

- $M$  is the number of elements in the **Shaft speed vector,  $w$**  parameter. The elements corresponding to zero flow rate must be in strictly ascending order.
- $N$  is the number of elements in the **Static pressure gain vector,  $Dp$**  parameter.

If your table has unknown data points, use NaN in place of these values. The block fills in the NaN elements by extrapolating based on the average slope of the fan curves. Do not use artificial numerical values because these values distort fan behavior when operating in that region. When using unknown data:

- The NaN elements in the table must be contiguous.
- The positions of the NaN elements in the **Volumetric flow rate table,  $q(w,dp)$** , **Efficiency table,  $\eta(w,dp)$** , and **Mechanical power table,  $W(w,dp)$**  parameters must match each other.
- NaN elements must be located in the upper-right portion of the table, which corresponds to the highest volumetric flow rate and lowest shaft speed.

### Dependencies

To enable this parameter, set **Fan parameterization** to 2D tabulated data - flow rate vs. shaft speed and static pressure and **Shaft power specification** to Brake power.

**Fan diameter scale factor** — Model-to-reference scale factor

1 (default) | positive scalar

Geometric scale factor to increase or decrease the size of the simulated fan from the given fan parameterization. The scaling may not be accurate for scale factors much larger or much smaller than 1.

**Mechanical orientation** — Rotational orientation

Positive angular velocity of port R relative to port C corresponds to normal fan operation (default) | Negative angular velocity of port R relative to port C corresponds to normal fan operation

Normal operating shaft direction. By default, flow and pressure gain are from port A to port B.

**Inlet flow area (port A)** — Port A area

$0.01 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the moist air flow at the fan inlet.

**Outlet flow area (port B)** — Port B area

$0.01 \text{ m}^2$  (default) | positive scalar

Cross-sectional area of the moist air flow at the fan outlet.

## Version History

**Introduced in R2018b**

### R2023a: Expose threshold for low shaft speed

Use the **Minimum shaft speed threshold as fraction of reference** parameter to control the minimum shaft speed threshold as a fraction of the reference shaft speed. The **Minimum shaft speed threshold as fraction of reference** parameter is available in the block when the **Fan parameterization** parameter is Static pressure and flow rate at reference shaft speed or 1D tabulated data – static pressure vs flow rate at reference shaft speed.

### R2022b: Extend performance beyond normal operating conditions

Both the 1-D and 2-D parameterizations now allow negative values. When simulation is outside the range of the provided table, block extrapolates the pressure based on the average slope of the fan curves.

You can now use NaN elements where data is unavailable. These 2-D tabulated fan parameters support contiguous NaN elements in the upper-right portion of the table:

- **Static pressure gain table,  $dp(w,q)$**
- **Efficiency table,  $eta(w,q)$**
- **Mechanical power table,  $W(w,q)$**
- **Volumetric flow rate table,  $q(w,dp)$**
- **Efficiency table,  $eta(w,dp)$**
- **Mechanical power table,  $W(w,dp)$**

For each block, if the shaft rotates opposite to the specified mechanical orientation, the pressure difference across the block drops to zero and the results may not be accurate.

### **R2021b: 2-D Tabulated Data Parameterization: Flow Rate as a Function of Shaft Speed and Pressure Ratio**

*Not recommended starting in R2021b*

In R2021b, the block no longer supports the 2-D Tabulated Data Parameterization: Flow Rate as a Function of Shaft Speed and Pressure Ratio parameterization. In R2021b and later, if you open models created in a prior release that include the Fan (G) block, Simscape Fluids replaces the block with the Fan (MA) - Legacy block. This block supports the 2-D Tabulated Data Parameterization: Flow Rate as a Function of Shaft Speed and Pressure Ratio setting.

You can preserve the functionality of a model using this parameterization by setting **Fan parameterization** to 2D tabulated data - flow rate vs. shaft speed and static pressure<sup>1</sup> and converting the ratios to absolute values. An example script that performs this conversion takes in the legacy parameters `omega_DpMax_TLU`, `DpMax_TLU`, `omega_flow_TLU`, `Dp_DpMax_TLU`, `flow_rate_TLU`, and `eta_flow_TLU` and returns the converted parameters `omega_g_TLU`, `pressure_g_TLU`, `pressure_g_TLU`, and `eta_g_TLU`:

```
% Shaft speed vector for maximum pressure rise vector
omega_DpMax_TLU = [1800, 2400, 3000];

% Maximum pressure rise vector
DpMax_TLU       = [400, 1200, 2000];

% Shaft speed vector, omega
omega_flow_TLU  = [1800, 2400, 3000];

% Static pressure rise ratio vector, Dp/DpMax
Dp_DpMax_TLU    = linspace(0, 1, 4);

% Flow rate table, q(omega,Dp/DpMax)
flow_rate_TLU   = [
    0.33    0.26    0.18    0.07
    1.20    0.91    0.64    0.26
```

1 Prior to R2021b, this setting was called 2D tabulated data - flow rate and total efficiency vs. angular speed and static pressure.

```

    1.84    1.61    1.13    0.46];

% Total efficiency table, Eta(omega,Dp/DpMax)
eta_flow_TLU = [
    0.22    0.25    0.27    0.28
    0.48    0.52    0.55    0.53
    0.42    0.45    0.49    0.44];

% Create interpolants of the tables
DpMax_TLU_interp = griddedInterpolant(omega_DpMax_TLU, DpMax_TLU, ...
    'linear', 'linear');

flow_rate_TLU_interp = griddedInterpolant({omega_flow_TLU, Dp_DpMax_TLU}, flow_rate_TLU, ...
    'linear', 'linear');

eta_flow_TLU_interp = griddedInterpolant({omega_flow_TLU, Dp_DpMax_TLU}, eta_flow_TLU, ...
    'linear', 'nearest');

% Maximum pressure rise
DpMax = DpMax_TLU_interp(max(omega_flow_TLU, omega_DpMax_TLU(1)));

% Shaft speed vector, w
omega_q_TLU = omega_flow_TLU;

% Static pressure gain vector, Dp
pressure_q_TLU = unique(DpMax(:)*Dp_DpMax_TLU(:)');

% Interpolation query points as full grid arrays
omega_grid = omega_q_TLU(:)*ones(1, length(pressure_q_TLU));

Dp_DpMax_grid = pressure_q_TLU(:)' ./ DpMax(:);

% Volumetric flow rate table, q(w,Dp)
flow_rate_q_TLU = flow_rate_TLU_interp(omega_grid, Dp_DpMax_grid);

flow_rate_q_TLU = max(flow_rate_q_TLU, 1e-4*flow_rate_TLU(1,1)); % keep it > 0

% Efficiency table, eta(w,Dp)
eta_q_TLU = eta_flow_TLU_interp(omega_grid, Dp_DpMax_grid);

```

## Fixed Orifice

(To be removed) Hydraulic orifice with constant cross-sectional area

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

### Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Orifices

### Description

The Fixed Orifice block models a sharp-edged constant-area orifice, flow rate through which is proportional to the pressure differential across the orifice. The flow rate is determined according to the following equations:

$$q = C_D \cdot A \sqrt{\frac{2}{\rho}} \cdot \frac{p}{(p^2 + p_{cr}^2)^{1/4}}$$

$$\Delta p = p_A - p_B,$$

where

$q$	Flow rate
$p$	Pressure differential
$p_A, p_B$	Gauge pressures at the block terminals
$C_D$	Flow discharge coefficient
$A$	Orifice passage area
$\rho$	Fluid density
$p_{cr}$	Minimum pressure for turbulent flow

The minimum pressure for turbulent flow,  $p_{cr}$ , is calculated according to the laminar transition specification method:

- By pressure ratio — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{cr} = (p_{avg} + p_{atm})(2 - B_{lam})$$

$$p_{avg} = (p_A + p_B)/2$$

where

$p_{\text{avg}}$	Average pressure between the block terminals
$p_{\text{atm}}$	Atmospheric pressure, 101325 Pa
$B_{\text{lam}}$	Pressure ratio at the transition between laminar and turbulent regimes ( <b>Laminar flow pressure ratio</b> parameter value)

- By Reynolds number — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{cr} = \frac{\rho}{2} \left( \frac{Re_{cr} \cdot \nu}{C_D \cdot D_H} \right)^2$$

$$D_H = \sqrt{\frac{4A}{\pi}}$$

where

$D_H$	Orifice hydraulic diameter
$\nu$	Fluid kinematic viscosity
$Re_{cr}$	Critical Reynolds number ( <b>Critical Reynolds number</b> parameter value)

The block positive direction is from port A to port B. This means that the flow rate is positive if it flows from A to B, and the pressure differential is determined as  $\Delta p = p_A - p_B$ .

## Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

## Assumptions and Limitations

- Fluid inertia is not taken into account.

## Ports

### Conserving

**A** — Hydraulic conserving port associated with the orifice inlet  
hydraulic

Hydraulic conserving port associated with the orifice inlet.

**B** — Hydraulic conserving port associated with the orifice outlet  
hydraulic

Hydraulic conserving port associated with the orifice outlet.

## Parameters

**Orifice area** — Orifice passage area  
1e-4 m<sup>2</sup> (default) | positive scalar

Orifice passage area.

**Flow discharge coefficient** — Semi-empirical parameter for orifice capacity characterization  
0.7 (default) | positive scalar

Semi-empirical parameter for orifice capacity characterization. Its value depends on the geometrical properties of the orifice, and usually is provided in textbooks or manufacturer data sheets.

**Laminar transition specification** — Select how block transitions between the laminar and turbulent regimes  
Pressure ratio (default) | Reynolds number

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

**Laminar flow pressure ratio** — Pressure ratio at which the flow transitions between laminar and turbulent regimes  
0.999 (default) | positive scalar in the range of (0,1)

Pressure ratio at which the flow transitions between laminar and turbulent regimes.

### Dependencies

To enable this parameter, set **Laminar transition specification** to **Pressure ratio**.

**Critical Reynolds number** — Maximum Reynolds number for laminar flow  
12 (default) | positive scalar

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 12, which corresponds to a round orifice in thin material with sharp edges.

### Dependencies

To enable this parameter, set **Laminar transition specification** to **Reynolds number**.

## Version History

## Library

Orifices

### Description

The Fixed Orifice Empirical block models a fixed orifice in hydraulic systems with data obtained from experimental testing. The data required for characterization is the set of pressure differentials across the orifice, together with associated flow rates determined for a particular fluid and temperature.

The flow rate through the orifice is determined with the table lookup block from the set of experimental measurements

$$q = f(p)$$

where

$q$	Volumetric flow rate
$p$	Pressure differential

You can select from two interpolation and two extrapolation methods.

---

**Note** Extrapolation could result in large errors if the operating point deviates significantly from the area of experiments.

---

The block positive direction is from port A to port B. This means that the flow rate is positive if it flows from A to B, and the pressure differential is determined as  $\Delta p = p_A - p_B$ .

## Parameters

### Tabulated pressure differentials

Specify the pressure differential vector as a one-dimensional array. The vector contains values of pressure differentials obtained during experimental characterization of the orifice. The vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation. The default values, in bar, are [-40.0, -30.0, -20.0, -10.0, -5.0, 0.0, 5.0, 10.0, 20.0, 30.0, 40.0].

### Tabulated flow rates

Specify the vector of flow rates through the orifice, corresponding to these pressure differentials, as a one-dimensional array. The vector must be of the same size as the **Tabulated pressure differentials** vector. The default values, in m<sup>3</sup>/s, are [ -0.0024436 -0.0021248 -0.0016852 -0.0012248 -8.4476e-4 0 8.5333e-4 0.0012068 0.0017067 0.0020902 0.0024136 ].

### Interpolation method

Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- **Linear** — Select this option to get the best performance.
- **Smooth** — Select this option to produce a continuous curve with continuous first-order derivatives.

For more information on interpolation algorithms, see the PS Lookup Table (1D) block reference page.

### Extrapolation method

Use extrapolation with extreme caution, because moving beyond the measurement limits could result in large errors. Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- **Linear** — Select this option to produce a curve with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.
- **Nearest** — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see the PS Lookup Table (1D) block reference page.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the orifice inlet.

B

Hydraulic conserving port associated with the orifice outlet.

## **Version History**

## Library

Orifices

## Description

The Fixed Orifice with Fluid Inertia block models a hydraulic fixed orifice and accounts for the fluid inertia, in addition to the static pressure loss.

Fluid inertia plays a noticeable role in orifices with a large ratio of orifice length to the orifice hydraulic diameter ( $L / D_H$ ) and in sharp-edged short orifices when the rate of change of flow rate (fluid acceleration) is relatively large.

The orifice is based on the following equations:

$$q = C_D \cdot A \sqrt{\frac{2}{\rho}} \cdot \frac{p_r}{(p_r^2 + p_{Cr}^2)^{1/4}}$$

$$p = p_{in} + p_r$$

$$p_{in} = \rho \frac{L}{A} \frac{dq}{dt}$$

where

$q$	Volumetric flow rate
$p$	Total pressure differential
$p_{in}$	Inertial pressure drop
$p_r$	Resistive pressure drop
$C_D$	Flow discharge coefficient
$A$	Orifice passage area

$L$	Orifice length
$\rho$	Fluid density
$p_{cr}$	Minimum pressure for turbulent flow

The minimum pressure for turbulent flow,  $p_{cr}$ , is calculated according to the laminar transition specification method:

- By pressure ratio — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{cr} = (p_{avg} + p_{atm})(1 - B_{lam})$$

$$p_{avg} = (p_A + p_B)/2$$

where

$p_{avg}$	Average pressure between the block terminals
$p_{atm}$	Atmospheric pressure, 101325 Pa
$B_{lam}$	Pressure ratio at the transition between laminar and turbulent regimes ( <b>Laminar flow pressure ratio</b> parameter value)

- By Reynolds number — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{cr} = \frac{\rho}{2} \left( \frac{Re_{cr} \cdot \nu}{C_D \cdot D_H} \right)^2$$

$$D_H = \sqrt{\frac{4A}{\Pi}}$$

where

$D_H$	Orifice hydraulic diameter
$\nu$	Fluid kinematic viscosity
$Re_{cr}$	Critical Reynolds number ( <b>Critical Reynolds number</b> parameter value)

Connections A and B are conserving hydraulic ports associated with the orifice inlet and outlet, respectively. The block positive direction is from port A to port B. This means that the flow rate is positive if it flows from A to B, and the pressure differential is determined as  $\Delta p = p_A - p_B$ .

## Parameters

### Orifice area

Cross-sectional area of the orifice. The default value is  $1e-4 \text{ m}^2$ .

### Orifice length

Total length of the orifice. Generally, increase the geometrical length of the orifice up to  $2 \cdot 0.8 \cdot D_H$  (where  $D_H$  is the orifice hydraulic diameter) to take into account the added volumes of fluid on both sides of the orifice. The default value is  $0.01 \text{ m}$ .

**Flow discharge coefficient**

Semi-empirical parameter for orifice capacity characterization. The coefficient affects the resistive pressure drop in the orifice. The default value is 0.6.

**Laminar transition specification**

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

**Laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

**Critical Reynolds number**

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 10. This parameter is visible only if the **Laminar transition specification** parameter is set to **Reynolds number**.

**Initial flow rate**

Flow rate through the orifice at the start of simulation. This parameter specifies the initial condition for use in computing the block's state at the beginning of a simulation run. For more information, see "Initial Conditions Computation". The default value is 0.

**Global Parameters**

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

**Ports**

The block has the following ports:

A

Hydraulic conserving port associated with the orifice inlet.

B

Hydraulic conserving port associated with the orifice outlet.

**Version History**

Introduced in R2013a

**R2023a: To be removed**

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

# Fixed-Displacement Motor

(To be removed) Hydraulic-to-mechanical power conversion device

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Pumps and Motors

## Description

The Fixed-Displacement Motor block represents a device that extracts power from a hydraulic (isothermal liquid) network and delivers it to a mechanical rotational network. The motor displacement is fixed at a constant value that you specify through the **Displacement** parameter.

Ports **A** and **B** represent the motor inlet and outlet, respectively. Port **S** represents the motor drive shaft. During normal operation, the angular velocity at port **S** is positive if the pressure drop from port **A** to port **B** is positive also. This operation mode is referred to here as forward motor.

## Operation Modes

A total of four operation modes are possible. The working mode depends on the pressure drop from port **A** to port **B** ( $\Delta p$ ) and on the angular velocity at port **S** ( $\omega$ ). The “Operation Modes” on page 1-835 figure maps the modes to the octants of a  $\Delta p$ - $\omega$ - $D$  chart. The modes are labeled 1-4:

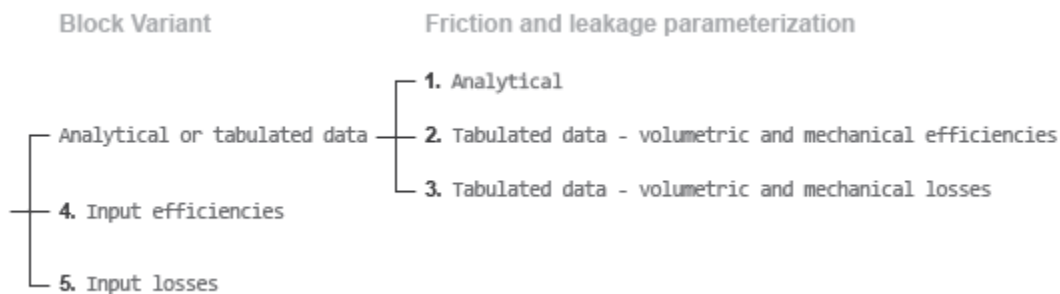

- Mode **1**: forward motor — A positive pressure drop generates a positive shaft angular velocity.
- Mode **2**: reverse pump — A negative shaft angular velocity generates a negative pressure gain (shown in the figure as a positive pressure drop).

- Mode 3: reverse motor — A negative pressure drop generates a negative shaft angular velocity.
- Mode 4: forward pump — A positive shaft angular velocity generates a positive pressure gain (shown in the figure as a negative pressure drop).

The response time of the motor is considered negligible in comparison with the system response time. The motor is assumed to reach steady state nearly instantaneously and is treated as a quasi-steady component.

### Block Variants and Loss Parameterizations

The motor model accounts for power losses due to leakage and friction. Leakage is internal and occurs between the motor inlet and outlet only. The block computes the leakage flow rate and friction torque using your choice of five loss parameterizations. You select a parameterization using block variants and, in the Analytical or tabulated data case, the **Leakage and friction parameterization** parameter.

### Loss Parameterizations

The block provides three Simscape variants to select from. To change the active block variant, use the **Modeling option** parameter. The available variants are:

- Analytical or tabulated data — Obtain the mechanical and volumetric efficiencies or losses from analytical models based on nominal parameters or from tabulated data. Use the **Leakage and friction parameterization** parameter to select the exact input type.
- Input efficiencies — Provide the mechanical and volumetric efficiencies directly through physical signal input ports.
- Input losses — Provide the mechanical and volumetric losses directly through physical signal input ports. The mechanical loss is defined as the internal friction torque. The volumetric loss is defined as the internal leakage flow rate.

### Flow Rate and Driving Torque

The volumetric flow rate required to power the motor is

$$q = q_{\text{Ideal}} + q_{\text{Leak}}$$

where:

- $q$  is the net volumetric flow rate.
- $q_{\text{Ideal}}$  is the ideal volumetric flow rate.
- $q_{\text{Leak}}$  is the internal leakage volumetric flow rate.

The torque generated at the motor is

$$\tau = \tau_{\text{Ideal}} - \tau_{\text{Friction}},$$

where:

- $\tau$  is the net torque.
- $\tau_{\text{Ideal}}$  is the ideal torque.
- $\tau_{\text{Friction}}$  is the friction torque.

### Ideal Flow Rate and Ideal Torque

The ideal volumetric flow rate is

$$q_{\text{Ideal}} = D\omega,$$

and the ideal generated torque is

$$\tau_{\text{Ideal}} = D\Delta p,$$

where:

- $D$  is the specified value of the **Displacement** block parameter.
- $\omega$  is the instantaneous angular velocity of the rotary shaft.
- $\Delta p$  is the instantaneous pressure drop from inlet to outlet.

### Leakage Flow Rate and Friction Torque

The internal leakage flow rate and friction torque calculations depend on the block variant selected. If the block variant is **Analytical** or **tabulated data**, the calculations depend also on the **Leakage and friction parameterization** parameter setting. There are five possible permutations of block variant and parameterization settings.

### Case 1: Analytical Efficiency Calculation

If the active block variant is **Analytical** or **tabulated data** and the **Leakage and friction parameterization** parameter is set to **Analytical**, the leakage flow rate is

$$q_{\text{Leak}} = K_{\text{HP}}\Delta p,$$

and the friction torque is

$$\tau_{\text{Friction}} = (\tau_0 + K_{\text{TP}}|\Delta p|)\tanh\left(\frac{4\omega}{\omega_{\text{Threshold}}}\right),$$

where:

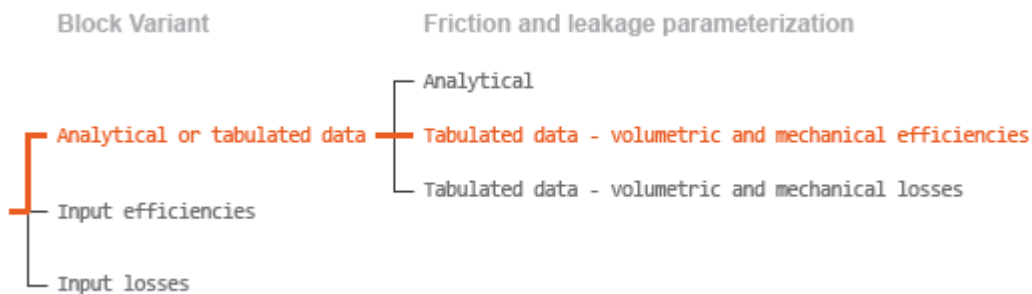

- $K_{HP}$  is the Hagen-Poiseuille coefficient for laminar pipe flows. This coefficient is computed from the specified nominal parameters.
- $K_{TP}$  is the specified value of the **Friction torque vs pressure drop coefficient** block parameter.
- $\tau_0$  is the specified value of the **No-load torque** block parameter.
- $\omega_{Threshold}$  is the threshold angular velocity for the motor-pump transition. The threshold angular velocity is an internally set fraction of the specified value of the **Nominal shaft angular velocity** block parameter.

The Hagen-Poiseuille coefficient is determined from nominal fluid and component parameters through the equation

$$K_{HP} = \frac{\nu_{Nom} \rho_{Nom} \omega_{Nom} D_{Max}}{\rho v \Delta p_{Nom}} \left( \frac{1}{\eta_{v,Nom}} - 1 \right),$$

where:

- $\nu_{Nom}$  is the specified value of the **Nominal kinematic viscosity** block parameter. This is the kinematic viscosity at which the nominal volumetric efficiency is specified.
- $\rho_{Nom}$  is the specified value of the **Nominal fluid density** block parameter. This is the density at which the nominal volumetric efficiency is specified.
- $\omega_{Nom}$  is the specified value of the **Nominal shaft angular velocity** block parameter. This is the angular velocity at which the nominal volumetric efficiency is specified.
- $\rho$  is the actual fluid density in the attached hydraulic (isothermal liquid) network. This density can differ from the specified value of the **Nominal fluid density** block parameter.
- $v$  is the kinematic viscosity of the fluid associated with the fluid network.
- $\Delta p_{Nom}$  is the specified value of the **Nominal pressure drop** block parameter. This is the pressure drop at which the nominal volumetric efficiency is specified.
- $\eta_{v,Nom}$  is the specified value of the **Volumetric efficiency at nominal conditions** block parameter. This is the volumetric efficiency corresponding to the specified nominal conditions.

### Case 2: Efficiency Tabulated Data

If the active block variant is **Analytical** or **tabulated data** and the **Leakage and friction parameterization** parameter is set to **Tabulated data – volumetric and mechanical efficiencies**, the leakage flow rate is

$$q_{Leak} = q_{Leak, Motor} \frac{(1 + \alpha)}{2} + q_{Leak, Pump} \frac{(1 - \alpha)}{2},$$

and the friction torque is

$$\tau_{\text{Friction}} = \tau_{\text{Friction, Motor}} \frac{1 + \alpha}{2} + \tau_{\text{Friction, Pump}} \frac{1 - \alpha}{2},$$

where:

- $\alpha$  is a numerical smoothing parameter for the motor-pump transition.
- $q_{\text{Leak, Motor}}$  is the leakage flow rate in motor mode.
- $q_{\text{Leak, Pump}}$  is the leakage flow rate in pump mode.
- $\tau_{\text{Friction, Motor}}$  is the friction torque in motor mode.
- $\tau_{\text{Friction, Pump}}$  is the friction torque in pump mode.

The smoothing parameter  $\alpha$  is given by the hyperbolic function

$$\alpha = \tanh\left(\frac{4\Delta p}{\Delta p_{\text{Threshold}}}\right) \cdot \tanh\left(\frac{4\omega}{\omega_{\text{Threshold}}}\right),$$

where:

- $\Delta p_{\text{Threshold}}$  is the specified value of the **Pressure drop threshold for motor-pump transition** block parameter.
- $\omega_{\text{Threshold}}$  is the specified value of the **Angular velocity threshold for motor-pump transition** block parameter.

The leakage flow rate is computed from efficiency tabulated data through the equation

$$q_{\text{Leak, Motor}} = (1 - \eta_v)q,$$

in motor mode and through the equation

$$q_{\text{Leak, Pump}} = -(1 - \eta_v)q_{\text{Ideal}}.$$

in pump mode, where:

- $\eta_v$  is the volumetric efficiency obtained through interpolation or extrapolation of the **Volumetric efficiency table, e\_v(dp,w)** parameter data.

Similarly, the friction torque is computed from efficiency tabulated data through the equation

$$\tau_{\text{Friction, Motor}} = (1 - \eta_m)\tau_{\text{Ideal}},$$

in motor mode and through the equation

$$\tau_{\text{Friction, Pump}} = -(1 - \eta_m)\tau.$$

in pump mode, where:

- $\eta_m$  is the mechanical efficiency obtained through interpolation or extrapolation of the **Mechanical efficiency table, e\_m(dp,w)** parameter data.

**Case 3: Loss Tabulated Data**

If the active block variant is Analytical or tabulated data and the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical losses, the leakage flow rate equation is

$$q_{Leak} = q_{Leak}(\Delta p, \omega).$$

and the friction torque equation is

$$\tau_{Friction} = \tau_{Friction}(\Delta p, \omega),$$

where  $q_{Leak}(\Delta p, \omega)$  and  $\tau_{Friction}(\Delta p, \omega)$  are the volumetric and mechanical losses, obtained through interpolation or extrapolation of the **Volumetric loss table, q\_loss(dp,w)** and **Mechanical loss table, torque\_loss (dp,w)** parameter data.

**Case 4: Efficiency Physical Signal Inputs**

If the active block variant is Input efficiencies, the leakage flow rate and friction torque calculations are as described for efficiency tabulated data (case 2). The volumetric and mechanical efficiency lookup tables are replaced with physical signal inputs that you specify through ports EV and EM.

### Case 5: Loss Physical Signal Inputs

If the block variant is `Input losses`, the leakage flow rate and friction torque calculations are as described for loss tabulated data (case 3). The volumetric and mechanical loss lookup tables are replaced with physical signal inputs that you specify through ports LV and LM.

### Characteristic Curve Visualization

If the block variant is set to `Analytical or tabulated data`, you can plot a variety of performance, efficiency, and loss curves from simulation data and component parameters. Use the context-sensitive menu of the block to plot the characteristic curves. Right-click the block to open the menu and select **Fluids > Plot characteristic**. A test harness opens with instructions on how to generate the curves.

### Assumptions

- Fluid compressibility is negligible.
- Loading on the motor shaft due to inertia, friction, and spring forces is negligible.

## Ports

### Input

**EV** — Volumetric efficiency, unitless  
physical signal

Physical signal input port for the volumetric efficiency coefficient. The input signal has an upper bound at the **Maximum volumetric efficiency** parameter value and a lower bound at the **Minimum volumetric efficiency** parameter value.

### Dependencies

This port is exposed only when the block variant is set to `Input efficiencies`.

**EM** — Mechanical efficiency, unitless  
physical signal

Physical signal input port for the mechanical efficiency coefficient. The input signal has an upper bound at the **Maximum mechanical efficiency** parameter value and a lower bound at the **Minimum mechanical efficiency** parameter value.

**Dependencies**

This port is exposed only when the block variant is set to `Input efficiencies`.

**LV** — Volumetric loss,  $m^3/s$   
physical signal

Physical signal input port for the volumetric loss, defined as the internal leakage flow rate between the motor inlets.

**Dependencies**

This port is exposed only when the block variant is set to `Input losses`.

**LM** — Mechanical loss,  $N*m$   
physical signal

Physical signal input port for the mechanical loss, defined as the friction torque on the rotating motor shaft.

**Dependencies**

This port is exposed only when the block variant is set to `Input losses`.

**Conserving**

**A** — Motor inlet  
hydraulic (isothermal)

Hydraulic (isothermal liquid) port representing the motor inlet.

**B** — Motor outlet  
hydraulic (isothermal)

Hydraulic (isothermal liquid) port representing the motor outlet.

**S** — Motor shaft  
mechanical rotational

Mechanical rotational port representing the motor shaft.

**Parameters**

The exposed block parameters depend on the active block variant. See “Block Variants and Loss Parameterizations” on page 1-836.

**Modeling option** — Loss parameterizations  
`Analytical or tabulated data` | `Input efficiencies` | `Input losses`

Set the variant for mechanical and volumetric efficiencies or losses for the block.

**Variant 1: Analytical or tabulated data**

**Displacement** — Fluid volume displaced per unit shaft rotation angle  
`30 cm3/rev` (default) | scalar with units of volume/angle

Fluid volume displaced per unit shaft rotation angle. The displacement is fixed at this value during simulation. The specified value must be greater than zero.

**Leakage and friction parameterization** — Parameterization used to compute leakage flow rate and friction torque

Analytical (default) | Tabulated data – volumetric and mechanical efficiencies |  
Tabulated data – volumetric and mechanical losses

Parameterization used to compute flow-rate and torque losses due to internal leaks and friction. The Analytical parameterization relies on nominal parameters generally available from component data sheets. The remaining, tabular, options rely on lookup tables to map pressure drop and angular velocity to component efficiencies or losses. The tabular options include:

- Tabulated data – volumetric and mechanical efficiencies
- Tabulated data – volumetric and mechanical losses

**Nominal shaft angular velocity** — Shaft angular velocity at which to specify the nominal volumetric efficiency

188 rad/s (default) | scalar with units of angle/time

Angular velocity of the rotating shaft at which the component's nominal volumetric efficiency is known. Nominal parameters are typically published for standard operating conditions in manufacturer's data sheets. The block uses this parameter to calculate, using simple linear functions, the leakage flow rate and friction torque.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Analytical.

**Nominal pressure drop** — Pressure gain at which to specify the nominal volumetric efficiency

100e5 Pa (default) | scalar with units of pressure

Pressure drop from inlet to outlet at which the component's nominal volumetric efficiency is known. Nominal parameters are typically published for standard operating conditions in manufacturer's data sheets. The block uses this parameter to calculate, using a simple linear function, the internal leakage flow rate.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Analytical.

**Nominal kinematic viscosity** — Kinematic viscosity at which to specify the nominal volumetric efficiency

18 cSt (default) | scalar with units of area/time

Kinematic viscosity of the hydraulic fluid at which the component's nominal volumetric efficiency is known. Nominal parameters are typically published for standard operating conditions in manufacturer's data sheets. The block uses this parameter to calculate, using a simple linear function, the internal leakage flow rate.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Analytical.

**Nominal fluid density** — Fluid density at which to specify the nominal volumetric efficiency  
900 kg/m<sup>3</sup> (default) | scalar with units of mass/volume

Mass density of the hydraulic fluid at which the component's nominal volumetric efficiency is known. Nominal parameters are typically published for standard operating conditions in manufacturer's data sheets. The block uses this parameter to calculate, using a simple linear function, the internal leakage flow rate.

**Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Analytical.

**Volumetric efficiency at nominal conditions** — Volumetric efficiency at the specified nominal conditions  
0.92 (default) | unitless scalar between 0 and 1

Volumetric efficiency, defined as the ratio of actual to ideal volumetric flow rates, at the specified nominal conditions. Nominal parameters are typically published for standard operating conditions in manufacturer's data sheets. The block uses this parameter to calculate, using a simple linear function, the internal leakage flow rate.

**Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Analytical.

**No-load torque** — Minimum torque required to induce shaft rotation  
0.05 N\*m (default) | scalar with units of torque

Torque required to overcome seal friction and induce rotation of the mechanical shaft. This torque is the load-independent component of the total friction torque.

**Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Analytical.

**Friction torque vs. pressure drop coefficient** — Proportionality constant between friction torque and pressure drop  
0.6e-6 N\*m/Pa (default) | scalar with units of torque/pressure

Proportionality constant between the friction torque on the mechanical shaft and the pressure drop from inlet to outlet.

**Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies.

**Check if lower side pressure violating minimum valid condition** — Simulation warning mode for minimum valid pressure  
None (default) | Warning

Simulation warning mode for invalid pressures at the component ports. Select Warning to be notified when pressure falls below a minimum specified value. The warning can be useful in models where

pressure can fall below the saturated vapor pressure of the hydraulic fluid, causing cavitation to occur.

**Minimum valid pressure** — Pressure required to trigger simulation warning

0 (default) | scalar with units of pressure

Lower bound of the pressure validity range. A warning is issued if pressure falls below the specified value.

#### Dependencies

This parameter is enabled when the **Check if lower side pressure violating minimum valid condition** parameter is set to Warning.

**Pressure drop vector for efficiencies, dp** — Pressure drops at which to specify the volumetric and mechanical efficiencies

$M$ -element vector with units of pressure (default)

$M$ -element vector of pressure gains at which to specify the efficiency tabular data. The vector size,  $M$ , must be two or greater. The vector elements need not be uniformly spaced. However, they must monotonically increase in value from left to right.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies.

**Shaft angular velocity vector for efficiencies, w** — Angular velocities at which to specify the volumetric and mechanical efficiencies

$N$ -element vector with units of angular velocity (default)

$N$ -element vector of shaft angular velocities at which to specify the efficiency tabular data. The vector size,  $N$ , must be two or greater. The vector elements need not be uniformly spaced. However, they must monotonically increase in value from left to right.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies.

**Volumetric efficiency table, e\_v(dp,w)** — Volumetric efficiencies at the specified pressure drops and angular velocities

unitless  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix with the volumetric efficiencies at the specified fluid pressure drops and shaft angular velocities. The efficiencies must fall in the range of 0-1.  $M$  and  $N$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure drop vector for efficiencies, dp** parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector for efficiencies, w** parameter.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies.

**Mechanical efficiency table,  $e_m(dp,w)$**  — Mechanical efficiencies at the specified pressure drops and angular velocities  
unitless  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix with the mechanical efficiencies corresponding to the specified fluid pressure drops and shaft angular velocities. The efficiencies must fall in the range of 0-1.  $M$  and  $N$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure drop vector for efficiencies,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector for efficiencies,  $w$**  parameter.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies.

**Pressure drop threshold for motor-pump transition** — Pressure drop at which to initiate a smooth transition between motoring and pumping modes  
 $1e5$  Pa (default) | scalar with units of pressure

Pressure drop from inlet to outlet below which the component begins to transition between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies.

**Angular velocity threshold for pump—motor transition** — Shaft angular velocity at which to initiate a smooth transition between motoring and pumping modes  
 $10$  rad/s (default) | scalar with units of angle/time

Shaft angular velocity below which the component begins to transition between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies.

**Check if operating beyond the quadrants of supplied tabulated data** — Simulation warning mode for operating conditions outside the range of tabulated data  
None (default) | Warning

Simulation warning mode for operating conditions outside the range of tabulated data. Select Warning to be notified when the fluid pressure gain or shaft angular velocity cross outside the specified tabular data. The warning does not cause simulation to stop.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies or Tabulated data – volumetric and mechanical losses.

**Pressure drop vector for losses,  $dp$**  — Pressure drops at which to specify the volumetric and mechanical losses

*M*-element vector with units of pressure (default)

*M*-element vector of pressure drops at which to specify the loss tabular data. The vector size, *M*, must be two or greater. The vector elements need not be uniformly spaced. However, they must monotonically increase in value from left to right.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical losses.

**Shaft angular velocity vector for losses,  $w$**  — Angular velocities at which to specify the volumetric and mechanical losses

*N*-element vector with units of angle/time (default)

*N*-element vector of shaft angular velocities at which to specify the component loss data. The vector size, *N*, must be two or greater. The vector elements need not be uniformly spaced. However, they must monotonically increase in value from left to right.

#### Dependencies

This parameter is enabled the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical losses.

**Volumetric loss table,  $q\_loss(dp,w)$**  — Internal leakage flow rates at the specified pressure gains and angular velocities

*M*-by-*N* matrix with units of volume/time

*M*-by-*N* matrix with the volumetric gains at the specified fluid pressure drops and shaft angular velocities. Volumetric loss is defined here as the internal leakage volumetric flow rate between port A and port B. *M* and *N* are the sizes of the specified lookup-table vectors:

- *M* is the number of vector elements in the **Pressure drop vector for losses,  $dp$**  parameter.
- *N* is the number of vector elements in the **Shaft angular velocity vector for losses,  $w$**  parameter.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical losses.

**Mechanical loss table,  $torque\_loss(dp,w)$**  — Friction torques at the specified pressure gains and angular velocities

*M*-by-*N* matrix with units of torque

*M*-by-*N* matrix with the mechanical losses at the specified fluid pressure drops and shaft angular velocities. Mechanical loss is defined here as the friction torque due to seals and internal components. *M* and *N* are the sizes of the specified lookup-table vectors:

- *M* is the number of vector elements in the **Pressure drop vector for losses,  $dp$**  parameter.
- *N* is the number of vector elements in the **Shaft angular velocity vector for losses,  $w$**  parameter.

**Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical losses.

**Variant 2: Input efficiencies**

**Displacement** — Fluid volume displaced per unit shaft rotation angle

30 cm<sup>3</sup>/rev (default) | scalar with units of volume/angle

Fluid volume displaced per unit shaft rotation angle. The displacement is fixed at this value during simulation. The specified value must be greater than zero.

**Minimum volumetric efficiency** — Lower saturation bound on the volumetric efficiency input signal

1e-3 (default) | unitless scalar between 0 and 1

Smallest allowed value of the volumetric efficiency. The input from physical signal port EV saturates at the specified value. If the input signal falls below the minimum volumetric efficiency, the volumetric efficiency is set to the minimum volumetric efficiency.

**Maximum volumetric efficiency** — Upper saturation bound on the volumetric efficiency input signal

1 (default) | unitless scalar between 0 and 1

Largest allowed value of the volumetric efficiency. The input from physical signal port EV saturates at the specified value. If the input signal rises above the maximum volumetric efficiency, the volumetric efficiency is set to the maximum volumetric efficiency.

**Minimum mechanical efficiency** — Lower saturation bound on the volumetric efficiency input signal

1e-3 (default) | unitless scalar between 0 and 1

Smallest allowed value of the mechanical efficiency. The input from physical signal port EM saturates at the specified value. If the input signal falls below the minimum mechanical efficiency, the mechanical efficiency is set to the minimum mechanical efficiency.

**Maximum mechanical efficiency** — Upper saturation bound on the volumetric efficiency input signal

1 (default) | unitless scalar between 0 and 1

Largest allowed value of the mechanical efficiency. The input from physical signal port EM saturates at this value. If the input signal rises above the maximum mechanical efficiency, the mechanical efficiency is set to the maximum mechanical efficiency.

**Pressure drop threshold for motor-pump transition** — Pressure drop at which to initiate a smooth transition between motoring and pumping modes

1e5 Pa (default) | scalar with units of pressure

Pressure drop from inlet to outlet below which the component begins to transition between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Angular velocity threshold for motor–pump transition** — Shaft angular velocity at which to initiate a smooth transition between motoring and pumping modes

10 rad/s (default) | scalar with units of angle/time

Shaft angular velocity below which the component begins to transition between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Check if lower side pressure violating minimum valid condition** — Simulation warning mode for minimum valid pressure  
None (default) | Warning

Simulation warning mode for invalid pressures at the component ports. Select **Warning** to be notified when pressure falls below a minimum specified value. The warning can be useful in models where pressure can fall below the saturated vapor pressure of the hydraulic fluid, causing cavitation to occur.

**Minimum valid pressure** — Pressure required to trigger simulation warning  
0 (default) | scalar with units of pressure

Lower bound of the pressure validity range. A warning is issued if pressure falls below the specified value.

### Dependencies

This parameter is enabled when the **Check if lower side pressure violating minimum valid condition** parameter is set to **Warning**.

### Variant 3: Input losses

**Displacement** — Fluid volume displaced per unit shaft rotation angle  
30 cm<sup>3</sup>/rev (default) | scalar with units of volume/angle

Fluid volume displaced per unit shaft rotation angle. The displacement is fixed at this value during simulation. The specified value must be greater than zero.

**Pressure drop threshold for motor-pump transition** — Pressure drop at which to initiate a smooth transition between motoring and pumping modes  
1e5 Pa (default) | scalar with units of pressure

Pressure drop from inlet to outlet below which the component begins to transition between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Angular velocity threshold for motor–pump transition** — Shaft angular velocity at which to initiate a smooth transition between motoring and pumping modes  
10 rad/s (default) | scalar with units of angle/time

Shaft angular velocity below which the component begins to transition between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Check if operating beyond the motor mode** — Simulation warning mode for operating conditions outside motoring mode  
None (default) | Warning

Simulation warning mode for operating conditions outside the motoring mode. A warning is issued if the motor transitions to pumping mode. Select **Warning** to be notified when this transition occurs. The warning does not cause simulation to stop.

**Check if lower side pressure violating minimum valid condition** — Simulation warning mode for minimum valid pressure  
None (default) | Warning

Simulation warning mode for invalid pressures at the component ports. Select **Warning** to be notified when pressure falls below a minimum specified value. The warning can be useful in models where pressure can fall below the saturated vapor pressure of the hydraulic fluid, causing cavitation to occur.

**Minimum valid pressure** — Pressure required to trigger simulation warning

0 (default) | scalar with units of pressure

Lower bound of the pressure validity range. A warning is issued if pressure falls below the specified value.

#### **Dependencies**

This parameter is enabled when the **Check if lower side pressure violating minimum valid condition** parameter is set to **Warning**.

## **Version History**

**Introduced in R2006b**

**R2023a: To be removed**

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## **Extended Capabilities**

# Fixed-Displacement Motor (IL)

Fixed-displacement motor in isothermal liquid system

## Libraries:

Simscape / Fluids / Isothermal Liquid / Pumps & Motors

## Description

The Fixed-Displacement Motor (IL) block models a motor with constant-volume displacement. The fluid may move from port **A** to port **B**, called *forward mode*, or from port **B** to port **A**, called *reverse mode*. Motor mode operation occurs when there is a pressure drop in the direction of the flow. Pump mode operation occurs when there is a pressure gain in the direction of the flow.

Shaft rotation corresponds to the sign of the fluid volume moving through the motor. Positive fluid displacement at corresponds to positive shaft rotation in forward mode. Negative fluid displacement corresponds to negative shaft angular velocity in forward mode.

## Operation Modes

The block has eight modes of operation. The working mode depends on the pressure drop from port **A** to port **B**,  $\Delta p = p_A - p_B$  and the angular velocity,  $\omega = \omega_R - \omega_C$ :

- Mode 1, *Forward Motor*: Flow from port **A** to port **B** causes a pressure decrease from **A** to **B** and a positive shaft angular velocity.
- Mode 2, *Reverse Pump*: Negative shaft angular velocity causes a pressure increase from port **B** to port **A** and flow from **B** to port **A**.
- Mode 3, *Reverse Motor*: Flow from port **B** to port **A** causes a pressure decrease from **B** to **A** and a negative shaft angular velocity.
- Mode 4, *Forward Pump*: Positive shaft angular velocity causes a pressure increase from port **A** to port **B** and flow from **A** to **B**.

The motor block has analytical, lookup table, and physical signal parameterizations. When using tabulated data or an input signal for parameterization, you can choose to characterize the motor operation based on efficiency or losses.

In the tabulated data and the input signal parameterization options, the threshold parameters **Pressure drop threshold for motor-pump transition** and **Angular velocity threshold for motor-pump transition** identify regions where numerically smoothed flow transition between the motor operational modes can occur. Choose a transition region that provides some margin for the transition term, but which is small enough relative to the pressure and angular velocity that it will not impact calculation results.

### Analytical Leakage and Friction Parameterization

If you set **Leakage and friction parameterization** to **Analytical**, the block calculates leakage and friction from constant values of shaft velocity, pressure drop, and friction torque. The leakage flow rate, which is correlated with the pressure differential over the motor, is calculated as:

$$\dot{m}_{leak} = K\rho_{avg}\Delta p,$$

where:

- $\Delta p$  is  $p_A - p_B$ .
- $\rho_{avg}$  is the average fluid density.
- $K$  is the Hagen-Poiseuille coefficient for analytical loss,

$$K = \frac{D\omega_{nom}\left(\frac{1}{\eta_{v,nom}} - 1\right)}{\Delta p_{nom}},$$

where:

- $D$  is the **Displacement**.
- $\omega_{nom}$  is the **Nominal shaft angular velocity**.
- $\eta_{v,nom}$  is the **Volumetric efficiency at nominal conditions**.
- $\Delta p_{nom}$  is the **Nominal pressure drop**.

The friction torque, which is correlated with shaft angular velocity, is calculated as:

$$\tau_{fr} = (\tau_0 + k|\Delta p|)\tanh\left(\frac{4\omega}{5 \times 10^{-5}\omega_{nom}}\right),$$

where:

- $\tau_0$  is the **No-load torque**.
- $k$  is the friction torque vs. pressure gain coefficient at nominal displacement, which is determined from the **Mechanical efficiency at nominal conditions**,  $\eta_m$ :

$$k = \frac{\tau_{fr,nom} - \tau_0}{\Delta p_{nom}}.$$

$\tau_{fric}$  is the friction torque at nominal conditions:

$$\tau_{fr,nom} = (1 - \eta_{m,nom})D\Delta p_{nom}.$$

- $\Delta p$  is the pressure drop between ports **A** and **B**.
- $\omega$  is the relative shaft angular velocity, or  $\omega_R - \omega_C$ .

### Tabulated Data Parameterizations

When using tabulated data for motor efficiencies or losses, you can provide data for one or more of the motor operational modes. The signs of the tabulated data determine the operational regime of the block. When data is provided for less than four operational modes, the block calculates the complementing data for the other mode(s) by extending the given data into the remaining quadrants.

#### The Tabulated data - volumetric and mechanical efficiencies parameterization

The leakage flow rate is calculated as:

$$\dot{m}_{leak} = \dot{m}_{leak, motor} \left( \frac{1 + \alpha}{2} \right) + \dot{m}_{leak, pump} \left( \frac{1 - \alpha}{2} \right),$$

where:

- $\dot{m}_{leak, pump} = (\eta_v - 1) \dot{m}_{ideal}$
- $\dot{m}_{leak, motor} = (1 - \eta_v) \dot{m}$

and  $\eta_v$  is the volumetric efficiency, which is interpolated from the user-provided tabulated data. The transition term,  $\alpha$ , is

$$\alpha = \tanh\left(\frac{4\Delta p}{\Delta p_{threshold}}\right) \tanh\left(\frac{4\omega}{\omega_{threshold}}\right),$$

where:

- $\Delta p$  is  $p_A - p_B$ .
- $p_{threshold}$  is the **Pressure drop threshold for motor-pump transition**.
- $\omega$  is  $\omega_R - \omega_C$ .
- $\omega_{threshold}$  is the **Angular velocity threshold for motor-pump transition**.

The friction torque is calculated as:

$$\tau_{fr} = \tau_{fr, pump} \left( \frac{1 + \alpha}{2} \right) + \tau_{fr, motor} \left( \frac{1 - \alpha}{2} \right),$$

where:

- $\tau_{fr, pump} = (\eta_m - 1) \tau$
- $\tau_{fr, motor} = (1 - \eta_m) \tau_{ideal}$

and  $\eta_m$  is the mechanical efficiency, which is interpolated from the user-provided tabulated data.

#### The Tabulated data - volumetric and mechanical losses parameterization

The leakage flow rate is calculated as:

$$\dot{m}_{leak} = \rho_{avg} q_{loss}(\Delta p, \omega),$$

where  $q_{loss}$  is interpolated from the **Volumetric loss table,  $q_{loss}(dp, w)$**  parameter, which is based on user-supplied data for pressure drop, shaft angular velocity, and fluid volumetric displacement.

The shaft friction torque is calculated as:

$$\tau_{fr} = \tau_{loss}(\Delta p, \omega),$$

where  $\tau_{loss}$  is interpolated from the **Mechanical loss table, torque\_loss(dp,w)** parameter, which is based on user-supplied data for pressure drop and shaft angular velocity.

### Input Signal Parameterization

When **Leakage and friction parameterization** is set to **Input signal - volumetric and mechanical efficiencies**, ports **EV** and **EM** are enabled. The internal leakage and shaft friction are calculated in the same way as the **Tabulated data - volumetric and mechanical efficiencies** parameterization, except that  $\eta_v$  and  $\eta_m$  are received directly at ports **EV** and **EM**, respectively.

When **Leakage and friction parameterization** is set to **Input signal - volumetric and mechanical losses**, ports **LV** and **LM** are enabled. These ports receive leakage flow and friction torque as positive physical signals. The leakage flow rate is calculated as:

$$\dot{m}_{leak} = \rho_{avg} q_{LV} \tanh\left(\frac{4\Delta p}{p_{thresh}}\right),$$

where:

- $q_{LV}$  is the leakage flow received at port **LV**.
- $p_{thresh}$  is the **Pressure drop threshold for motor-pump transition** parameter.

The friction torque is calculated as:

$$\tau_{fr} = \tau_{LM} \tanh\left(\frac{4\omega}{\omega_{thresh}}\right),$$

where

- $\tau_{LM}$  is the friction torque received at port **LM**.
- $\omega_{thresh}$  is the **Angular velocity threshold for motor-pump transition** parameter.

The volumetric and mechanical efficiencies range between the user-defined specified minimum and maximum values. Any values lower or higher than this range will take on the minimum and maximum specified values, respectively.

### Pump Operation

The motor flow rate is:

$$\dot{m} = \dot{m}_{ideal} + \dot{m}_{leak},$$

where  $\dot{m}_{ideal} = \rho_{avg} D \cdot \omega$ .

The motor torque is:

$$\tau = \tau_{ideal} - \tau_{fr},$$

where  $\tau_{ideal} = D \cdot \Delta p$ .

The mechanical power extracted by the motor shaft is:

$$\varphi_{mech} = \tau\omega,$$

and the motor hydraulic power is:

$$\varphi_{hyd} = \frac{\Delta p \dot{m}}{\rho_{avg}}.$$

If you would like to know if the block is operating beyond the supplied tabulated data, you can set **Check if operating beyond the quadrants of supplied tabulated data** to Warning to receive a warning if this occurs, or Error to stop the simulation when this occurs. For parameterization by input signal for volumetric or mechanical losses, you can be notified if the simulation surpasses operating modes with the **Check if operating outside of motor mode** parameter.

You can also monitor motor functionality. Set **Check if pressures are less than motor minimum pressure** to Warning to receive a warning if this occurs, or Error to stop the simulation when this occurs.

### Predefined Parameterization

Pre-parameterized manufacturer data is available for this block. This data allows you to model a specific supplier component.

To load a predefined parameterization,

- 1 Click the "Select a predefined parameterization" hyperlink in the block dialog description.
- 2 Select a part from the drop-down menu and click **Update block with selected part**.
- 3 If you change any parameter settings after loading a parameterization, you can check your changes by clicking **Compare block settings with selected part**. Any difference in settings between the block and pre-defined parameterization will display in the MATLAB command window.

---

**Note** Predefined block parameterizations use available data sources to supply parameter values. The block substitutes engineering judgement and simplifying assumptions for missing data. As a result, expect some deviation between simulated and actual physical behavior. To ensure accuracy, validate the simulated behavior against experimental data and refine your component models as necessary.

---

To learn more, see "List of Pre-Parameterized Components".

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Entry or exit port to the motor.

**B** — Liquid port  
isothermal liquid

Entry or exit port to the motor.

**R** — Mechanical port  
mechanical rotational

Rotating shaft angular velocity and torque.

**C** — Mechanical port  
mechanical rotational

Motor casing reference angular velocity and torque.

### **Input**

**EV** — Volumetric efficiency  
physical signal

Motor efficiency for fluid displacement, specified as a physical signal. The value must be between 0 and 1.

### **Dependencies**

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**EM** — Mechanical efficiency  
physical signal

Motor efficiency for the mechanical extraction of energy, specified as a physical signal. The value must be between 0 and 1.

### **Dependencies**

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**LV** — Leakage flow rate,  $m^3/s$   
physical signal

Motor losses associated with fluid displacement in  $m^3/s$ , specified as a physical signal.

### **Dependencies**

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

**LM** — Friction torque,  $N*m$   
physical signal

Motor losses associated with the mechanical extraction of energy in  $N*m$ , specified as a physical signal.

### **Dependencies**

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

## Parameters

**Leakage and friction parameterization** — Method of calculating leakage flow rate and friction torque

Analytical (default) | Tabulated data - volumetric and mechanical efficiencies | Tabulated data - volumetric and mechanical losses | Input signal - volumetric and mechanical efficiencies | Input signal - volumetric and mechanical losses

Parameterization of the leakage and friction characteristics of the pump.

- In the **Analytical** parameterization, the leakage flow rate and the friction torque are calculated by analytical equations.
- In the **Tabulated data - volumetric and mechanical efficiencies** parameterization, the volumetric and mechanical efficiencies are calculated from the user-supplied **Pressure drop vector,  $\mathbf{dp}$**  and **Shaft angular velocity vector,  $\mathbf{w}$**  parameters and interpolated from the 2-D dependent **Volumetric efficiency table,  $e_v(\mathbf{dp},\mathbf{w})$**  and **Mechanical efficiency table,  $e_m(\mathbf{dp},\mathbf{w})$**  tables.
- In the **Tabulated data - volumetric and mechanical loss** parameterization, the leakage flow rate and torque friction are calculated from user-supplied **Pressure drop vector,  $\mathbf{dp}$**  and **Shaft angular velocity vector,  $\mathbf{w}$**  parameters and interpolated from the 2-D dependent **Volumetric loss table,  $q_{loss}(\mathbf{dp},\mathbf{w})$**  and **Mechanical loss table,  $torque_{loss}(\mathbf{dp},\mathbf{w})$**  tables.
- In the **Input signal - volumetric and mechanical efficiencies** parameterization, the volumetric and mechanical efficiencies are received as physical signals at ports **EV** and **EM**, respectively.
- In the **Input signal - volumetric and mechanical loss** parameterization, the leakage flow rate and torque friction are received as physical signals at ports **LV** and **LM**, respectively.

**Displacement** — Fixed-volume fluid displacement

30 cm<sup>3</sup>/rev (default) | scalar

Amount of fixed-volume fluid displacement.

**Nominal shaft angular velocity** — Shaft angular velocity

1800 rpm (default) | scalar

Angular velocity of the shaft under nominal operating conditions.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to **Analytical**.

**Nominal pressure drop** — Pressure drop between fluid entry and exit

10 MPa (default) | scalar

Motor pressure drop between the fluid entry and exit under nominal operating conditions.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to **Analytical**.

**Volumetric efficiency at nominal conditions** — Ratio of actual flow rate to ideal flow rate at nominal conditions

0.92 (default) | positive scalar in the range of (0,1]

Ratio of actual flow rate to ideal flow rate at nominal conditions.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**No-load torque** — Baseline torque

0 N\*m (default) | scalar

Minimum value of torque to overcome seal friction and induce shaft motion.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Mechanical efficiency at nominal conditions** — Ratio of actual torque to ideal torque generated

0.88 (default) | positive scalar

Ratio of actual torque to ideal torque generated at nominal conditions.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Pressure drop vector, dp** — Vector of pressure data for tabulated data parameterization

[.1, 1, 2] MPa (default) | 1-by-*n* vector

Vector of pressure differential values for the tabular parameterization of leakage and torque friction. This vector forms an independent axis with the **Shaft angular velocity vector, w** parameter for the 3-D dependent **Volumetric efficiency table, e\_v(dp,w)** and **Mechanical efficiency table, e\_m(dp,w)** parameters. The vector elements must be listed in ascending order.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to either:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Shaft angular velocity vector, w** — Vector of angular velocity data for tabulated data parameterization

[250, 500, 1000, 2000, 3000, 4000] rpm (default) | 1-by-*n* vector

Vector of angular velocity data for the tabular parameterization of leakage and torque friction. This vector forms an independent axis with the **Shaft angular velocity vector, w** parameter for the 3-D dependent **Volumetric efficiency table, e\_v(dp,w)** and **Mechanical efficiency table, e\_m(dp,w)** parameters. The vector elements must be listed in ascending order.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to either:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Volumetric efficiency table,  $e_v(dp,w)$**  — Volumetric efficiency for tabulated data parameterization  
 [.816, .908, .954, .977, .981, .984; .325, .663, .831, .916, .925, .946; .137, .568, .78, .892, .893, .91] (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of volumetric efficiencies at the specified fluid pressure drop and shaft angular velocity. Linear interpolation is employed between table elements.  $M$  and  $N$  are the sizes of the correlated vectors:

- $M$  is the number of vector elements in the **Pressure drop vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Mechanical efficiency table,  $e_m(dp,w)$**  — Mechanical efficiency for tabulated data parameterization  
 [.996, .996, .996, .996, .996, .996; .988, .989, .989, .989, .989, .99; .981, .981, .982, .982, .983, .984] (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of mechanical efficiencies at the specified fluid pressure drop and shaft angular velocity. Linear interpolation is employed between table elements.  $M$  and  $N$  are the sizes of the correlated vectors:

- $M$  is the number of vector elements in the **Pressure drop vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Volumetric loss table,  $q_{loss}(dp,w)$**  — Volumetric losses for tabulated data parameterization  
 [.023, .023, .023, .023, .0285, .032; .0844, .0842, .0845, .084, .1125, .108; .1079, .108, .11, .108, .1605, .18] \*  $1e^{-3}$  m<sup>3</sup>/s (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of volumetric efficiencies at the specified fluid pressure drop and shaft angular velocity. Linear interpolation is employed between table elements.  $M$  and  $N$  are the sizes of the correlated vectors:

- $M$  is the number of vector elements in the **Pressure drop vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical losses.

**Mechanical loss table, torque\_loss(dp,w)** — Mechanical losses for tabulated data parameterization  
 [.002, .002, .002, .002, .002, .002; .0607, .0556, .0556, .0556, .0556, .0505; .1937, .1937, .1833, .1833, .1729, .1626] N\*m (default) |  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix of mechanical losses at the specified fluid pressure drop and shaft angular velocity. Linear interpolation is employed between table elements.  $M$  and  $N$  are the sizes of the correlated vectors:

- $M$  is the number of vector elements in the **Pressure drop vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.

#### **Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical losses.

**Minimum volumetric efficiency** — Minimum value of volumetric efficiency  
1e-3 (default) | positive scalar in the range of (0,1]

Minimum value of volumetric efficiency. If the input signal is below this value, the volumetric efficiency is set to the minimum volumetric efficiency.

#### **Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum volumetric efficiency** — Maximum value of volumetric efficiency  
1 (default) | positive scalar in the range of (0,1]

Maximum value of volumetric efficiency. If the input signal is above this value, the volumetric efficiency is set to the maximum volumetric efficiency.

#### **Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Minimum mechanical efficiency** — Minimum value of mechanical efficiency  
1e-3 (default) | positive scalar in the range of (0,1]

Minimum value of mechanical efficiency. If the input signal is below this value, the mechanical efficiency is set to the minimum mechanical efficiency.

#### **Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum mechanical efficiency** — Maximum value of mechanical efficiency  
1 (default) | positive scalar in the range of (0,1]

Maximum value of mechanical efficiency. If the input signal is above this value, the mechanical efficiency is set to the maximum mechanical efficiency.

#### **Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Pressure drop threshold for motor-pump transition** — Pressure threshold for mode transition  
1e-3 MPa (default) | positive scalar

Threshold pressure drop value for the transition between pump and motor functionality. A transition region is defined around 0 MPa between the positive and negative values of the pressure drop threshold. Within this transition region, the computed leakage flow rate and friction torque are adjusted according to the transition term  $\alpha$  to ensure smooth transition from one mode to the other.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to either:

- Tabulated data - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical losses

**Angular velocity threshold for motor-pump transition** — Angular velocity threshold for mode transition

100 rpm (default) | positive scalar

Threshold angular velocity value for the transition between pump and motor functionality. A transition region is defined around 0 rpm between the positive and negative values of the angular velocity threshold. Within this transition region, the computed leakage flow rate and friction torque are adjusted according to the transition term  $\alpha$  to ensure smooth transition from one mode to the other.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to either:

- Tabulated data - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical losses

**Check if operating beyond the quadrants of supplied tabulated data** — Whether to notify if extents of supplied data are surpassed

None (default) | Warning | Error

Whether to notify if the extents of the supplied data are surpassed. Select **Warning** to be notified when the block uses values beyond the supplied data range. Select **Error** to stop the simulation when the block uses values beyond the supplied data range.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Check if operating outside of motor mode** — Whether to notify if block operates outside of the motor mode functionality

None (default) | Warning | Error

Whether to notify if block operates outside of the motor mode functionality. This block has four operation modes: forward motor, reverse motor, reverse pump, and forward pump. Select **Warning** to

be notified when the block operates in the forward or reverse motor pump modes. Select **Error** to stop the simulation when the block operates in the forward or reverse pump modes.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to `Input signal - volumetric and mechanical losses`.

**Check if pressures are less than motor minimum pressure** — Whether to notify if fluid exit pressure is low

None (default) | Warning | Error

Whether to notify if the fluid at port **A** or **B** experiences low pressure. Select **Warning** to be notified when the outlet pressure falls below a minimum specified value. Select **Error** to stop the simulation when the outlet pressure falls below a minimum specified value.

The parameter helps identify potential conditions for cavitation, when the fluid pressure falls below the fluid vapor pressure.

**Motor minimum pressure** — Lower threshold to acceptable pressure at the motor outlet

0.101325 MPa (default) | positive scalar

Lower threshold of acceptable pressure at the motor inlet or outlet.

### Dependencies

To enable this parameter, set **Check if pressures are less than motor minimum pressure** to either:

- Warning
- Error

## Version History

## Libraries:

Simscape / Fluids / Thermal Liquid / Pumps & Motors

## Description

The Fixed-Displacement Motor (TL) block represents a device that extracts power from a thermal liquid network and delivers it to a mechanical rotational network. The motor displacement is fixed at a constant value that you specify through the **Displacement** parameter.

Ports **A** and **B** represent the motor inlets. Ports **R** and **C** represent the motor drive shaft and case. During normal operation, a pressure drop from port **A** to port **B** causes a positive flow rate from port **A** to port **B** and a positive rotation of the motor shaft relative to the motor case. This operation mode is referred to here as *forward motor*.

## Operation Modes

The block has four modes of operation. The working mode depends on the pressure drop from port **A** to port **B**,  $\Delta p = p_B - p_A$  and the angular velocity,  $\omega = \omega_R - \omega_C$ :

- Mode 1, *Forward Motor*: Flow from port **A** to port **B** causes a pressure decrease from **A** to **B** and a positive shaft angular velocity.
- Mode 2, *Reverse Pump*: Negative shaft angular velocity causes a pressure increase from port **B** to port **A** and flow from **B** to port **A**.
- Mode 3, *Reverse Motor*: Flow from port **B** to port **A** causes a pressure decrease from **B** to **A** and a negative shaft angular velocity.
- Mode 4, *Forward Pump*: Positive shaft angular velocity causes a pressure increase from port **A** to port **B** and flow from **A** to **B**.

The response time of the motor is considered negligible in comparison with the system response time. The motor is assumed to reach steady state nearly instantaneously and is treated as a quasi-steady component.

### Energy Balance

Mechanical work done by the pump is associated with an energy exchange. The governing energy balance equation is:

$$\phi_A + \phi_B - P_{hydro} = 0,$$

where:

- $\Phi_A$  and  $\Phi_B$  are energy flow rates at ports **A** and **B**, respectively.
- $P_{hydro}$  is the motor hydraulic power. It is a function of the pressure difference between the motor ports:  $P_{hydro} = \Delta p \frac{\dot{m}}{\rho}$

The motor mechanical power is generated from the motor torque,  $\tau$  and angular velocity,  $\omega$ :

$$P_{mech} = T\omega.$$

### Flow Rate and Driving Torque

The mass flow rate generated at the motor is

$$\dot{m} = \dot{m}_{Ideal} + \dot{m}_{Leak},$$

where:

- $\dot{m}$  is the actual mass flow rate.
- $\dot{m}_{Ideal}$  is the ideal mass flow rate.
- $\dot{m}_{Leak}$  is the internal leakage mass flow rate.

The torque generated at the motor is

$$\tau = \tau_{Ideal} - \tau_{Friction},$$

where:

- $\tau$  is the actual torque.
- $\tau_{Ideal}$  is the ideal torque.
- $\tau_{Friction}$  is the friction torque.

### Ideal Flow Rate and Ideal Torque

The ideal mass flow rate is

$$\dot{m}_{Ideal} = \rho D\omega,$$

and the ideal generated torque is

$$\tau_{Ideal} = D\Delta p,$$

where:

- $\rho$  is the average of the fluid densities at thermal liquid ports **A** and **B**.
- $D$  is the **Displacement** parameter.
- $\omega$  is the shaft angular velocity.
- $\Delta p$  is the pressure drop from inlet to outlet.

### Leakage and friction parameterization

You can parameterize leakage and friction analytically, using tabulated efficiencies or losses, or by input efficiencies or input losses.

#### Analytical

When you set **Leakage and Friction Parameterization** to **Analytical**, the leakage flow rate is

$$\dot{m}_{\text{Leak}} = \frac{K_{\text{HP}}\rho_{\text{Avg}}\Delta p}{\mu_{\text{Avg}}},$$

and the friction torque is

$$\tau_{\text{Friction}} = \left( \tau_0 + K_{\text{TP}}|\Delta p| \tanh\left(\frac{4\omega}{(5 \cdot 10^{-5})\omega_{\text{Nom}}}\right) \right),$$

where:

- $K_{\text{HP}}$  is the Hagen-Poiseuille coefficient for laminar pipe flows. This coefficient is computed from the specified nominal parameters.
- $\mu$  is the dynamic viscosity of the thermal liquid, taken here as the average of its values at the thermal liquid ports.
- $K_{\text{TP}}$  is the friction torque vs. pressure gain coefficient at nominal displacement, which is determined from the **Mechanical efficiency at nominal conditions**,  $\eta_m$ :

$$k = \frac{\tau_{fr, \text{nom}} - \tau_0}{\Delta p_{\text{nom}}}.$$

$\tau_{fric}$  is the friction torque at nominal conditions:

$$\tau_{fr, \text{nom}} = (1 - \eta_{m, \text{nom}})D\Delta p_{\text{nom}}.$$

- $\tau_0$  is the specified value of the **No-load torque** parameter.
- $\omega_{\text{Nom}}$  is the specified value of the **Nominal shaft angular velocity** parameter.
- $\Delta p_{\text{Nom}}$  is the specified value of the **Nominal pressure drop** parameter. This is the pressure drop at which the nominal volumetric efficiency is specified.

The Hagen-Poiseuille coefficient is determined from nominal fluid and component parameters through the equation

$$K_{\text{HP}} = \frac{D\omega_{\text{Nom}}\mu_{\text{Nom}}\left(\frac{1}{\eta_{v, \text{Nom}}} - 1\right)}{\Delta p_{\text{Nom}}},$$

where:

- $\omega_{\text{Nom}}$  is the specified value of the **Nominal shaft angular velocity** parameter. This is the angular velocity at which the nominal volumetric efficiency is specified.
- $\mu_{\text{Nom}}$  is the specified value of the **Nominal Dynamic viscosity** block parameter. This is the dynamic viscosity at which the nominal volumetric efficiency is specified.
- $\eta_{\text{v,Nom}}$  is the specified value of the **Volumetric efficiency at nominal conditions** block parameter. This is the volumetric efficiency corresponding to the specified nominal conditions.

### Tabulated Efficiencies

When you set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies, the leakage flow rate is

$$\dot{m}_{\text{Leak}} = \dot{m}_{\text{Leak, Motor}} \frac{(1 + \alpha)}{2} + \dot{m}_{\text{Leak, Pump}} \frac{(1 - \alpha)}{2},$$

and the friction torque is

$$\tau_{\text{Friction}} = \tau_{\text{Friction, Motor}} \frac{1 + \alpha}{2} + \tau_{\text{Friction, Pump}} \frac{1 - \alpha}{2},$$

where:

- $\alpha$  is a numerical smoothing parameter for the motor-pump transition.
- $\dot{m}_{\text{Leak, Motor}}$  is the leakage flow rate in motor mode.
- $\dot{m}_{\text{Leak, Pump}}$  is the leakage flow rate in pump mode.
- $\tau_{\text{Friction, Motor}}$  is the friction torque in motor mode.
- $\tau_{\text{Friction, Pump}}$  is the friction torque in pump mode.

The smoothing parameter  $\alpha$  is given by the hyperbolic function

$$\alpha = \tanh\left(\frac{4\Delta p}{\Delta p_{\text{Threshold}}}\right) \cdot \tanh\left(\frac{4\omega}{\omega_{\text{Threshold}}}\right) \cdot \tanh\left(\frac{4D}{D_{\text{Threshold}}}\right),$$

where:

- $\Delta p_{\text{Threshold}}$  is the specified value of the **Pressure drop threshold for motor-pump transition** block parameter.
- $\omega_{\text{Threshold}}$  is the specified value of the **Angular velocity threshold for motor-pump transition** block parameter.
- $D_{\text{Threshold}}$  is the specified value of the **Angular velocity threshold for motor-pump transition** block parameter.

The leakage flow rate is calculated from the volumetric efficiency, a quantity that is specified in tabulated form over the  $\Delta p$ - $\omega$ - $D$  domain via the **Volumetric efficiency table** block parameter. When operating in motor mode (quadrants **1** and **3** of the  $\Delta p$ - $\omega$ - $D$  chart shown in the "Operation Modes" on page 1-835 figure), the leakage flow rate is:

$$\dot{m}_{\text{Leak, Motor}} = (1 - \eta_v)\dot{m},$$

where  $\eta_v$  is the volumetric efficiency, obtained either by interpolation or extrapolation of the tabulated data. Similarly, when operating in pump mode (quadrants **2** and **4** of the  $\Delta p$ - $\omega$ - $D$  chart), the leakage flow rate is:

$$\dot{m}_{\text{Leak,Pump}} = -(1 - \eta_v)\dot{m}_{\text{Ideal}}.$$

The friction torque is similarly calculated from the mechanical efficiency, a quantity that is specified in tabulated form over the  $\Delta p$ - $\omega$ - $D$  domain via the **Mechanical efficiency table** block parameter. When operating in motor mode (quadrants **1** and **3** of the  $\Delta p$ - $\omega$ - $D$  chart):

$$\tau_{\text{Friction,Motor}} = (1 - \eta_m)\tau_{\text{Ideal}},$$

where  $\eta_m$  is the mechanical efficiency, obtained either by interpolation or extrapolation of the tabulated data. Similarly, when operating in pump mode (quadrants **2** and **4** of the  $\Delta p$ - $\omega$ - $D$  chart):

$$\tau_{\text{Friction,Pump}} = -(1 - \eta_m)\tau.$$

### Tabulated Losses

When you set **Leakage and friction parameterization** to **Tabulated data - volumetric and mechanical losses**, the leakage (volumetric) flow rate is specified directly in tabulated form over the  $\Delta p$ - $\omega$  domain:

$$q_{\text{Leak}} = q_{\text{Leak}}(\Delta p, \omega).$$

The mass flow rate due to leakage is calculated from the volumetric flow rate:

$$\dot{m}_{\text{Leak}} = \rho q_{\text{Leak}}.$$

The friction torque is similarly specified in tabulated form:

$$\tau_{\text{Friction}} = \tau_{\text{Friction}}(\Delta p, \omega),$$

where  $q_{\text{Leak}}(\Delta p, \omega)$  and  $\tau_{\text{Friction}}(\Delta p, \omega)$  are the volumetric and mechanical losses, obtained through interpolation or extrapolation of the tabulated data specified via the **Volumetric loss table** and **Mechanical loss table** block parameters.

### Input Efficiencies

When you set **Leakage and friction parameterization** to **Input signal - volumetric and mechanical efficiencies**, the leakage flow rate and friction torque calculations are identical to the **Tabulated data - volumetric and mechanical efficiencies** setting. The volumetric and mechanical efficiency lookup tables are replaced with physical signal inputs that you specify through ports **EV** and **EM**.

The efficiencies are positive quantities with value between 0 and 1. Input values outside of these bounds are set equal to the nearest bound (0 for inputs smaller than 0, 1 for inputs greater than 1). The efficiency signals are saturated at the **Minimum volumetric efficiency** or **Minimum mechanical efficiency** and **Maximum volumetric efficiency** or **Maximum mechanical efficiency**.

### Input Losses

When you set **Leakage and friction parameterization** to **Input signal - volumetric and mechanical efficiencies**, the leakage flow rate and friction torque calculations are identical to the **Tabulated data - volumetric and mechanical efficiencies** setting. The volumetric and mechanical loss lookup tables are replaced with physical signal inputs that you specify through ports **LV** and **LM**.

The block expects the inputs to be positive. It sets the signs automatically from the operating conditions established during simulation—more precisely, from the  $\Delta p$ - $\omega$  quadrant in which the component happens to be operating.

### Assumptions and Limitations

- The motor is treated as a quasi-steady component.
- The effects of fluid inertia and elevation are ignored.
- The motor wall is rigid.
- External leakage is ignored.

## Ports

### Input

**EV** — Volumetric efficiency, unitless  
physical signal

Physical signal input port for the volumetric efficiency coefficient. The input signal has an upper bound at the **Maximum volumetric efficiency** parameter value and a lower bound at the **Minimum volumetric efficiency** parameter value.

### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**EM** — Mechanical efficiency, unitless  
physical signal

Physical signal input port for the mechanical efficiency coefficient. The input signal has an upper bound at the **Maximum mechanical efficiency** parameter value and a lower bound at the **Minimum mechanical efficiency** parameter value.

### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**LV** — Volumetric loss,  $m^3/s$   
physical signal

Physical signal input port for the volumetric loss, defined as the internal leakage flow rate between the motor inlets.

### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

**LM** — Mechanical loss,  $N\cdot m$   
physical signal

Physical signal input port for the mechanical loss, defined as the friction torque on the rotating motor shaft.

## Dependencies

To enable this port, set **Leakage and friction parameterization** to `Input signal - volumetric and mechanical losses`.

## Conserving

**A** — Motor inlet  
thermal liquid

Thermal liquid conserving port associated with the motor inlet.

**B** — Motor outlet  
thermal liquid

Thermal liquid conserving port associated with the motor outlet.

**C** — Motor Case  
mechanical rotational

Mechanical rotational conserving port associated with the motor case.

**R** — Motor Shaft  
mechanical rotational

Mechanical rotational conserving port associated with the rotational motor shaft.

## Parameters

**Leakage and friction parameterization** — Parameterization of leakage flow rate and friction torque  
Analytical (default) | Tabulated data - volumetric and mechanical efficiencies |  
Tabulated data - volumetric and mechanical losses | Input signal - volumetric  
and mechanical efficiencies | Input signal - volumetric and mechanical losses

Method to compute flow-rate and torque losses due to internal leaks and friction. When you select `Analytical`, the block parameters are generally available from component data sheets. When you select `Tabulated data - volumetric and mechanical efficiencies` or `Tabulated data - volumetric and mechanical losses`, the block uses lookup tables to map pressure drop, angular velocity, and displacement to component efficiencies or losses.

When you select `Input signal - volumetric and mechanical efficiencies` or `Input signal - volumetric and mechanical losses`, the block performs the leakage flow rate and friction torque calculations the same as the `Tabulated data - volumetric and mechanical efficiencies` or `Tabulated data - volumetric and mechanical losses` settings, respectively. When you select `Input signal - volumetric and mechanical efficiencies` the block enables the physical signal ports, **EV** and **EM**. You use these ports to specify the volumetric and mechanical efficiency. When you select `Input signal - volumetric and mechanical losses` the block enables the physical signal ports, **LV** and **LM**. You use these ports to specify the volumetric and mechanical losses.

**Displacement** — Fluid volume displaced per shaft rotation  
30 cm<sup>3</sup>/rev (default) | positive scalar

Fluid volume displaced per shaft rotation. The block maintains this value throughout the simulation.

**Nominal shaft angular velocity** — Shaft angular velocity for given volumetric efficiency  
1800 rpm (default) | scalar

Angular velocity of the rotary shaft that corresponds to the given volumetric efficiency. These values are typically available at standard operating conditions in the manufacturer data sheet. The block uses this parameter to calculate the leakage flow rate and friction torque.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Nominal pressure drop** — Pressure drop for corresponding volumetric efficiency  
10 MPa (default) | scalar

Pressure drop that corresponds to the given volumetric efficiency. These values are typically available at standard operating conditions in manufacturer data sheet. The block uses this parameter to calculate the internal leakage flow rate.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Nominal dynamic viscosity** — Dynamic viscosity at which to specify the volumetric efficiency  
0.9 cP (default) | scalar

Dynamic viscosity of the hydraulic fluid for the given volumetric efficiency. These values are typically available at standard operating conditions in manufacturer data sheet. The block uses this parameter to calculate the internal leakage flow rate.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Volumetric efficiency at nominal conditions** — Volumetric efficiency at the specified nominal conditions  
0.92 (default) | scalar in the range (0,1)

Volumetric efficiency for the given conditions. The block defines the volumetric efficiency as the ratio of actual to ideal volumetric flow rates. These values are typically available at standard operating conditions in manufacturer data sheet. The block uses this parameter to calculate the internal leakage flow rate.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Mechanical efficiency at nominal conditions** — Ratio of actual to ideal mechanical power  
0.88 (default) | positive scalar

Ratio of actual mechanical power to ideal mechanical power at nominal conditions.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**No-load torque** — Minimum torque required to induce shaft rotation  
0 N\*m (default) | scalar

Torque to overcome the seal friction and induce rotation of the mechanical shaft. This torque is the load-independent component of the total friction torque.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Pressure drop vector, dp** — Pressure drops for given volumetric and mechanical efficiencies  
[.1, 1, 2] MPa (default) | vector

Pressure drops for the corresponding tabular efficiency data. The vector must be at least two elements in strictly increasing order.

You can specify the data for a single quadrant, ( $\omega$ ,  $\Delta p$ ). Refer to the block description for the operation modes corresponding to the various quadrants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Shaft angular velocity vector, w** — Angular velocities at which to specify the volumetric and mechanical efficiencies  
[250, 500, 1000, 2000, 3000, 4000] rpm | vector

Shaft angular velocities for the corresponding tabular efficiency data. The vector must be at least two elements in strictly increasing order.

You can specify the data for a single quadrant, ( $\omega$ ,  $\Delta p$ ). Refer to the block description for the operation modes corresponding to the various quadrants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies or Tabulated data - volumetric and mechanical losses.

**Volumetric efficiency table, e\_v(dp,w)** — Volumetric efficiencies for given pressure drops and angular velocities  
[.816, .908, .954, .977, .981, .984; .325, .663, .831, .916, .925, .946; .137, .568, .78, .892, .893, .91] | matrix

Volumetric efficiencies for the given fluid pressure drops and shaft angular velocities.. The efficiencies must be in the range (0,1].  $M$  and  $N$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure drop vector, dp** parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector, w** parameter.

You can specify the data for a single quadrant, ( $\omega$ ,  $\Delta p$ ). Refer to the block description for the operation modes corresponding to the various quadrants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Mechanical efficiency table,  $e_m(dp,w)$**  — Mechanical efficiencies for given pressure drops and angular velocities

[.996, .996, .996, .996, .996, .996; .988, .989, .989, .989, .989, .99; .981, .981, .982, .982, .983, .984] | matrix

Mechanical efficiencies for the given fluid pressure drops and shaft angular velocities. The efficiencies must be in the range (0,1].  $M$  and  $N$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure drop vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.

You can specify the data for a single quadrant, ( $\omega$ ,  $\Delta p$ ). Refer to the block description for the operation modes corresponding to the various quadrants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Pressure drop vector,  $dp$**  — Pressure drop for corresponding losses

[.1, 1, 2] MPa (default)

Pressure drops for the corresponding tabular efficiency data. The vector must be at least two elements in strictly increasing order.

You can specify the data for a single quadrant, ( $\omega$ ,  $\Delta p$ ). Refer to the block description for the operation modes corresponding to the various quadrants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical losses.

**Volumetric loss table,  $q_{loss}(dp,w)$**  — Internal leakage flow rates for corresponding pressure drops and angular velocities

[.023, .023, .023, .023, .0285, .032; .0844, .0842, .0845, .084, .1125, .108; .1079, .108, .11, .108, .1605, .18] \* 1e-3 m<sup>3</sup>/s

Volumetric losses at the specified fluid pressure drops and shaft angular velocities. Volumetric loss is defined here as the internal leakage volumetric flow rate between port A and port B.  $M$  and  $N$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure drop vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.

You can specify the data for a single quadrant, ( $\omega$ ,  $\Delta p$ ). Refer to the block description for the operation modes corresponding to the various quadrants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical losses.

**Mechanical loss table, torque\_loss(dp,w)** — Friction torques for the corresponding pressure drops and angular velocities

[.002, .002, .002, .002, .002, .002; .0607, .0556, .0556, .0556, .0556, .0505  
; .1937, .1937, .1833, .1833, .1729, .1626] N\*m

Mechanical losses for the given pressure drops and shaft angular velocities. The block defines mechanical loss as the friction torque due to seals and internal components.  $M$  and  $N$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure drop vector, dp** parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector, w** parameter.

You can specify the data for a single quadrant,  $(\omega, \Delta p)$ . Refer to the block description for the operation modes corresponding to the various quadrants. The tabulated data for the mechanical losses must obey the convention in the figure, with positive values at positive angular velocities and negative values at negative angular velocities.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical losses.

**Minimum volumetric efficiency** — Lower saturation bound on the volumetric efficiency input signal  $1e-3$  (default) | scalar in the range (0,1)

Smallest allowed value of the volumetric efficiency. The input from the physical signal port **EV** saturates inputs below this value.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum volumetric efficiency** — Upper saturation bound on the volumetric efficiency input signal 1 (default) | scalar in the range (0,1)

Largest allowed value of the volumetric efficiency. The input from the physical signal port **EV** saturates inputs above this value.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Minimum mechanical efficiency** — Lower saturation bound on the volumetric efficiency input signal  $1e-3$  (default) | scalar in the range (0,1)

Smallest allowed value of the mechanical efficiency. The input from the physical signal port **EM** saturates inputs below this value.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum mechanical efficiency** — Upper saturation bound on the volumetric efficiency input signal  
1 (default) | scalar in the range (0,1)

Largest allowed value of the mechanical efficiency. The input from the physical signal port **EM** saturates inputs above this value.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Pressure drop threshold for motor-pump transition** — Pressure drop at which to initiate a smooth transition between motor and pump modes  
1e-3 MPa (default) | scalar

Pressure drop from inlet to outlet below which the block begins to transition between motoring and pumping modes. The block uses a hyperbolic tangent function to smooth the leakage flow rate and friction torque.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies or Input signal - volumetric and mechanical losses.

**Angular velocity threshold for motor-pump transition** — Angular velocity at which to initiate a smooth transition between pump and motor modes  
100 rpm (default) | scalar

Shaft angular velocity below which the block begins to transition between motoring and pumping modes. The block uses the hyperbolic tangent function to smooth the leakage flow rate and friction torque.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies or Input signal - volumetric and mechanical losses.

**Cross-sectional area at ports A and B** — Flow area at the component inlet and outlet  
0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the component inlet and outlet. The areas are assumed equal.

**Check if operating beyond the quadrants of supplied tabulated data** — Simulation warning mode for operating conditions outside the range of tabulated data  
None (default) | Warning

Simulation warning mode for operating conditions outside the range of tabulated data. Select **Warning** to be notified when the fluid pressure drop or shaft angular velocity cross outside the specified tabular data. The warning does not cause simulation to stop.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses
- Input signal - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical losses

**Check if operating outside of motor mode** — Simulation warning mode for operating conditions outside motoring mode

None (default) | Warning

Simulation warning mode for operating conditions outside the motoring mode. The block generates a warning if the motor transitions to pumping mode. Select **Warning** to be notified when this transition occurs. The warning does not cause simulation to stop.

# Fixed-Displacement Pump

(To be removed) Mechanical-to-hydraulic power conversion device

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Pumps and Motors

## Description

The Fixed-Displacement Pump block represents a device that extracts power from a mechanical rotational network and delivers it to a hydraulic (isothermal liquid) network. The pump displacement is fixed at a constant value that you specify through the **Displacement** parameter.

Ports **T** and **P** represent the pump inlets. Port **S** represents the pump drive shaft. During normal operation, the pressure gain from port **T** to port **P** is positive if the angular velocity at port **S** is positive also. This operation mode is referred to here as *forward pump*.

## Operation Modes

A total of four operation modes are possible. The working mode depends on the pressure gain from port **T** to port **P** ( $\Delta p$ ) and on the angular velocity at port **S** ( $\omega$ ). The “Operation Modes” on page 1-876 figure maps the modes to the quadrants of a  $\Delta p$ - $\omega$  chart. The modes are labeled 1-4:

- Mode **1**: forward pump — A positive shaft angular velocity generates a positive pressure gain.
- Mode **2**: reverse motor — A negative pressure drop (shown in the figure as a positive pressure gain) generates a negative shaft angular velocity.

- Mode 3: reverse pump — A negative shaft angular velocity generates a negative pressure gain.
- Mode 4: forward motor — A positive pressure drop (shown in the figure as a negative pressure gain) generates a positive shaft angular velocity.

The response time of the pump is considered negligible in comparison with the system response time. The pump is assumed to reach steady state nearly instantaneously and is treated as a quasi-steady component.

### Block Variants and Loss Parameterizations

The pump model accounts for power losses due to leakage and friction. Leakage is internal and occurs between the pump inlet and outlet only. The block computes the leakage flow rate and friction torque using your choice of five loss parameterizations. You select a parameterization using block variants and, in the Analytical or tabulated data case, the **Leakage and friction parameterization** parameter.

### Loss Parameterizations

The block provides three Simscape variants to select from. To change the active block variant, use the **Modeling option** parameter. The available variants are:

- Analytical or tabulated data — Obtain the mechanical and volumetric efficiencies or losses from analytical models based on nominal parameters or from tabulated data. Use the **Leakage and friction parameterization** parameter to select the exact input type.
- Input efficiencies — Provide the mechanical and volumetric efficiencies directly through physical signal input ports.
- Input losses — Provide the mechanical and volumetric losses directly through physical signal input ports. The mechanical loss is defined as the internal friction torque. The volumetric loss is defined as the internal leakage flow rate.

### Flow Rate and Driving Torque

The volumetric flow rate generated at the pump is

$$q = q_{\text{Ideal}} + q_{\text{Leak}}$$

where:

- $q$  is the net volumetric flow rate.
- $q_{\text{Ideal}}$  is the ideal volumetric flow rate.
- $q_{\text{Leak}}$  is the internal leakage volumetric flow rate.

The driving torque required to power the pump is

$$\tau = \tau_{\text{Ideal}} + \tau_{\text{Friction}},$$

where:

- $\tau$  is the net driving torque.
- $\tau_{\text{Ideal}}$  is the ideal driving torque.
- $\tau_{\text{Friction}}$  is the friction torque.

### Ideal Flow Rate and Ideal Torque

The ideal volumetric flow rate is

$$q_{\text{Ideal}} = D\omega,$$

and the ideal driving torque is

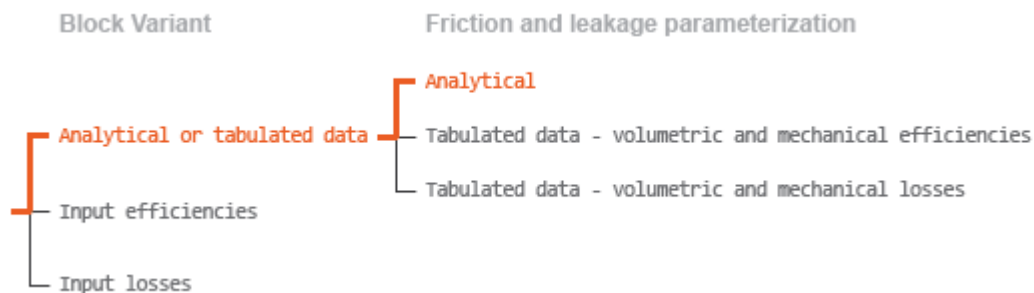

$$\tau_{\text{Ideal}} = D\Delta p,$$

where:

- $D$  is the specified value of the **Displacement** block parameter.
- $\omega$  is the instantaneous angular velocity of the rotary shaft.
- $\Delta p$  is the instantaneous pressure gain from inlet to outlet.

### Leakage Flow Rate and Friction Torque

The internal leakage flow rate and friction torque calculations depend on the block variant selected. If the block variant is `Analytical` or `tabulated data`, the calculations depend also on the **Leakage and friction parameterization** parameter setting. There are five possible permutations of block variant and parameterization settings.

### Case 1: Analytical Efficiency Calculation

If the active block variant is `Analytical` or `tabulated data` and the **Leakage and friction parameterization** parameter is set to `Analytical`, the leakage flow rate is

$$q_{\text{Leak}} = K_{\text{HP}}\Delta p,$$

and the friction torque is

$$\tau_{\text{Friction}} = (\tau_0 + K_{\text{TP}}|\Delta p|)\tanh\left(\frac{4\omega}{\omega_{\text{Threshold}}}\right),$$

where:

- $K_{HP}$  is the Hagen-Poiseuille coefficient for laminar pipe flows. This coefficient is computed from the specified nominal parameters.
- $K_{TP}$  is the specified value of the **Friction torque vs pressure gain coefficient** block parameter.
- $\tau_0$  is the specified value of the **No-load torque** block parameter.
- $\omega_{Threshold}$  is the threshold angular velocity for the motor-pump transition. The threshold angular velocity is an internally set fraction of the specified value of the **Nominal shaft angular velocity** block parameter.

The Hagen-Poiseuille coefficient is determined from nominal fluid and component parameters through the equation

$$K_{HP} = \frac{\nu_{Nom} \rho_{Nom} \omega_{Nom} D_{Max}}{\rho v \Delta p_{Nom}} (1 - \eta_{v,Nom}),$$

where:

- $\nu_{Nom}$  is the specified value of the **Nominal kinematic viscosity** block parameter. This is the kinematic viscosity at which the nominal volumetric efficiency is specified.
- $\rho_{Nom}$  is the specified value of the **Nominal fluid density** block parameter. This is the density at which the nominal volumetric efficiency is specified.
- $\omega_{Nom}$  is the specified value of the **Nominal shaft angular velocity** block parameter. This is the angular velocity at which the nominal volumetric efficiency is specified.
- $\rho$  is the actual fluid density in the attached hydraulic (isothermal liquid) network. This density can differ from the specified value of the **Nominal fluid density** block parameter.
- $v$  is the kinematic viscosity of the fluid associated with the fluid network.
- $\Delta p_{Nom}$  is the specified value of the **Nominal pressure gain** block parameter. This is the pressure drop at which the nominal volumetric efficiency is specified.
- $\eta_{v,Nom}$  is the specified value of the **Volumetric efficiency at nominal conditions** block parameter. This is the volumetric efficiency corresponding to the specified nominal conditions.

### Case 2: Efficiency Tabulated Data

If the active block variant is Analytical or tabulated data and the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies, the leakage flow rate is

$$q_{Leak} = q_{Leak,Pump} \frac{(1 + \alpha)}{2} + q_{Leak,Motor} \frac{(1 - \alpha)}{2},$$

and the friction torque is

$$\tau_{\text{Friction}} = \tau_{\text{Friction,Pump}} \frac{1 + \alpha}{2} + \tau_{\text{Friction,Motor}} \frac{1 - \alpha}{2},$$

where:

- $\alpha$  is a numerical smoothing parameter for the pump-pump transition.
- $q_{\text{Leak,Pump}}$  is the leakage flow rate in pump mode.
- $q_{\text{Leak,Motor}}$  is the leakage flow rate in motor mode.
- $\tau_{\text{Friction,Pump}}$  is the friction torque in pump mode.
- $\tau_{\text{Friction,Motor}}$  is the friction torque in motor mode.

The smoothing parameter  $\alpha$  is given by the hyperbolic function

$$\alpha = \tanh\left(\frac{4\Delta p}{\Delta p_{\text{Threshold}}}\right) \cdot \tanh\left(\frac{4\omega}{\omega_{\text{Threshold}}}\right),$$

where:

- $\Delta p_{\text{Threshold}}$  is the specified value of the **Pressure drop threshold for motor-pump transition** block parameter.
- $\omega_{\text{Threshold}}$  is the specified value of the **Angular velocity threshold for motor-pump transition** block parameter.

The leakage flow rate is computed from efficiency tabulated data through the equation

$$q_{\text{Leak,Pump}} = (1 - \eta_v)q_{\text{Ideal}},$$

in pump mode and through the equation

$$q_{\text{Leak,Motor}} = -(1 - \eta_v)q,$$

in motor mode, where:

- $\eta_v$  is the volumetric efficiency obtained through interpolation or extrapolation of the **Volumetric efficiency table, e\_v(dp,w)** parameter data.

Similarly, the friction torque is computed from efficiency tabulated data through the equation

$$\tau_{\text{Friction,Pump}} = (1 - \eta_m)\tau,$$

in pump mode and through the equation

$$\tau_{\text{Friction,Motor}} = -(1 - \eta_m)\tau_{\text{Ideal}},$$

in motor mode, where:

- $\eta_m$  is the mechanical efficiency obtained through interpolation or extrapolation of the **Mechanical efficiency table, e\_m(dp,w)** parameter data.

### Case 3: Loss Tabulated Data

If the active block variant is Analytical or tabulated data and the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical losses, the leakage flow rate equation is

$$q_{\text{Leak}} = q_{\text{Leak}}(\Delta p, \omega).$$

and the friction torque equation is

$$\tau_{\text{Friction}} = \tau_{\text{Friction}}(\Delta p, \omega),$$

where  $q_{\text{Leak}}(\Delta p, \omega)$  and  $\tau_{\text{Friction}}(\Delta p, \omega)$  are the volumetric and mechanical losses, obtained through interpolation or extrapolation of the **Volumetric loss table,  $q_{\text{loss}}(\text{dp}, \text{w})$**  and **Mechanical loss table, torque\_loss (dp,w)** parameter data.

### Case 4: Efficiency Physical Signal Inputs

If the active block variant is Input efficiencies, the leakage flow rate and friction torque calculations are as described for efficiency tabulated data (case 2). The volumetric and mechanical efficiency lookup tables are replaced with physical signal inputs that you specify through ports EV and EM.

### Case 5: Loss Physical Signal Inputs

If the block variant is `Input losses`, the leakage flow rate and friction torque calculations are as described for loss tabulated data (case 3). The volumetric and mechanical loss lookup tables are replaced with physical signal inputs that you specify through ports LV and LM.

### Characteristic Curve Visualization

If the block variant is set to `Analytical or tabulated data`, you can plot a variety of performance, efficiency, and loss curves from simulation data and component parameters. Use the context-sensitive menu of the block to plot the characteristic curves. Right-click the block to open the menu and select **Fluids > Plot characteristic**. A test harness opens with instructions on how to generate the curves.

### Assumptions

- Fluid compressibility is negligible.
- Loading on the pump shaft due to inertia, friction, and spring forces is negligible.

## Ports

### Input

**EV** — Volumetric efficiency, unitless  
physical signal

Physical signal input port for the volumetric efficiency coefficient. The input signal has an upper bound at the **Maximum volumetric efficiency** parameter value and a lower bound at the **Minimum volumetric efficiency** parameter value.

### Dependencies

This port is exposed only when the block variant is set to `Input efficiencies`.

**EM** — Mechanical efficiency, unitless  
physical signal

Physical signal input port for the mechanical efficiency coefficient. The input signal has an upper bound at the **Maximum mechanical efficiency** parameter value and a lower bound at the **Minimum mechanical efficiency** parameter value.

**Dependencies**

This port is exposed only when the block variant is set to `Input efficiencies`.

**LV** — Volumetric loss,  $m^3/s$   
physical signal

Physical signal input port for the volumetric loss, defined as the internal leakage flow rate between the pump inlets.

**Dependencies**

This port is exposed only when the block variant is set to `Input losses`.

**LM** — Mechanical loss,  $N*m$   
physical signal

Physical signal input port for the mechanical loss, defined as the friction torque on the rotating pump shaft.

**Dependencies**

This port is exposed only when the block variant is set to `Input losses`.

**Conserving**

**P** — Pump outlet  
hydraulic (isothermal liquid)

Hydraulic (isothermal liquid) conserving port representing the pump outlet.

**T** — Pump inlet  
hydraulic (isothermal liquid)

Hydraulic (isothermal liquid) conserving port representing the pump inlet.

**S** — Pump shaft  
mechanical rotational

Mechanical rotational conserving port representing the pump shaft.

**Parameters**

The exposed block parameters depend on the active block variant. See “Block Variants and Loss Parameterizations” on page 1-877.

**Modeling option** — Loss parameterizations  
`Analytical or tabulated data` | `Input efficiencies` | `Input losses`

Set the variant for mechanical and volumetric efficiencies or losses for the block.

**Variant 1: Analytical or tabulated data**

**Displacement** — Fluid volume displaced per unit shaft rotation angle  
`30 cm3/rev` (default) | scalar with units of volume/angle

Fluid volume displaced per unit shaft rotation angle. The displacement is fixed at this value during simulation. The specified value must be greater than zero.

**Leakage and friction parameterization** — Parameterization used to compute leakage flow rate and friction torque

Analytical (default) | Tabulated data – volumetric and mechanical efficiencies |  
Tabulated data – volumetric and mechanical losses

Parameterization used to compute flow-rate and torque losses due to internal leaks and friction. The **Analytical** parameterization relies on nominal parameters generally available from component data sheets. The remaining, tabular, options rely on lookup tables to map pressure drop and angular velocity to component efficiencies or losses. The tabular options include:

- Tabulated data – volumetric and mechanical efficiencies
- Tabulated data – volumetric and mechanical losses

**Nominal shaft angular velocity** — Shaft angular velocity at which to specify the nominal volumetric efficiency

188 rad/s (default) | scalar with units of angle/time

Angular velocity of the rotating shaft at which the component's nominal volumetric efficiency is known. Nominal parameters are typically published for standard operating conditions in manufacturer's data sheets. The block uses this parameter to calculate, using simple linear functions, the leakage flow rate and friction torque.

#### **Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to **Analytical**.

**Nominal pressure gain** — Pressure gain at which to specify the nominal volumetric efficiency

100e5 Pa (default) | scalar with units of pressure

Pressure gain from inlet to outlet at which the component's nominal volumetric efficiency is known. Nominal parameters are typically published for standard operating conditions in manufacturer's data sheets. The block uses this parameter to calculate, using a simple linear function, the internal leakage flow rate.

#### **Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to **Analytical**.

**Nominal kinematic viscosity** — Kinematic viscosity at which to specify the nominal volumetric efficiency

18 cSt (default) | scalar with units of area/time

Kinematic viscosity of the hydraulic fluid at which the component's nominal volumetric efficiency is known. Nominal parameters are typically published for standard operating conditions in manufacturer's data sheets. The block uses this parameter to calculate, using a simple linear function, the internal leakage flow rate.

#### **Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to **Analytical**.

**Nominal fluid density** — Fluid density at which to specify the nominal volumetric efficiency  
 900 kg/m<sup>3</sup> (default) | scalar with units of mass/volume

Mass density of the hydraulic fluid at which the component's nominal volumetric efficiency is known. Nominal parameters are typically published for standard operating conditions in manufacturer's data sheets. The block uses this parameter to calculate, using a simple linear function, the internal leakage flow rate.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Analytical.

**Volumetric efficiency at nominal conditions** — Volumetric efficiency at the specified nominal conditions  
 0.92 (default) | unitless scalar between 0 and 1

Volumetric efficiency, defined as the ratio of actual to ideal volumetric flow rates, at the specified nominal conditions. Nominal parameters are typically published for standard operating conditions in manufacturer's data sheets. The block uses this parameter to calculate, using a simple linear function, the internal leakage flow rate.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Analytical.

**No-load torque** — Minimum torque required to induce shaft rotation  
 0.05 N\*m (default) | scalar with units of torque

Torque required to overcome seal friction and induce rotation of the mechanical shaft. This torque is the smoothed load-independent component of the total friction torque.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Analytical.

**Friction torque vs. pressure gain coefficient** — Proportionality constant between friction torque and pressure gain  
 0.6e-6 N\*m/Pa (default) | scalar with units of torque/pressure

Proportionality constant between the friction torque on the mechanical shaft and the pressure gain from inlet to outlet.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies.

**Check if lower side pressure violating minimum valid condition** — Simulation warning mode for minimum valid pressure  
 None (default) | Warning

Simulation warning mode for invalid pressures at the component ports. Select Warning to be notified when pressure falls below a minimum specified value. The warning can be useful in models where

pressure can fall below the saturated vapor pressure of the hydraulic fluid, causing cavitation to occur.

**Minimum valid pressure** — Pressure required to trigger simulation warning  
0 (default) | scalar with units of pressure

Lower bound of the pressure validity range. A warning is issued if pressure falls below the specified value.

#### Dependencies

This parameter is enabled when the **Check if lower side pressure violating minimum valid condition** parameter is set to Warning.

**Pressure gain vector for efficiencies, dp** — Pressure gains at which to specify the volumetric and mechanical efficiencies  
 $M$ -element vector with units of pressure (default)

$M$ -element vector of pressure gains at which to specify the efficiency tabular data. The vector size,  $M$ , must be two or greater. The vector elements need not be uniformly spaced. However, they must monotonically increase in value from left to right.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies.

**Shaft angular velocity vector for efficiencies, w** — Angular velocities at which to specify the volumetric and mechanical efficiencies  
 $N$ -element vector with units of angular velocity (default)

$N$ -element vector of shaft angular velocities at which to specify the efficiency tabular data. The vector size,  $N$ , must be two or greater. The vector elements need not be uniformly spaced. However, they must monotonically increase in value from left to right.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies.

**Volumetric efficiency table, e\_v(dp,w)** — Volumetric efficiencies at the specified pressure gains and angular velocities  
unitless  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix with the volumetric efficiencies at the specified fluid pressure gains and shaft angular velocities. The efficiencies must fall in the range of 0-1.  $M$  and  $N$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure gain vector for efficiencies, dp** parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector for efficiencies, w** parameter.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies.

**Mechanical efficiency table,  $e_m(dp,w)$**  — Mechanical efficiencies at the specified pressure gains and angular velocities  
unitless  $M$ -by- $N$  matrix

$M$ -by- $N$  matrix with the mechanical efficiencies corresponding to the specified fluid pressure gains and shaft angular velocities. The efficiencies must fall in the range of 0-1.  $M$  and  $N$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure gain vector for efficiencies,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector for efficiencies,  $w$**  parameter.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies.

**Pressure gain threshold for pump—motor transition** — Pressure gain at which to initiate a smooth transition between pumping and motoring modes  
 $1e5$  Pa (default) | scalar with units of pressure

Pressure gain from inlet to outlet below which the component begins to transition between pumping and motoring modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies.

**Angular velocity threshold for pump—motor transition** — Shaft angular velocity at which to initiate a smooth transition between pumping and motoring modes  
 $10$  rad/s (default) | scalar with units of angle/time

Shaft angular velocity below which the component begins to transition between pumping and motoring modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies.

**Check if operating beyond the quadrants of supplied tabulated data** — Simulation warning mode for operating conditions outside the range of tabulated data  
None (default) | Warning

Simulation warning mode for operating conditions outside the range of tabulated data. Select Warning to be notified when the fluid pressure gain or shaft angular velocity cross outside the specified tabular data. The warning does not cause simulation to stop.

#### Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical efficiencies or Tabulated data – volumetric and mechanical losses.

**Pressure gain vector for losses,  $dp$**  — Pressure gains at which to specify the volumetric and mechanical losses

*M*-element vector with units of pressure (default)

*M*-element vector of pressure gains at which to specify the loss tabular data. The vector size, *M*, must be two or greater. The vector elements need not be uniformly spaced. However, they must monotonically increase in value from left to right.

#### **Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical losses.

**Shaft angular velocity vector for losses,  $w$**  — Angular velocities at which to specify the volumetric and mechanical losses

*N*-element vector with units of angle/time (default)

*N*-element vector of shaft angular velocities at which to specify the component loss data. The vector size, *N*, must be two or greater. The vector elements need not be uniformly spaced. However, they must monotonically increase in value from left to right.

#### **Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical losses.

**Volumetric loss table,  $q\_loss(dp,w)$**  — Internal leakage flow rates at the specified pressure gains and angular velocities

*M*-by-*N* matrix with units of volume/time

*M*-by-*N* matrix with the volumetric gains at the specified fluid pressure gains and shaft angular velocities. Volumetric loss is defined here as the internal leakage volumetric flow rate between port A and port B. *M* and *N* are the sizes of the specified lookup-table vectors:

- *M* is the number of vector elements in the **Pressure gain vector for losses,  $dp$**  parameter.
- *N* is the number of vector elements in the **Shaft angular velocity vector for losses,  $w$**  parameter.

#### **Dependencies**

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical losses.

**Mechanical loss table,  $torque\_loss(dp,w)$**  — Friction torques at the specified pressure gains and angular velocities

*M*-by-*N* matrix with units of torque

*M*-by-*N* matrix with the mechanical losses at the specified fluid pressure gains and shaft angular velocities. Mechanical loss is defined here as the friction torque due to seals and internal components. *M* and *N* are the sizes of the specified lookup-table vectors:

- *M* is the number of vector elements in the **Pressure gain vector for losses,  $dp$**  parameter.
- *N* is the number of vector elements in the **Shaft angular velocity vector for losses,  $w$**  parameter.

## Dependencies

This parameter is enabled when the **Leakage and friction parameterization** parameter is set to Tabulated data – volumetric and mechanical losses.

### Variant 2: Input efficiencies

**Displacement** — Fluid volume displaced per unit shaft rotation angle

30 cm<sup>3</sup>/rev (default) | scalar with units of volume/angle

Fluid volume displaced per unit shaft rotation angle. The displacement is fixed at this value during simulation. The specified value must be greater than zero.

**Minimum volumetric efficiency** — Lower saturation bound on the volumetric efficiency input signal

1e-3 (default) | unitless scalar between 0 and 1

Smallest allowed value of the volumetric efficiency. The input from physical signal port EV saturates at the specified value. If the input signal falls below the minimum volumetric efficiency, the volumetric efficiency is set to the minimum volumetric efficiency.

**Maximum volumetric efficiency** — Upper saturation bound on the volumetric efficiency input signal

1 (default) | unitless scalar between 0 and 1

Largest allowed value of the volumetric efficiency. The input from physical signal port EV saturates at the specified value. If the input signal rises above the maximum volumetric efficiency, the volumetric efficiency is set to the maximum volumetric efficiency.

**Minimum mechanical efficiency** — Lower saturation bound on the volumetric efficiency input signal

1e-3 (default) | unitless scalar between 0 and 1

Smallest allowed value of the mechanical efficiency. The input from physical signal port EM saturates at the specified value. If the input signal falls below the minimum mechanical efficiency, the mechanical efficiency is set to the minimum mechanical efficiency.

**Maximum mechanical efficiency** — Upper saturation bound on the volumetric efficiency input signal

1 (default) | unitless scalar between 0 and 1

Largest allowed value of the mechanical efficiency. The input from physical signal port EM saturates at the specified value. If the input signal rises above the maximum mechanical efficiency, the mechanical efficiency is set to the maximum mechanical efficiency.

**Pressure gain threshold for pump—motor transition** — Pressure gain at which to initiate a smooth transition between motor and pump modes

1e5 Pa (default) | scalar with units of pressure

Pressure gain from inlet to outlet below which the component begins to transition between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Angular velocity threshold for pump—motor transition** — Shaft angular velocity at which to initiate a smooth transition between pump and motor modes

10 rad/s (default) | scalar with units of angle/time

Shaft angular velocity below which the component begins to transition between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Check if lower side pressure violating minimum valid condition** — Simulation warning mode for minimum valid pressure  
None (default) | Warning

Simulation warning mode for invalid pressures at the component ports. Select **Warning** to be notified when pressure falls below a minimum specified value. The warning can be useful in models where pressure can fall below the saturated vapor pressure of the hydraulic fluid, causing cavitation to occur.

**Minimum valid pressure** — Pressure required to trigger simulation warning  
0 (default) | scalar with units of pressure

Lower bound of the pressure validity range. A warning is issued if pressure falls below the specified value.

#### **Dependencies**

This parameter is enabled when the **Check if lower side pressure violating minimum valid condition** parameter is set to **Warning**.

#### **Variant 3: Input losses**

**Displacement** — Fluid volume displaced per unit shaft rotation angle  
30 cm<sup>3</sup>/rev (default) | scalar with units of volume/angle

Fluid volume displaced per unit shaft rotation angle. The displacement is fixed at this value during simulation. The specified value must be greater than zero.

**Pressure gain threshold for pump—motor transition** — Pressure gain at which to initiate a smooth transition between motor and pump modes  
1e5 Pa (default) | scalar with units of pressure

Pressure gain from inlet to outlet below which the component begins to transition between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Angular velocity threshold for pump—motor transition** — Shaft angular velocity at which to initiate a smooth transition between pump and motor modes  
10 rad/s (default) | scalar with units of angle/time

Shaft angular velocity below which the component begins to transition between motoring and pumping modes. A hyperbolic Tanh function transforms the leakage flow rate and friction torque such that the transition is continuous and smooth.

**Check if operating beyond the pump mode** — Simulation warning mode for operating conditions outside pumping mode  
None (default) | Warning

Simulation warning mode for operating conditions outside the pumping mode. A warning is issued if the pump transitions to motoring mode. Select **Warning** to be notified when this transition occurs. The warning does not cause simulation to stop.

**Check if lower side pressure violating minimum valid condition** — Simulation warning mode for minimum valid pressure  
None (default) | Warning

Simulation warning mode for invalid pressures at the component ports. Select **Warning** to be notified when pressure falls below a minimum specified value. The warning can be useful in models where pressure can fall below the saturated vapor pressure of the hydraulic fluid, causing cavitation to occur.

**Minimum valid pressure** — Pressure required to trigger simulation warning

0 (default) | scalar with units of pressure

Lower bound of the pressure validity range. A warning is issued if pressure falls below the specified value.

#### **Dependencies**

This parameter is enabled when the **Check if lower side pressure violating minimum valid condition** parameter is set to **Warning**.

## **Version History**

**Introduced in R2006b**

**R2023a: To be removed**

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## **Extended Capabilities**

### **C/C++ Code Generation**

Generate C and C++ code using Simulink® Coder™.

# Fixed-Displacement Pump (IL)

Fixed-displacement pump in isothermal liquid system

## Libraries:

Simscape / Fluids / Isothermal Liquid / Pumps & Motors

## Description

The Fixed-Displacement Pump (IL) block models a pump with constant-volume displacement. The fluid may move from port **A** to port **B**, called *forward mode*, or from port **B** to port **A**, called *reverse mode*. Pump mode operation occurs when there is a pressure gain in the direction of the flow. Motor mode operation occurs when there is a pressure drop in the direction of the flow.

Shaft rotation corresponds to the sign of the fluid volume. Positive fluid displacement corresponds to positive shaft rotation in forward mode. Negative fluid displacement corresponds to negative shaft angular velocity in forward mode.

## Operation Modes

The block has four modes of operation. The working mode depends on the pressure gain from port **A** to port **B**,  $\Delta p = p_B - p_A$  and the angular velocity,  $\omega = \omega_R - \omega_C$ :

- Mode 1, *Forward Pump*: Positive shaft angular velocity causes a pressure increase from port **A** to port **B** and flow from port **A** to port **B**.
- Mode 2, *Reverse Motor*: Flow from port **B** to port **A** causes a pressure decrease from **B** to **A** and negative shaft angular velocity.
- Mode 3, *Reverse Pump*: Negative shaft angular velocity causes a pressure increase from port **B** to port **A** and flow from **B** to **A**.
- Mode 4, *Forward Motor*: Flow from port **A** to **B** causes a pressure decrease from **A** to **B** and positive shaft angular velocity.

The pump block has analytical, lookup table, and physical signal parameterizations. When using tabulated data or an input signal for parameterization, you can choose to characterize pump operation based on efficiency or losses.

The threshold parameters **Pressure gain threshold for pump-motor transition** and **Angular velocity threshold for pump-motor transition** identify regions where numerically smoothed flow transition between the pump operational modes can occur. For the pressure and angular velocity thresholds, choose a transition region that provides some margin for the transition term, but which is small enough relative to the typical pump pressure gain and angular velocity so that it will not impact calculation results.

### Analytical Leakage and Friction Parameterization

If you set **Leakage and friction parameterization** to **Analytical**, the block calculates leakage and friction from constant values of shaft velocity, pressure gain, and friction torque. The leakage flow rate, which is correlated with the pressure differential over the pump, is calculated as:

$$\dot{m}_{leak} = K\rho_{avg}\Delta p,$$

where:

- $\Delta p$  is  $p_B - p_A$ .
- $\rho_{avg}$  is the average fluid density.
- $K$  is the Hagen-Poiseuille coefficient for analytical loss,

$$K = \frac{D\omega_{nom}(1 - \eta_{v, nom})}{\Delta p_{nom}},$$

where:

- $D$  is the **Displacement**.
- $\omega_{nom}$  is the **Nominal shaft angular velocity**.
- $\eta_{v, nom}$  is the **Volumetric efficiency at nominal conditions**.
- $\Delta p_{nom}$  is the **Nominal pressure gain**.

The friction torque, which is related to the pump pressure differential, is calculated as:

$$\tau_{fr} = (\tau_0 + k|\Delta p|)\tanh\left(\frac{4\omega}{5 \times 10^{-5}\omega_{nom}}\right),$$

where:

- $\tau_0$  is the **No-load torque**.
- $k$  is the friction torque vs. pressure gain coefficient at nominal displacement, which is determined from the **Mechanical efficiency at nominal conditions**,  $\eta_{m, nom}$ :

$$k = \frac{\tau_{fr, nom} - \tau_0}{\Delta p_{nom}}.$$

$\tau_{fr, nom}$  is the friction torque at nominal conditions:

$$\tau_{fr, nom} = \left(\frac{1 - \eta_{m, nom}}{\eta_{m, nom}}\right)D\Delta p_{nom}.$$

- $\omega$  is the relative shaft angular velocity, or  $\omega_R - \omega_C$ .

### Tabulated Data Parameterizations

When using tabulated data for pump efficiencies or losses, you can provide data for one or more of the pump operational modes. The signs of the tabulated data determine the operational regime of the block. When data is provided for less than four operational modes, the block calculates the complementing data for the other modes by extending the given data into the remaining quadrants.

#### The Tabulated data - volumetric and mechanical efficiencies parameterization

The leakage flow rate is calculated as:

$$\dot{m}_{leak} = \dot{m}_{leak, pump} \left( \frac{1 + \alpha}{2} \right) + \dot{m}_{leak, motor} \left( \frac{1 - \alpha}{2} \right),$$

where:

- $\dot{m}_{leak, pump} = (1 - \eta_v) \dot{m}_{ideal}$
- $\dot{m}_{leak, motor} = (\eta_v - 1) \dot{m}$

and  $\eta_v$  is the volumetric efficiency, which is interpolated from the user-provided tabulated data. The transition term,  $\alpha$ , is

$$\alpha = \tanh\left(\frac{4\Delta p}{\Delta p_{threshold}}\right) \tanh\left(\frac{4\omega}{\omega_{threshold}}\right),$$

where:

- $\Delta p$  is  $p_B - p_A$ .
- $p_{threshold}$  is the **Pressure gain threshold for pump-motor transition**.
- $\omega$  is  $\omega_R - \omega_C$ .
- $\omega_{threshold}$  is the **Angular velocity threshold for pump-motor transition**.

The friction torque is calculated as:

$$\tau_{fr} = \tau_{fr, pump} \left( \frac{1 + \alpha}{2} \right) + \tau_{fr, motor} \left( \frac{1 - \alpha}{2} \right),$$

where:

- $\tau_{fr, pump} = (1 - \eta_m) \tau$
- $\tau_{fr, motor} = (\eta_m - 1) \tau_{ideal}$

and  $\eta_m$  is the mechanical efficiency, which is interpolated from the user-provided tabulated data.

#### The Tabulated data - volumetric and mechanical losses parameterization

The leakage flow rate is calculated as:

$$\dot{m}_{leak} = \rho_{avg} q_{loss}(\Delta p, \omega),$$

where  $q_{loss}$  is interpolated from the **Volumetric loss table,  $q\_loss(dp, w)$**  parameter, which is based on user-supplied data for pressure drop, shaft angular velocity, and fluid volumetric displacement.

The shaft friction torque is calculated as:

$$\tau_{fr} = \tau_{loss}(\Delta p, \omega),$$

where  $\tau_{loss}$  is interpolated from the **Mechanical loss table, torque\_loss(dp,w)** parameter, which is based on user-supplied data for pressure drop and shaft angular velocity.

### Input Signal Parameterization

When you select **Input signal - volumetric and mechanical efficiencies**, ports **EV** and **EM** are enabled. The internal leakage and shaft friction are calculated in the same way as the **Tabulated data - volumetric and mechanical efficiencies** parameterization, except that  $\eta_v$  and  $\eta_m$  are received directly at ports **EV** and **EM**, respectively.

When you select **Input signal - volumetric and mechanical losses**, ports **LV** and **LM** are enabled. These ports receive leakage flow and friction torque as positive physical signals. The leakage flow rate is calculated as:

$$\dot{m}_{leak} = \rho_{avg} q_{LV} \tanh\left(\frac{4\Delta p}{p_{thresh}}\right),$$

where:

- $q_{LV}$  is the leakage flow received at port **LV**.
- $p_{thresh}$  is the **Pressure gain threshold for pump-motor transition** parameter.

The friction torque is calculated as:

$$\tau_{fr} = \tau_{LM} \tanh\left(\frac{4\omega}{\omega_{thresh}}\right),$$

where

- $\tau_{LM}$  is the friction torque received at port **LM**.
- $\omega_{thresh}$  is the **Angular velocity threshold for pump-motor transition** parameter.

The volumetric and mechanical efficiencies range between the user-defined specified minimum and maximum values. Any values lower or higher than this range will take on the minimum and maximum specified values, respectively.

### Pump Operation

The pump flow rate is:

$$\dot{m} = \dot{m}_{ideal} - \dot{m}_{leak},$$

where  $\dot{m}_{ideal} = \rho_{avg} D \cdot \omega$ .

The pump torque is:

$$\tau = \tau_{ideal} + \tau_{fr},$$

where  $\tau_{ideal} = D \cdot \Delta p$ .

The mechanical power delivered by the pump shaft is:

$$\varphi_{mech} = \tau\omega,$$

and the pump hydraulic power is:

$$\varphi_{hyd} = \frac{\Delta p \dot{m}}{\rho_{avg}}.$$

If you would like to know if the block is operating beyond the supplied tabulated data, you can set **Check if operating beyond the quadrants of supplied tabulated data** to `Warning` to receive a warning if this occurs, or `Error` to stop the simulation when this occurs. For parameterization by input signal for volumetric or mechanical losses, you can be notified if the simulation surpasses operating modes with the **Check if operating beyond pump mode** parameter.

You can also monitor pump functionality. Set **Check if pressures are less than pump minimum pressure** to `Warning` to receive a warning if this occurs, or `Error` to stop the simulation when this occurs.

### Predefined Parameterization

Pre-parameterization of the Fixed-Displacement Pump (IL) block with manufacturer data is available. This data allows you to model a specific supplier component.

To load a predefined parameterization,

- 1 Click the "Select a predefined parameterization" hyperlink in the Fixed-Displacement Pump (IL) block dialog description.
- 2 Select a part from the drop-down menu and click **Update block with selected part**.
- 3 If you change any parameter settings after loading a parameterization, you can check your changes by clicking **Compare block settings with selected part**. Any difference in settings between the block and pre-defined parameterization will display in the MATLAB command window.

---

**Note** Predefined parameterizations of Simscape components use available data sources for supplying parameter values. Engineering judgement and simplifying assumptions are used to fill in for missing data. As a result, deviations between simulated and actual physical behavior should be expected. To ensure requisite accuracy, you should validate simulated behavior against experimental data and refine component models as necessary.

---

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Liquid entry or exit port to the pump.

**B** — Liquid port  
isothermal liquid

Liquid entry or exit port to the pump.

**R** — Mechanical port  
mechanical rotational

Rotating shaft angular velocity and torque.

**C** — Mechanical port  
mechanical rotational

Pump casing angular velocity and torque.

### Input

**EV** — Volumetric efficiency  
physical signal

Pump efficiency for fluid displacement, specified as a physical signal. The value must be between 0 and 1.

### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**EM** — Mechanical efficiency  
physical signal

Pump efficiency for the mechanical supply of energy, specified as a physical signal. The value must be between 0 and 1.

### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**LV** — Leakage flow rate,  $m^3/s$   
physical signal

Pump volumetric losses in  $m^3/s$ , specified as a physical signal.

### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

**LM** — Friction torque,  $N*m$   
physical signal

Pump mechanical losses in  $N*m$ , specified as a physical signal.

### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

## Parameters

**Leakage and friction parameterization** — Method of calculating leakage flow rate and friction torque

Analytical (default) | Tabulated data - volumetric and mechanical efficiencies | Tabulated data - volumetric and mechanical losses | Input signal - volumetric and mechanical efficiencies | Input signal - volumetric and mechanical losses

Parameterization of the leakage and friction characteristics of the pump.

- In the `Analytical` parameterization, the leakage flow rate and the friction torque are calculated by analytical equations.
- In the `Tabulated data - volumetric and mechanical efficiencies` parameterization, the volumetric and mechanical efficiencies are calculated from the user-supplied **Pressure gain vector,  $dp$**  and **Shaft angular velocity vector,  $w$**  parameters and interpolated from the 2-D dependent **Volumetric efficiency table,  $e_v(dp,w)$**  and **Mechanical efficiency table,  $e_m(dp,w)$**  tables.
- In the `Tabulated data - volumetric and mechanical loss` parameterization, the leakage flow rate and friction torque are calculated from the user-supplied **Pressure gain vector,  $dp$**  and **Shaft angular velocity vector,  $w$**  parameters and interpolated from the 2-D dependent **Volumetric loss table,  $q_{loss}(dp,w)$**  and **Mechanical loss table,  $torque_{loss}(dp,w)$**  tables.
- In the `Input signal - volumetric and mechanical efficiencies` parameterization, the volumetric and mechanical efficiencies are received as physical signals at ports **EV** and **EM**, respectively.
- In the `Input signal - volumetric and mechanical loss` parameterization, the leakage flow rate and torque friction are received as physical signals at ports **LV** and **LM**, respectively.

**Displacement** — Fixed-volume fluid displacement

30 cm<sup>3</sup>/rev (default) | scalar

Amount of fluid displaced by shaft rotating under nominal or typical operating conditions.

**Nominal shaft angular velocity** — Shaft angular velocity

1800 rpm (default) | scalar

Angular velocity of the shaft under nominal operating conditions.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to `Analytical`.

**Nominal pressure gain** — Pressure gain between fluid entry and exit

10 MPa (default) | scalar

Pump pressure gain between the fluid entry and exit under nominal or typical operating conditions.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to `Analytical`.

**Volumetric efficiency at nominal conditions** — Ratio of actual flow rate to ideal flow rate

0.92 (default) | positive scalar in the range of (0,1]

Ratio of actual flow rate to ideal flow rate at nominal conditions.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**No-load torque** — Baseline torque

0 N\*m (default) | scalar

Minimum value of torque to overcome seal friction and induce shaft motion.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Mechanical efficiency at nominal conditions** — Ratio of actual torque to ideal torque generated

0.88 (default) | positive scalar

Ratio of actual torque to ideal torque generated at nominal conditions.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Pressure gain vector, dp** — Vector of pressure data for tabulated data parameterization

[.1, 1, 2] MPa (default) | 1-by-*n* vector

Vector of pressure differential values for the tabular parameterization of leakage and torque friction. This vector forms an independent axis with the **Shaft angular velocity vector, w** parameter for the 2-D dependent **Volumetric efficiency table, e\_v(dp,w)** and **Mechanical efficiency table, e\_m(dp,w,D)** parameters. The vector elements must be listed in ascending order.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to either:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Shaft angular velocity vector, w** — Vector of angular velocity data for tabulated data parameterization

[250, 500, 1000, 2000, 3000, 4000] rpm (default) | 1-by-*n* vector

Vector of angular velocity data for the tabular parameterization of leakage and torque friction. This vector forms an independent axis with the **Shaft angular velocity vector, w** parameter for the 2-D dependent **Volumetric efficiency table, e\_v(dp,w)** and **Mechanical efficiency table, e\_m(dp,w)** parameters. The vector elements must be listed in ascending order.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to either:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Volumetric efficiency table, e\_v(dp,w)** — Volumetric efficiency for tabulated data parameterization

[.816, .908, .954, .977, .981, .984; .325, .663, .831, .916, .925, .946; .137, .568, .78, .892, .893, .91] (default) | *M*-by-*N*-by-*P* matrix

$M$ -by- $N$  matrix of volumetric efficiencies at the specified fluid pressure gain and shaft angular velocity. Linear interpolation is employed between table elements.  $M$  and  $N$  are the sizes of the correlated vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Mechanical efficiency table,  $e_m(dp,w)$**  — Mechanical efficiency for tabulated data parameterization

[.996, .996, .996, .996, .996, .996; .988, .989, .989, .989, .989, .99; .981, .981, .982, .982, .983, .984] (default) |  $M$ -by- $N$ -by- $P$  matrix

$M$ -by- $N$  matrix of mechanical efficiencies at the specified fluid pressure gain and shaft angular velocity. Linear interpolation is employed between table elements.  $M$  and  $N$  are the sizes of the correlated vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Volumetric loss table,  $q_{loss}(dp,w)$**  — Volumetric losses for tabulated data parameterization

[.023, .023, .023, .023, .0285, .032; .0844, .0842, .0845, .084, .1125, .108; .1079, .108, .11, .108, .1605, .18] \*  $1e-3$  m<sup>3</sup>/s (default) |  $M$ -by- $N$ -by- $P$  matrix

$M$ -by- $N$  matrix of volumetric efficiencies at the specified fluid pressure gain and shaft angular velocity. Linear interpolation is employed between table elements.  $M$  and  $N$  are the sizes of the correlated vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical loss.

**Mechanical loss table, torque\_loss(dp,w)** — Mechanical losses for tabulated data parameterization

[.002, .002, .002, .002, .002, .002; .0607, .0556, .0556, .0556, .0556, .0505; .1937, .1937, .1833, .1833, .1729, .1626] N\*m (default) |  $M$ -by- $N$ -by- $P$  matrix

$M$ -by- $N$  matrix of mechanical losses at the specified fluid pressure gain and shaft angular velocity. Linear interpolation is employed between table elements.  $M$  and  $N$  are the sizes of the correlated vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.

- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical loss.

**Minimum volumetric efficiency** — Minimum value of volumetric efficiency  
1e-3 (default) | positive scalar in the range of (0,1]

Minimum value of volumetric efficiency. If the input signal is below this value, the volumetric efficiency is set to the minimum volumetric efficiency.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum volumetric efficiency** — Maximum value of volumetric efficiency  
1 (default) | positive scalar in the range of (0,1]

Maximum value of volumetric efficiency. If the input signal is above this value, the volumetric efficiency is set to the maximum volumetric efficiency.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Minimum mechanical efficiency** — Minimum value of mechanical efficiency  
1e-3 (default) | positive scalar in the range of (0,1]

Minimum value of mechanical efficiency. If the input signal is below this value, the mechanical efficiency is set to the minimum mechanical efficiency.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum mechanical efficiency** — Maximum value of mechanical efficiency  
1 (default) | positive scalar in the range of (0,1]

Maximum value of mechanical efficiency. If the input signal is above this value, the mechanical efficiency is set to the maximum mechanical efficiency.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Pressure gain threshold for pump-motor transition** — Pressure threshold for mode transition  
1e-3 MPa (default) | positive scalar

Threshold pressure gain value for the transition between pump and motor functionality. A transition region is defined around 0 MPa between the positive and negative values of the pressure gain threshold. Within this transition region, the computed leakage flow rate and friction torque are adjusted according to the transition term  $\alpha$  to ensure smooth transition from one mode to the other.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to either:

- Tabulated data - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical losses

**Angular velocity threshold for pump-motor transition** — Angular velocity threshold for mode transition

100 rpm (default) | positive scalar

Threshold angular velocity value for the transition between pump and motor functionality. A transition region is defined around 0 rpm between the positive and negative values of the angular velocity threshold. Within this transition region, the computed leakage flow rate and friction torque are adjusted according to the transition term  $\alpha$  to ensure smooth transition from one mode to the other.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to:

- Tabulated data - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical efficiencies
- Input signal - volumetric and mechanical losses

**Check if operating beyond the quadrants of supplied tabulated data** — Whether to notify if extents of supplied data are surpassed

None (default) | Warning | Error

Whether to notify if the extents of the supplied data are surpassed. Select **Warning** to be notified when the block uses values beyond the supplied data range. Select **Error** to stop the simulation when the block uses values beyond the supplied data range.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Check if operating outside of pump mode** — Whether to notify if block operates outside of the pump mode functionality

None (default) | Warning | Error

Whether to notify if block operates outside of the pump mode functionality. This block has four operation modes: forward pump, reverse pump, reverse motor, and forward motor. Select **Warning** to be notified when the block operates in the forward or reverse motor modes. Select **Error** to stop the simulation when the block operates in the forward or reverse motor modes.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to **Input signal - volumetric and mechanical losses**.

**Check if pressures are less than pump minimum pressure** — Whether to notify if fluid exit pressure is low  
None (default) | Warning | Error

Whether to notify if the fluid at port **A** or **B** experiences low pressure. Select **Warning** to be notified when the outlet pressure falls below a minimum specified value. Select **Error** to stop the simulation when the outlet pressure falls below a minimum specified value.

The parameter helps to identify potential conditions for cavitation, when the fluid pressure falls below the fluid vapor pressure.

**Pump minimum pressure** — Lower threshold to acceptable pressure at the pump outlet  
0.101325 MPa (default) | positive scalar

Lower threshold of acceptable pressure at the pump inlet and outlet.

#### **Dependencies**

To enable this parameter, set **Check if pressures are less than pump minimum pressure** to:

- Warning
- Error

## Fixed-Displacement Pump (TL)

Mechanical-hydraulic power conversion device

### Libraries:

Simscape / Fluids / Thermal Liquid / Pumps & Motors

### Description

The Fixed-Displacement Pump (TL) block represents a pump that extracts power from a mechanical rotational network and delivers it to a thermal liquid network. The pump displacement is fixed at a constant value that you specify through the **Displacement** parameter.

Ports **A** and **B** represent the pump inlets. Ports **R** and **C** represent the drive shaft and case. During normal operation, the pressure gain from port **A** to port **B** is positive if the angular velocity at port **R** relative to port **C** is positive.

### Operating Modes

The block has four modes of operation, as shown by this image.

The working mode depends on the pressure gain from port **A** to port **B**,  $\Delta p = p_B - p_A$  and the angular velocity,  $\omega = \omega_R - \omega_C$ :

- The quadrant labeled **1** represents the forward pump mode. In this mode, the positive shaft angular velocity causes a pressure increase from port **A** to port **B** and flow from port **A** to port **B**
- The quadrant labeled **2** represents the reverse motor mode. In this mode, the flow from port **B** to port **A** causes a pressure decrease from **B** to **A** and negative shaft angular velocity.
- The quadrant labeled **3** represents the reverse pump mode. In this mode, the negative shaft angular velocity causes a pressure increase from port **B** to port **A** and flow from port **B** to port **A**
- The quadrant labeled **4** represents the forward motor mode. In this mode, the flow from port **A** to port **B** causes a pressure decrease from **A** to **B** and positive shaft angular velocity.

The response time of the pump is negligible in comparison with the system response time. The pump reaches steady state nearly instantaneously and is treated as a quasi-steady component.

## Energy Balance

The block associates the mechanical work done by the pump with an energy exchange. The governing energy balance equation is

$$\phi_A + \phi_B + P_{hydro} = 0,$$

where:

- $\Phi_A$  and  $\Phi_B$  are the energy flow rates at ports **A** and **B**, respectively.
- $P_{hydro}$  is the pump hydraulic power, which is a function of the pressure difference between the pump ports:  $P_{hydro} = \Delta p \frac{\dot{m}}{\rho}$ .

The block generates mechanical power due to torque,  $\tau$ , and angular velocity,  $\omega$ :

$$P_{mech} = \tau\omega.$$

## Flow Rate and Driving Torque

The mass flow rate generated at the pump is

$$\dot{m} = \dot{m}_{Ideal} - \dot{m}_{Leak},$$

where:

- $\dot{m}$  is the actual mass flow rate.
- $\dot{m}_{Ideal}$  is the ideal mass flow rate.
- $\dot{m}_{Leak}$  is the internal leakage mass flow rate.

The driving torque required to power the pump is

$$\tau = \tau_{Ideal} + \tau_{Friction},$$

where:

- $\tau$  is the actual driving torque.
- $\tau_{Ideal}$  is the ideal driving torque.
- $\tau_{Friction}$  is the friction torque.

## Ideal Flow Rate and Ideal Torque

The ideal mass flow rate is

$$\dot{m}_{Ideal} = \rho D\omega,$$

and the ideal required torque is

$$\tau_{Ideal} = D\Delta p,$$

where:

- $\rho$  is the average of the fluid densities at thermal liquid ports **A** and **B**.
- $D$  is the **Displacement** parameter.

- $\omega$  is the shaft angular velocity.
- $\Delta p$  is the pressure gain from inlet to outlet.

### Leakage and Friction Parameterization

You can parameterize leakage and friction analytically, by using tabulated efficiencies or losses, or by using input efficiencies or input losses.

#### Analytical

When you set the **Leakage and friction parameterization** parameter to `Analytical`, the leakage flow rate is

$$\dot{m}_{\text{Leak}} = \frac{K_{\text{HP}}\rho_{\text{Avg}}\Delta p}{\mu_{\text{Avg}}},$$

and the friction torque is

$$\tau_{\text{Friction}} = \left( \tau_0 + K_{\text{TP}}|\Delta p| \tanh\left(\frac{4\omega}{(5 \cdot 10^{-5})\omega_{\text{Nom}}}\right) \right),$$

where:

- $K_{\text{HP}}$  is the Hagen-Poiseuille coefficient for laminar pipe flows. The block computes this coefficient from the specified nominal parameters.
- $\mu$  is the dynamic viscosity of the fluid, which is the average of the values at the ports.
- $K_{\text{TP}}$  is the friction torque vs. pressure gain coefficient at nominal displacement, which the block determines from the **Mechanical efficiency at nominal conditions** parameter,  $\eta_m$ :

$$k = \frac{\tau_{fr, nom} - \tau_0}{\Delta p_{nom}}.$$

$\tau_{fr, nom}$  is the friction torque at nominal conditions:

$$\tau_{fr, nom} = \left( \frac{1 - \eta_{m, nom}}{\eta_{m, nom}} \right) D \Delta p_{nom}.$$

- $\Delta p_{\text{Nom}}$  is the value of the **Nominal pressure gain** parameter. This value is the pressure gain at which the nominal volumetric efficiency is specified.
- $\tau_0$  is the value of the **No-load torque** parameter.
- $\omega_{\text{Nom}}$  is the value of the **Nominal shaft angular velocity** parameter.

The block determines the Hagen-Poiseuille coefficient from the nominal fluid and component parameters

$$K_{\text{HP}} = \frac{D\omega_{\text{Nom}}\mu_{\text{Nom}}(1 - \eta_{v, \text{Nom}})}{\Delta p_{\text{Nom}}},$$

where:

- $\omega_{\text{Nom}}$  is the value of the **Nominal shaft angular velocity** parameter. This value is the angular velocity at which the block specifies the nominal volumetric efficiency.

- $\mu_{\text{Nom}}$  is the value of the **Nominal Dynamic viscosity** parameter. This value is the dynamic viscosity at which the block specifies the nominal volumetric efficiency.
- $\eta_{\text{v,Nom}}$  is the value of the **Volumetric efficiency at nominal conditions** parameter. This is the volumetric efficiency that corresponds to the specified nominal conditions.

### Tabulated Efficiencies

When you set the **Leakage and friction parameterization** parameter to Tabulated data - volumetric and mechanical efficiencies, the leakage flow rate is

$$\dot{m}_{\text{Leak}} = \dot{m}_{\text{Leak,Pump}} \frac{(1 + \alpha)}{2} + \dot{m}_{\text{Leak,Motor}} \frac{(1 - \alpha)}{2},$$

and the friction torque is

$$\tau_{\text{Friction}} = \tau_{\text{Friction,Pump}} \frac{1 + \alpha}{2} + \tau_{\text{Friction,Motor}} \frac{1 - \alpha}{2},$$

where:

- $\alpha$  is a numerical smoothing parameter for the motor-pump transition.
- $\dot{m}_{\text{Leak,Motor}}$  is the leakage flow rate in motor mode.
- $\dot{m}_{\text{Leak,Pump}}$  is the leakage flow rate in pump mode.
- $\tau_{\text{Friction,Motor}}$  is the friction torque in motor mode.
- $\tau_{\text{Friction,Pump}}$  is the friction torque in pump mode.

This hyperbolic function describes the smoothing parameter  $\alpha$

$$\alpha = \tanh\left(\frac{4\Delta p}{\Delta p_{\text{Threshold}}}\right) \cdot \tanh\left(\frac{4\omega}{\omega_{\text{Threshold}}}\right),$$

where:

- $\Delta p_{\text{Threshold}}$  is the value of the **Pressure gain threshold for motor-pump transition** parameter.
- $\omega_{\text{Threshold}}$  is the value of the **Angular velocity threshold for motor-pump transition** parameter.

The block calculates the leakage flow rate from the volumetric efficiency, which the **Volumetric efficiency table** parameter specifies over the  $\Delta p$ - $\omega$  domain. When operating in pump mode, the leakage flow rate is:

$$\dot{m}_{\text{Leak,Pump}} = (1 - \eta_{\text{v}})\dot{m}_{\text{Ideal}},$$

where  $\eta_{\text{v}}$  is the volumetric efficiency, which the block obtains either by interpolation or extrapolation of the tabulated data. Similarly, when operating in motor mode, the leakage flow rate is:

$$\dot{m}_{\text{Leak,Motor}} = -(1 - \eta_{\text{v}})\dot{m}.$$

The block calculates the friction torque from the mechanical efficiency, which the **Mechanical efficiency table** parameter specifies over the  $\Delta p$ - $\omega$  domain. When operating in pump mode, the friction torque is

$$\tau_{\text{Friction,Pump}} = (1 - \eta_{\text{m}})\tau,$$

where  $\eta_m$  is the mechanical efficiency, which the block obtains either by interpolation or extrapolation of the tabulated data. Similarly, when operating in motor mode, the friction torque is

$$\tau_{\text{Friction, Motor}} = -(1 - \eta_m)\tau_{\text{Ideal}}.$$

### Tabulated Losses

When you set the **Leakage and friction parameterization** parameter to **Tabulated data - volumetric and mechanical losses**, the block specifies the leakage volumetric flow rate in tabulated form over the  $\Delta p$ - $\omega$  domain:

$$q_{\text{Leak}} = q_{\text{Leak}}(\Delta p, \omega).$$

The block calculates the mass flow rate due to leakage from the volumetric flow rate:

$$\dot{m}_{\text{Leak}} = \rho q_{\text{Leak}}.$$

The block calculates the friction torque in tabulated form:

$$\tau_{\text{Friction}} = \tau_{\text{Friction}}(\Delta p, \omega),$$

where  $q_{\text{Leak}}(\Delta p, \omega)$  and  $\tau_{\text{Friction}}(\Delta p, \omega)$  are the volumetric and mechanical losses, specified through interpolation or extrapolation of the tabulated data in the **Volumetric loss table** and **Mechanical loss table** parameters.

### Input Efficiencies

When you set the **Leakage and friction parameterization** parameter to **Input signal - volumetric and mechanical efficiencies**, the leakage flow rate and friction torque calculations are identical to the **Tabulated data - volumetric and mechanical efficiencies** setting. The block replaces the volumetric and mechanical efficiency lookup tables with the physical signal input ports **EV** and **EM**.

The efficiencies are positive quantities with values between 0 and 1. The block sets input values outside of these bounds to 0 for inputs smaller than 0 or 1 for inputs greater than 1. The block saturates the efficiency signals at the value of the **Minimum volumetric efficiency** or **Minimum mechanical efficiency** parameter and the **Maximum volumetric efficiency** or **Maximum mechanical efficiency** parameter.

### Input Losses

When you set the **Leakage and friction parameterization** parameter to **Input signal - volumetric and mechanical losses**, the leakage flow rate and friction torque calculations are identical to the **Tabulated data - volumetric and mechanical efficiencies** setting. The block replaces the volumetric and mechanical loss lookup tables with the physical signal input ports **LV** and **LM**.

The block expects the inputs to be positive and sets the signs automatically from the  $\Delta p$ - $\omega$  quadrant where the component is operating. If you provide a negative signal, the block returns zero losses.

### Assumptions and Limitations

- The block treats the pump as a quasi-steady component.
- The block ignores the effects of fluid inertia and elevation.
- The pump wall is rigid.

- The block ignores external leakage.

## Ports

### Input

**EV** — Volumetric efficiency, unitless  
physical signal

Physical signal input port for the volumetric efficiency coefficient. The input signal has an upper bound at the **Maximum volumetric efficiency** parameter value and a lower bound at the **Minimum volumetric efficiency** parameter value.

### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**EM** — Mechanical efficiency, unitless  
physical signal

Physical signal input port for the mechanical efficiency coefficient. The input signal has an upper bound at the **Maximum mechanical efficiency** parameter value and a lower bound at the **Minimum mechanical efficiency** parameter value.

### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**LV** — Volumetric loss,  $m^3/s$   
physical signal

Physical signal input port for the volumetric loss which is the internal leakage flow rate between the pump inlets.

### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

**LM** — Mechanical loss,  $N\cdot m$   
physical signal

Physical signal input port for the mechanical loss which is the friction torque on the rotating pump shaft.

### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

## Conserving

**A** — Pump inlet  
thermal liquid

Thermal liquid conserving port associated with the pump inlet.

**B** — Pump outlet  
thermal liquid

Thermal liquid conserving port associated with the pump outlet.

**C** — Pump case  
mechanical rotational

Mechanical rotational conserving port associated with the pump case.

**R** — Pump shaft  
mechanical rotational

Mechanical rotational conserving port associated with the rotational pump shaft.

## Parameters

**Leakage and friction parameterization** — Parameterization of leakage flow rate and friction torque  
Analytical (default) | Tabulated data - volumetric and mechanical efficiencies |  
Tabulated data - volumetric and mechanical losses | Input signal - volumetric  
and mechanical efficiencies | Input signal - volumetric and mechanical losses

Method to compute the flow-rate and torque losses due to internal leaks and friction. Use the Analytical if the block parameters are generally available from component data sheets. When you select Tabulated data - volumetric and mechanical efficiencies or Tabulated data - volumetric and mechanical losses, the block uses lookup tables to map pressure gains and shaft angular velocities to component efficiencies or losses.

When you select Input signal - volumetric and mechanical efficiencies or Input signal - volumetric and mechanical losses, the block performs the leakage flow rate and friction torque calculations the same as the Tabulated data - volumetric and mechanical efficiencies or Tabulated data - volumetric and mechanical losses settings, respectively. When you select Input signal - volumetric and mechanical efficiencies, the block enables the **EV** and **EM** ports. You use these ports to specify the volumetric and mechanical efficiency. When you select Input signal - volumetric and mechanical losses, the block enables the **LV** and **LM** ports. You use these ports to specify the volumetric and mechanical losses.

**Displacement** — Fluid volume displaced per shaft rotation  
30 cm<sup>3</sup>/rev (default) | positive scalar

Fluid volume displaced per shaft rotation. The block maintains this value throughout the simulation.

**Nominal shaft angular velocity** — Shaft angular velocity for given volumetric efficiency  
1800 rpm (default) | scalar

Angular velocity of the rotary shaft that corresponds to the given volumetric efficiency. The standard operating conditions in the manufacturer data sheet typically list these values. The block uses this parameter to calculate the leakage flow rate and friction torque.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Nominal pressure gain** — Pressure gain for corresponding volumetric efficiency

10 MPa (default) | scalar

Pressure gain that corresponds to the given volumetric efficiency. The standard operating conditions in the manufacturer data sheet typically list these values. The block uses this parameter to calculate the internal leakage flow rate.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Nominal dynamic viscosity** — Dynamic viscosity at which to specify the volumetric efficiency

0.9 cP (default) | scalar

Dynamic viscosity of the hydraulic fluid for the given volumetric efficiency. The standard operating conditions in the manufacturer data sheet typically list these values. The block uses this parameter to calculate the internal leakage flow rate.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Volumetric efficiency at nominal conditions** — Volumetric efficiency at specified nominal conditions

0.92 (default) | scalar in the range (0,1)

Volumetric efficiency for the given conditions. The block defines the volumetric efficiency as the ratio of actual to ideal volumetric flow rates. The standard operating conditions in the manufacturer data sheet typically list these values. The block uses this parameter to calculate the internal leakage flow rate.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Mechanical efficiency at nominal conditions** — Ratio of ideal-to-actual mechanical power

0.88 (default) | positive scalar

Ratio of ideal mechanical power to actual mechanical power at nominal conditions.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**No-load torque** — Minimum torque required to induce shaft rotation

0 N\*m (default) | scalar

Torque to overcome the seal friction and induce rotation of the mechanical shaft. This torque is the load-independent component of the total friction torque.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Pressure gain vector, dp** — Pressure gains for given volumetric and mechanical efficiencies or losses

[.1, 1, 2] MPa (default) | vector

Pressure gains for the corresponding tabular efficiency or loss data. The vector must be at least two elements in strictly increasing order.

Specify the data for a single quadrant,  $(\omega, \Delta p)$ . Refer to “Operating Modes” on page 1-904 for the operation modes corresponding to parameter specifications and the resulting quadrants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies or Tabulated data - volumetric and mechanical losses.

**Shaft angular velocity vector,  $w$**  — Angular velocities at which to specify volumetric and mechanical efficiencies or losses

[250, 500, 1000, 2000, 3000, 4000] rpm (default) | vector

Shaft angular velocities for the corresponding tabular efficiency or loss data. The vector must be at least two elements in strictly increasing order.

Specify the data for a single quadrant,  $(\omega, \Delta p)$ . Refer to “Operating Modes” on page 1-904 for the operation modes corresponding to parameter specifications and the resulting quadrants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies or Tabulated data - volumetric and mechanical losses.

**Volumetric efficiency table,  $e_v(dp,w)$**  — Volumetric efficiencies for given pressure gains and angular velocities

[.816, .908, .954, .977, .981, .984; .325, .663, .831, .916, .925, .946; .137, .568, .78, .892, .893, .91] (default) | matrix

Volumetric efficiencies for the given fluid pressure gains and shaft angular velocities. The efficiencies must be in the range (0,1].  $M$  and  $N$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.

Specify the data for a single quadrant,  $(\omega, \Delta p)$ . Refer to “Operating Modes” on page 1-904 for the operation modes corresponding to parameter specifications and the resulting quadrants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Mechanical efficiency table,  $e_m(dp,w)$**  — Mechanical efficiencies for given pressure gains and angular velocities

[.996, .996, .996, .996, .996, .996; .988, .989, .989, .989, .989, .99; .981, .981, .982, .982, .983, .984] (default) | matrix

Mechanical efficiencies for the given fluid pressure gains and shaft angular velocities. The efficiencies must be in the range (0,1].  $M$  and  $N$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.

Specify the data for a single quadrant,  $(\omega, \Delta p)$ . Refer to “Operating Modes” on page 1-904 for the operation modes corresponding to parameter specifications and the resulting quadrants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Volumetric loss table,  $q\_loss(dp,w)$**  — Internal leakage flow rates for corresponding pressure gains and angular velocities

[.023, .023, .023, .023, .0285, .032; .0844, .0842, .0845, .084, .1125, .108; .1079, .108, .11, .108, .1605, .18] \*  $1e-3$  m<sup>3</sup>/s (default) | matrix

Volumetric losses at the specified fluid pressure gains and shaft angular velocities. Volumetric loss is the internal leakage volumetric flow rate between port **A** and port **B**.  $M$  and  $N$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.

Specify the data for a single quadrant,  $(\omega, \Delta p)$ . Refer to “Operating Modes” on page 1-904 for the operation modes corresponding to parameter specifications and the resulting quadrants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical losses.

**Mechanical loss table,  $torque\_loss(dp,w)$**  — Friction torques for corresponding pressure gains and angular velocities

[.002, .002, .002, .002, .002, .002; .0607, .0556, .0556, .0556, .0556, .0505; .1937, .1937, .1833, .1833, .1729, .1626] N\*m (default) | matrix

Mechanical losses for the given pressure gains and shaft angular velocities. The block defines mechanical loss as the friction torque due to seals and internal components.  $M$  and  $N$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.

Specify the data for a single quadrant,  $(\omega, \Delta p)$ . Refer to “Operating Modes” on page 1-904 for the operation modes corresponding to parameter specifications and the resulting quadrants. The tabulated data for the mechanical losses must obey the convention in the figure, with positive values at positive angular velocities and negative values at negative angular velocities.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical losses.

**Minimum volumetric efficiency** — Lower saturation bound on volumetric efficiency input signal  $1e-3$  (default) | scalar in the range (0,1)

Smallest allowed value of the volumetric efficiency. The input from the physical signal port **EV** saturates inputs below this value.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum volumetric efficiency** — Upper saturation bound on volumetric efficiency input signal 1 (default) | scalar in the range (0,1)

Largest allowed value of the volumetric efficiency. The input from the physical signal port **EV** saturates inputs above this value.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Minimum mechanical efficiency** — Lower saturation bound on volumetric efficiency input signal  $1e-3$  (default) | scalar in the range (0,1)

Smallest allowed value of the mechanical efficiency. The input from the physical signal port **EM** saturates inputs below this value.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum mechanical efficiency** — Upper saturation bound on volumetric efficiency input signal 1 (default) | scalar in the range (0,1)

Largest allowed value of the mechanical efficiency. The input from the physical signal port **EM** saturates inputs above this value.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Pressure gain threshold for motor-pump transition** — Pressure gain at which to initiate smooth transition between motor and pump modes

1e-3 MPa (default) | scalar

Pressure gain from the inlet to the outlet below which the block begins to transition between the motor and pump modes. The block uses a hyperbolic tangent function to smooth the leakage flow rate and friction torque.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies or Input signal - volumetric and mechanical losses.

**Angular velocity threshold for motor-pump transition** — Angular velocity at which to initiate smooth transition between pump and motor modes

100 rpm (default) | scalar

Shaft angular velocity below which the block begins to transition between the motor and pump modes. The block uses the hyperbolic tangent function to smooth the leakage flow rate and friction torque.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies or Input signal - volumetric and mechanical losses.

**Cross-sectional area at ports A and B** — Flow area at component inlet and outlet

0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the component inlet and outlet. The areas are assumed equal.

**Check if operating beyond the quadrants of supplied tabulated data** — Simulation warning mode for operating conditions outside range of tabulated data

None (default) | Warning | Error

Simulation warning mode for operating conditions outside the range of tabulated data. If you select **Warning**, the block generates a warning when the fluid pressure gain or the shaft angular velocity cross outside the specified tabular data. The warning does not cause simulation to stop. If you select **Error**, the simulation will stop for conditions outside the range of tabulated data.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Check if operating outside of pump mode** — Simulation warning mode for operating conditions outside pump mode

None (default) | Warning | Error

Simulation warning mode for operating conditions outside the pump mode. When you set this parameter to **Warning**, the block generates a warning if the pump transitions to motoring mode. The warning does not cause simulation to stop. If you select **Error**, the simulation will stop for conditions outside the pump mode.

#### **Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

## Fixed-Displacement Pump (2P)

Mechanical-hydraulic power conversion device

### Libraries:

Simscape / Fluids / Two-Phase Fluid / Fluid Machines

### Description

The Fixed-Displacement Pump (2P) block represents a pump that extracts power from a mechanical rotational network and delivers it to a two-phase fluid network. The pump displacement is fixed at a constant value that you specify through the **Displacement** parameter.

Ports **A** and **B** represent the pump inlets. Ports **R** and **C** represent the drive shaft and case. During normal operation, the pressure gain from port **A** to port **B** is positive if the angular velocity at port **R** relative to port **C** is positive.

The Fixed-Displacement Pump (2P) block assumes that liquid enters the pump inlet. You can use the **Report when fluid is not fully liquid** parameter to choose what the block does when the fluid does not meet liquid conditions. To move vapor in a two-phase fluid network, use a compressor.

### Operating Modes

The block has four modes of operation, as shown by this image.

The working mode depends on the pressure gain from port **A** to port **B**,  $\Delta p = p_B - p_A$  and the angular velocity,  $\omega = \omega_R - \omega_C$ :

- The quadrant labeled **1** represents the forward pump mode. In this mode, the positive shaft angular velocity causes a pressure increase from port **A** to port **B** and flow from port **A** to port **B**
- The quadrant labeled **2** represents the reverse motor mode. In this mode, the flow from port **B** to port **A** causes a pressure decrease from **B** to **A** and negative shaft angular velocity.

- The quadrant labeled **3** represents the reverse pump mode. In this mode, the negative shaft angular velocity causes a pressure increase from port **B** to port **A** and flow from port **B** to port **A**
- The quadrant labeled **4** represents the forward motor mode. In this mode, the flow from port **A** to port **B** causes a pressure decrease from **A** to **B** and positive shaft angular velocity.

The response time of the pump is negligible in comparison with the system response time. The pump reaches steady state nearly instantaneously and is treated as a quasi-steady component.

### Energy Balance

The block associates the mechanical work done by the pump with an energy exchange. The governing energy balance equation is

$$\phi_A + \phi_B + P_{hydro} = 0,$$

where:

- $\Phi_A$  and  $\Phi_B$  are the energy flow rates at ports **A** and **B**, respectively.
- $P_{hydro}$  is the pump hydraulic power, which is a function of the pressure difference between the pump ports:  $P_{hydro} = \Delta p \frac{\dot{m}}{\rho}$ .

The block generates mechanical power due to torque,  $\tau$ , and angular velocity,  $\omega$ :

$$P_{mech} = \tau\omega.$$

### Flow Rate and Driving Torque

The mass flow rate generated at the pump is

$$\dot{m} = \dot{m}_{Ideal} - \dot{m}_{Leak},$$

where:

- $\dot{m}$  is the actual mass flow rate.
- $\dot{m}_{Ideal}$  is the ideal mass flow rate.
- $\dot{m}_{Leak}$  is the internal leakage mass flow rate.

The driving torque required to power the pump is

$$\tau = \tau_{Ideal} + \tau_{Friction},$$

where:

- $\tau$  is the actual driving torque.
- $\tau_{Ideal}$  is the ideal driving torque.
- $\tau_{Friction}$  is the friction torque.

### Ideal Flow Rate and Ideal Torque

The ideal mass flow rate is

$$\dot{m}_{Ideal} = \rho D\omega,$$

and the ideal required torque is

$$\tau_{\text{Ideal}} = D\Delta p,$$

where:

- $\rho$  is the average of the fluid densities at ports **A** and **B**.
- $D$  is the **Displacement** parameter.
- $\omega$  is the shaft angular velocity.
- $\Delta p$  is the pressure gain from inlet to outlet.

### Leakage and Friction Parameterization

You can parameterize leakage and friction analytically, by using tabulated efficiencies or losses, or by using input efficiencies or input losses.

#### Analytical

When you set the **Leakage and friction parameterization** parameter to **Analytical**, the leakage flow rate is

$$\dot{m}_{\text{Leak}} = \frac{K_{\text{HP}}\rho_{\text{Avg}}\Delta p}{\mu_{\text{Avg}}},$$

and the friction torque is

$$\tau_{\text{Friction}} = \left( \tau_0 + K_{\text{TP}}|\Delta p| \tanh\left(\frac{4\omega}{(5 \cdot 10^{-5})\omega_{\text{Nom}}}\right) \right),$$

where:

- $K_{\text{HP}}$  is the Hagen-Poiseuille coefficient for laminar pipe flows. The block computes this coefficient from the specified nominal parameters.
- $\mu$  is the dynamic viscosity of the fluid, which is the average of the values at the ports.
- $K_{\text{TP}}$  is the friction torque vs. pressure gain coefficient at nominal displacement, which the block determines from the **Mechanical efficiency at nominal conditions** parameter,  $\eta_m$ :

$$k = \frac{\tau_{fr, \text{nom}} - \tau_0}{\Delta p_{\text{nom}}}.$$

$\tau_{fr, \text{nom}}$  is the friction torque at nominal conditions:

$$\tau_{fr, \text{nom}} = \left( \frac{1 - \eta_{m, \text{nom}}}{\eta_{m, \text{nom}}} \right) D\Delta p_{\text{nom}}.$$

- $\Delta p_{\text{Nom}}$  is the value of the **Nominal pressure gain** parameter. This value is the pressure gain at which the nominal volumetric efficiency is specified.
- $\tau_0$  is the value of the **No-load torque** parameter.
- $\omega_{\text{Nom}}$  is the value of the **Nominal shaft angular velocity** parameter.

The block determines the Hagen-Poiseuille coefficient from the nominal fluid and component parameters

$$K_{HP} = \frac{D\omega_{Nom}\mu_{Nom}(1 - \eta_{v,Nom})}{\Delta p_{Nom}},$$

where:

- $\omega_{Nom}$  is the value of the **Nominal shaft angular velocity** parameter. This value is the angular velocity at which the block specifies the nominal volumetric efficiency.
- $\mu_{Nom}$  is the value of the **Nominal Dynamic viscosity** parameter. This value is the dynamic viscosity at which the block specifies the nominal volumetric efficiency.
- $\eta_{v,Nom}$  is the value of the **Volumetric efficiency at nominal conditions** parameter. This is the volumetric efficiency that corresponds to the specified nominal conditions.

### Tabulated Efficiencies

When you set the **Leakage and friction parameterization** parameter to `Tabulated data - volumetric and mechanical efficiencies`, the leakage flow rate is

$$\dot{m}_{Leak} = \dot{m}_{Leak,Pump} \frac{(1 + \alpha)}{2} + \dot{m}_{Leak,Motor} \frac{(1 - \alpha)}{2},$$

and the friction torque is

$$\tau_{Friction} = \tau_{Friction,Pump} \frac{1 + \alpha}{2} + \tau_{Friction,Motor} \frac{1 - \alpha}{2},$$

where:

- $\alpha$  is a numerical smoothing parameter for the motor-pump transition.
- $\dot{m}_{Leak,Motor}$  is the leakage flow rate in motor mode.
- $\dot{m}_{Leak,Pump}$  is the leakage flow rate in pump mode.
- $\tau_{Friction,Motor}$  is the friction torque in motor mode.
- $\tau_{Friction,Pump}$  is the friction torque in pump mode.

This hyperbolic function describes the smoothing parameter  $\alpha$

$$\alpha = \tanh\left(\frac{4\Delta p}{\Delta p_{Threshold}}\right) \cdot \tanh\left(\frac{4\omega}{\omega_{Threshold}}\right),$$

where:

- $\Delta p_{Threshold}$  is the value of the **Pressure gain threshold for motor-pump transition** parameter.
- $\omega_{Threshold}$  is the value of the **Angular velocity threshold for motor-pump transition** parameter.

The block calculates the leakage flow rate from the volumetric efficiency, which the **Volumetric efficiency table** parameter specifies over the  $\Delta p$ - $\omega$  domain. When operating in pump mode, the leakage flow rate is:

$$\dot{m}_{Leak,Pump} = (1 - \eta_v)\dot{m}_{Ideal},$$

where  $\eta_v$  is the volumetric efficiency, which the block obtains either by interpolation or extrapolation of the tabulated data. Similarly, when operating in motor mode, the leakage flow rate is:

$$\dot{m}_{Leak,Motor} = -(1 - \eta_v)\dot{m}.$$

The block calculates the friction torque from the mechanical efficiency, which the **Mechanical efficiency table** parameter specifies over the  $\Delta p$ - $\omega$  domain. When operating in pump mode, the friction torque is

$$\tau_{\text{Friction,Pump}} = (1 - \eta_m)\tau,$$

where  $\eta_m$  is the mechanical efficiency, which the block obtains either by interpolation or extrapolation of the tabulated data. Similarly, when operating in motor mode, the friction torque is

$$\tau_{\text{Friction,Motor}} = -(1 - \eta_m)\tau_{\text{Ideal}}.$$

### Tabulated Losses

When you set the **Leakage and friction parameterization** parameter to **Tabulated data - volumetric and mechanical losses**, the block specifies the leakage volumetric flow rate in tabulated form over the  $\Delta p$ - $\omega$  domain:

$$q_{\text{Leak}} = q_{\text{Leak}}(\Delta p, \omega).$$

The block calculates the mass flow rate due to leakage from the volumetric flow rate:

$$\dot{m}_{\text{Leak}} = \rho q_{\text{Leak}}.$$

The block calculates the friction torque in tabulated form:

$$\tau_{\text{Friction}} = \tau_{\text{Friction}}(\Delta p, \omega),$$

where  $q_{\text{Leak}}(\Delta p, \omega)$  and  $\tau_{\text{Friction}}(\Delta p, \omega)$  are the volumetric and mechanical losses, specified through interpolation or extrapolation of the tabulated data in the **Volumetric loss table** and **Mechanical loss table** parameters.

### Input Efficiencies

When you set the **Leakage and friction parameterization** parameter to **Input signal - volumetric and mechanical efficiencies**, the leakage flow rate and friction torque calculations are identical to the **Tabulated data - volumetric and mechanical efficiencies** setting. The block replaces the volumetric and mechanical efficiency lookup tables with the physical signal input ports **EV** and **EM**.

The efficiencies are positive quantities with values between 0 and 1. The block sets input values outside of these bounds to 0 for inputs smaller than 0 or 1 for inputs greater than 1. The block saturates the efficiency signals at the value of the **Minimum volumetric efficiency** or **Minimum mechanical efficiency** parameter and the **Maximum volumetric efficiency** or **Maximum mechanical efficiency** parameter.

### Input Losses

When you set the **Leakage and friction parameterization** parameter to **Input signal - volumetric and mechanical losses**, the leakage flow rate and friction torque calculations are identical to the **Tabulated data - volumetric and mechanical efficiencies** setting. The block replaces the volumetric and mechanical loss lookup tables with the physical signal input ports **LV** and **LM**.

The block expects the inputs to be positive and sets the signs automatically from the  $\Delta p$ - $\omega$  quadrant where the component is operating. If you provide a negative signal, the block returns zero losses.

### Assumptions and Limitations

- The block treats the pump as a quasi-steady component.
- The block ignores the effects of fluid inertia and elevation.
- The pump wall is rigid.
- The block ignores external leakage.

### Ports

#### Input

**EV** — Volumetric efficiency, unitless  
physical signal

Physical signal input port for the volumetric efficiency coefficient. The input signal has an upper bound at the **Maximum volumetric efficiency** parameter value and a lower bound at the **Minimum volumetric efficiency** parameter value.

#### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**EM** — Mechanical efficiency, unitless  
physical signal

Physical signal input port for the mechanical efficiency coefficient. The input signal has an upper bound at the **Maximum mechanical efficiency** parameter value and a lower bound at the **Minimum mechanical efficiency** parameter value.

#### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**LV** — Volumetric loss,  $m^3/s$   
physical signal

Physical signal input port for the volumetric loss which is the internal leakage flow rate between the pump inlets.

#### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

**LM** — Mechanical loss,  $N\cdot m$   
physical signal

Physical signal input port for the mechanical loss which is the friction torque on the rotating pump shaft.

#### Dependencies

To enable this port, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical losses.

**Conserving**

**A** — Pump inlet  
two-phase fluid

Two-phase fluid conserving port associated with the pump inlet.

**B** — Pump outlet  
two-phase fluid

Two-phase fluid conserving port associated with the pump outlet.

**C** — Pump case  
mechanical rotational

Mechanical rotational conserving port associated with the pump case.

**R** — Pump shaft  
mechanical rotational

Mechanical rotational conserving port associated with the rotational pump shaft.

**Parameters**

**Leakage and friction parameterization** — Parameterization of leakage flow rate and friction torque  
Analytical (default) | Tabulated data - volumetric and mechanical efficiencies |  
Tabulated data - volumetric and mechanical losses | Input signal - volumetric  
and mechanical efficiencies | Input signal - volumetric and mechanical losses

Method to compute the flow-rate and torque losses due to internal leaks and friction. Use the Analytical if the block parameters are generally available from component data sheets. When you select Tabulated data - volumetric and mechanical efficiencies or Tabulated data - volumetric and mechanical losses, the block uses lookup tables to map pressure gains and shaft angular velocities to component efficiencies or losses.

When you select Input signal - volumetric and mechanical efficiencies or Input signal - volumetric and mechanical losses, the block performs the leakage flow rate and friction torque calculations the same as the Tabulated data - volumetric and mechanical efficiencies or Tabulated data - volumetric and mechanical losses settings, respectively. When you select Input signal - volumetric and mechanical efficiencies, the block enables the **EV** and **EM** ports. You use these ports to specify the volumetric and mechanical efficiency. When you select Input signal - volumetric and mechanical losses, the block enables the **LV** and **LM** ports. You use these ports to specify the volumetric and mechanical losses.

**Displacement** — Fluid volume displaced per shaft rotation  
30 cm<sup>3</sup>/rev (default) | positive scalar

Fluid volume displaced per shaft rotation. The block maintains this value throughout the simulation.

**Nominal shaft angular velocity** — Shaft angular velocity for given volumetric efficiency  
1800 rpm (default) | scalar

Angular velocity of the rotary shaft that corresponds to the given volumetric efficiency. The standard operating conditions in the manufacturer data sheet typically list these values. The block uses this parameter to calculate the leakage flow rate and friction torque.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Nominal pressure gain** — Pressure gain for corresponding volumetric efficiency

10 MPa (default) | scalar

Pressure gain that corresponds to the given volumetric efficiency. The standard operating conditions in the manufacturer data sheet typically list these values. The block uses this parameter to calculate the internal leakage flow rate.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Nominal dynamic viscosity** — Dynamic viscosity at which to specify the volumetric efficiency

0.9 cP (default) | scalar

Dynamic viscosity of the hydraulic fluid for the given volumetric efficiency. The standard operating conditions in the manufacturer data sheet typically list these values. The block uses this parameter to calculate the internal leakage flow rate.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Volumetric efficiency at nominal conditions** — Volumetric efficiency at specified nominal conditions

0.92 (default) | scalar in the range (0,1)

Volumetric efficiency for the given conditions. The block defines the volumetric efficiency as the ratio of actual to ideal volumetric flow rates. The standard operating conditions in the manufacturer data sheet typically list these values. The block uses this parameter to calculate the internal leakage flow rate.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Mechanical efficiency at nominal conditions** — Ratio of ideal-to-actual mechanical power

0.88 (default) | positive scalar

Ratio of ideal mechanical power to actual mechanical power at nominal conditions.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**No-load torque** — Minimum torque required to induce shaft rotation

0 N\*m (default) | scalar

Torque to overcome the seal friction and induce rotation of the mechanical shaft. This torque is the load-independent component of the total friction torque.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Analytical.

**Pressure gain vector,  $\mathbf{dp}$**  — Pressure gains for given volumetric and mechanical efficiencies or losses  
[.1, 1, 2] MPa (default) | vector

Pressure gains for the corresponding tabular efficiency or loss data. The vector must be at least two elements in strictly increasing order.

Specify the data for a single quadrant,  $(\omega, \Delta p)$ . Refer to “Operating Modes” on page 1-917 for the operation modes corresponding to parameter specifications and the resulting quadrants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies or Tabulated data - volumetric and mechanical losses.

**Shaft angular velocity vector,  $\mathbf{w}$**  — Angular velocities at which to specify volumetric and mechanical efficiencies or losses

[250, 500, 1000, 2000, 3000, 4000] rpm (default) | vector

Shaft angular velocities for the corresponding tabular efficiency or loss data. The vector must be at least two elements in strictly increasing order.

Specify the data for a single quadrant,  $(\omega, \Delta p)$ . Refer to “Operating Modes” on page 1-917 for the operation modes corresponding to parameter specifications and the resulting quadrants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies or Tabulated data - volumetric and mechanical losses.

**Volumetric efficiency table,  $\mathbf{e}_v(\mathbf{dp}, \mathbf{w})$**  — Volumetric efficiencies for given pressure gains and angular velocities

[.816, .908, .954, .977, .981, .984; .325, .663, .831, .916, .925, .946; .137, .568, .78, .892, .893, .91] (default) | matrix

Volumetric efficiencies for the given fluid pressure gains and shaft angular velocities. The efficiencies must be in the range (0,1].  $M$  and  $N$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $\mathbf{dp}$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $\mathbf{w}$**  parameter.

Specify the data for a single quadrant,  $(\omega, \Delta p)$ . Refer to “Operating Modes” on page 1-917 for the operation modes corresponding to parameter specifications and the resulting quadrants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Mechanical efficiency table,  $\mathbf{e}_m(\mathbf{dp}, \mathbf{w})$**  — Mechanical efficiencies for given pressure gains and angular velocities

[.996, .996, .996, .996, .996, .996; .988, .989, .989, .989, .989, .99; .981, .981, .982, .982, .983, .984] (default) | matrix

Mechanical efficiencies for the given fluid pressure gains and shaft angular velocities. The efficiencies must be in the range (0,1].  $M$  and  $N$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.

Specify the data for a single quadrant,  $(\omega, \Delta p)$ . Refer to “Operating Modes” on page 1-917 for the operation modes corresponding to parameter specifications and the resulting quadrants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical efficiencies.

**Volumetric loss table,  $q\_loss(dp,w)$**  — Internal leakage flow rates for corresponding pressure gains and angular velocities

[.023, .023, .023, .023, .0285, .032; .0844, .0842, .0845, .084, .1125, .108; .1079, .108, .11, .108, .1605, .18] \* 1e-3 m<sup>3</sup>/s (default) | matrix

Volumetric losses at the specified fluid pressure gains and shaft angular velocities. Volumetric loss is the internal leakage volumetric flow rate between port **A** and port **B**.  $M$  and  $N$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.

Specify the data for a single quadrant,  $(\omega, \Delta p)$ . Refer to “Operating Modes” on page 1-917 for the operation modes corresponding to parameter specifications and the resulting quadrants.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical losses.

**Mechanical loss table,  $torque\_loss(dp,w)$**  — Friction torques for corresponding pressure gains and angular velocities

[.002, .002, .002, .002, .002, .002; .0607, .0556, .0556, .0556, .0556, .0505; .1937, .1937, .1833, .1833, .1729, .1626] N\*m (default) | matrix

Mechanical losses for the given pressure gains and shaft angular velocities. The block defines mechanical loss as the friction torque due to seals and internal components.  $M$  and  $N$  are the sizes of the specified lookup-table vectors:

- $M$  is the number of vector elements in the **Pressure gain vector,  $dp$**  parameter.
- $N$  is the number of vector elements in the **Shaft angular velocity vector,  $w$**  parameter.

Specify the data for a single quadrant,  $(\omega, \Delta p)$ . Refer to “Operating Modes” on page 1-917 for the operation modes corresponding to parameter specifications and the resulting quadrants. The tabulated data for the mechanical losses must obey the convention in the figure, with positive values at positive angular velocities and negative values at negative angular velocities.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Tabulated data - volumetric and mechanical losses.

**Minimum volumetric efficiency** — Lower saturation bound on volumetric efficiency input signal 1e-3 (default) | scalar in the range (0,1)

Smallest allowed value of the volumetric efficiency. The input from the physical signal port **EV** saturates inputs below this value.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum volumetric efficiency** — Upper saturation bound on volumetric efficiency input signal 1 (default) | scalar in the range (0,1)

Largest allowed value of the volumetric efficiency. The input from the physical signal port **EV** saturates inputs above this value.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Minimum mechanical efficiency** — Lower saturation bound on volumetric efficiency input signal 1e-3 (default) | scalar in the range (0,1)

Smallest allowed value of the mechanical efficiency. The input from the physical signal port **EM** saturates inputs below this value.

### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Maximum mechanical efficiency** — Upper saturation bound on volumetric efficiency input signal 1 (default) | scalar in the range (0,1)

Largest allowed value of the mechanical efficiency. The input from the physical signal port **EM** saturates inputs above this value.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies.

**Pressure gain threshold for motor-pump transition** — Pressure gain at which to initiate smooth transition between motor and pump modes  
1e-3 MPa (default) | scalar

Pressure gain from the inlet to the outlet below which the block begins to transition between the motor and pump modes. The block uses a hyperbolic tangent function to smooth the leakage flow rate and friction torque.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies or Input signal - volumetric and mechanical losses.

**Angular velocity threshold for motor-pump transition** — Angular velocity at which to initiate smooth transition between pump and motor modes  
100 rpm (default) | scalar

Shaft angular velocity below which the block begins to transition between the motor and pump modes. The block uses the hyperbolic tangent function to smooth the leakage flow rate and friction torque.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to Input signal - volumetric and mechanical efficiencies or Input signal - volumetric and mechanical losses.

**Cross-sectional area at ports A and B** — Flow area at component inlet and outlet  
0.01 m<sup>2</sup> (default) | positive scalar

Flow area at the component inlet and outlet. The areas are assumed equal.

**Report when fluid is not fully liquid** — Notification when fluid is not fully liquid  
None (default) | Warning | Error

Whether the block does nothing, generates a warning, or generates an error when the vapor quality is greater than 0, which indicates that the fluid is not fully liquid.

**Check if operating beyond the quadrants of supplied tabulated data** — Simulation warning mode for operating conditions outside range of tabulated data  
None (default) | Warning | Error

Simulation warning mode for operating conditions outside the range of tabulated data. If you select **Warning**, the block generates a warning when the fluid pressure gain or the shaft angular velocity cross outside the specified tabular data. The warning does not cause simulation to stop. If you select **Error**, the simulation will stop for conditions outside the range of tabulated data.

**Dependencies**

To enable this parameter, set **Leakage and friction parameterization** to:

- Tabulated data - volumetric and mechanical efficiencies
- Tabulated data - volumetric and mechanical losses

**Check if operating outside of pump mode** — Simulation warning mode for operating conditions outside pump mode

None (default) | Warning | Error

Simulation warning mode for operating conditions outside the pump mode. When you set this parameter to `Warning`, the block generates a warning if the pump transitions to motoring mode. The warning does not cause simulation to stop. If you select `Error`, the simulation will stop for conditions outside the pump mode.

#### Dependencies

To enable this parameter, set **Leakage and friction parameterization** to `Input signal - volumetric and mechanical losses`.

## Flow Coefficient Parameterized Valve (TL)

Valve with flow area modeled in terms of its Cv or Kv flow coefficient

### Libraries:

Simscape / Fluids / Thermal Liquid / Valves & Orifices

### Description

The Flow Coefficient Parameterized Valve (TL) block models the flow characteristics of a valve using the flow coefficient as a means to relate the flow rate through the ports to the pressure drop across them. The flow coefficient parameterization suits those cases in which the internal geometry of a valve is known in poor detail or in which the flow coefficient is the preferred means of characterizing a valve. The valve model is sufficiently general in its assumptions that it can be applied to a variety of valves; no single valve type is assumed in this block.

### Flow Coefficient Parameterization

The flow coefficient measures the ease with which a fluid driven by a pressure differential flows across a valve. It is an important parameter in the sizing of valves and a convenient way of characterizing one in a model. In this role it is especially useful, as it quantifies in a single number all of the losses incurred in the flow passages of the valve. The flow coefficient is typically measured by the valve manufacturer and reported in a data sheet provided for the valve.

Strictly speaking there are two flow coefficients in common use:  $C_v$  and  $K_v$ . These describe what is fundamentally the same quantity: the volumetric flow rate of water passing through a valve that has been opened to its maximum and set to some standard operating conditions. The flow coefficients differ only in the temperature and pressure drop established during the measurement (the operating conditions) and in the physical units used in its expression:

- $C_v$  is measured at a generally accepted temperature of 60 °F and pressure drop of 1 PSI; it is expressed in imperial units of US gpm. This is the flow coefficient used in the model when the **Flow coefficient specification** block parameter is set to Cv coefficient (USG/min) [1 on page 1-935].
- $K_v$  is measured at a generally accepted temperature of 15 °C and pressure drop of 1 bar; it is expressed in metric units of m<sup>3</sup>/h. This is the flow coefficient used in the model when the **Flow coefficient specification** block parameter is set to Kv coefficient (m<sup>3</sup>/h). [2 on page 1-935].

Two values are required of the flow coefficient, a *maximum* and a *minimum*. The maximum corresponds to a valve open to full capacity; this is the value frequently reported in valve data sheets. The minimum corresponds to a valve closed tight, when only leakage flow remains, if any at all. This lower bound imposed on the flow coefficient serves primarily to ensure the numerical robustness of the model. Its exact value is less important than its being a (generally very small) number greater than zero.

### Valve Opening Parameterization

The opening fraction of the valve (the ratio of the valve opening area to its maximum value) is determined during simulation from the input specified at port L. This input is the *control signal* and it

is, in some valves, associated with *stroke* or *lift percent*. The control signal can range in value from  $\theta$  to 1. If a lesser or greater value is specified, it is adjusted to the nearest of the two limits. In other words, the signal is *saturated* at  $\theta$  and 1.

The conversion from control signal to opening fraction depends on the **Valve opening characteristics** parameterization selected in the block. The calculation result is the same for all parameterizations when the control signal is either  $\theta$  or 1: a value of  $\theta$  at port **L** always means a maximally (though not necessarily *completely*) closed valve; a value of 1 always means a maximally open valve. At intermediate values, the opening fractions differ:

- **Linear** — The valve opening fraction (denoted  $f(L)$  in the figure) is equal to the control signal at port **L**. The two vary in tandem until the control signal either drops below zero (the valve is fully closed) or rises above its maximum value (the valve is fully open). The opening fraction ranges from  $\theta$  to 1 (a statement that does not apply to all valve opening parameterizations).

$$f(L) = L.$$

- **Quick opening** — The valve opening fraction,  $f(L)$ , is a power function of the control signal at port **L**. The opening fraction rises quickly with the control signal at values near  $\theta$  and slowly at values near 1. The exponent ( $\alpha$ ) in the calculation determines how the opening rate changes with the control signal. The opening fraction ranges from  $\theta$  to 1.

$$f(L) = L^{1/\alpha}, \quad \alpha > 1.$$

- **Equal percentage** — The valve opening fraction is an exponential function of the control signal at port **L**. The opening fraction rises slowly with the control signal at values near  $\theta$  and quickly at values near 1. The base of the exponent ( $R$ , the *rangeability* of the valve, the ratio between the maximum and minimum flow rates through the ports) determines how the opening rate changes with the control signal. The opening fraction ranges from a small fraction ( $\theta .02$ – $\theta .05$  for typical rangeability values of 20–50) to 1.

$$f(L) = \frac{R^{L-1} - \frac{1}{R}}{1 - \frac{1}{R}}, \quad R \approx 20 - 50.$$

### Mass Balance

The volume of fluid inside the valve, and therefore the mass of the same, is assumed to be very small and it is, for modeling purposes, ignored. As a result, no amount of fluid can accumulate there. By the principle of conservation of mass, the mass flow rate into the valve through one port must therefore equal that out of the valve through the other port:

$$\dot{m}_A + \dot{m}_B = 0,$$

where  $\dot{m}$  is defined as the mass flow rate *into* the valve through the port indicated by the subscript (**A** or **B**).

### Momentum Balance

The causes of those pressure losses incurred in the passages of the valve are ignored in the block. Whatever their natures—sudden area changes, flow passage contortions—only their cumulative effect is considered during simulation. It is this cumulative effect that the flow coefficient of the valve enables the block to capture in a model. This constant factors in the momentum balance of the valve *indirectly*, by way of the effective opening area ( $S$ ) of the same:

$$p_A - p_B = \frac{\dot{m}\sqrt{\dot{m}^2 + \dot{m}_{cr}^2}}{\rho_{avg}S^2},$$

where:

- $p$  is the pressure at the port indicated by the subscript (**A** or **B**).
- $\rho_{avg}$  is the arithmetic mean of the fluid densities at the ports.
- $\dot{m}$  is the mass flow rate at a port.
- $\dot{m}_{cr}$  is the critical mass flow rate, that at which the flow is assumed to switch between laminar and turbulent regimes:

$$\dot{m}_{cr} = Re_{cr}\mu_{avg}\sqrt{\frac{\pi}{4}}S,$$

where  $Re_{cr}$  is the Reynolds number at the transition point and  $\mu_{avg}$  is the average of the dynamic viscosities at the ports.

The effective opening area ( $S$ ) is the product of scaling of the maximum opening area of the valve by the opening fraction ( $f(L)$ ). The calculation imposes a lower bound on the opening area at which only leakage flow remains:

$$S(L) = \begin{cases} S_{max}f(L), & \text{if } S_{max}f(L) > S_{min} \\ S_{min}, & \text{else} \end{cases},$$

where the subscripts **max** and **min** refer to a valve in the fully opened and maximally closed positions; the function  $f(L)$  is the opening fraction calculated from the control signal specified at port **L**:

$$f(L) = \begin{cases} L, & \text{Linear parameterization} \\ L^{1/\alpha}, & \text{Quick opening parameterization} \\ R^L - 1, & \text{Equal percentages parameterization} \end{cases},$$

where  $\alpha$  is obtained from the **Exponent number** block parameter and  $R$  from the **Rangeability** parameter. The maximum opening area is obtained by multiplying the (maximum) flow coefficient by an appropriate conversion factor:

$$S_{\text{Max}} = \begin{cases} \lambda_C C_{v,\text{max}}, & \text{if } C_v \text{ is used} \\ \lambda_K K_{v,\text{max}}, & \text{if } K_v \text{ is used} \end{cases}$$

where:

- $\lambda_C$  is the conversion factor between the maximum flow coefficient in imperial units ( $C_{v,\text{max}}$ ) and the maximum opening area:  $2.4015 \times 10^{-5} \text{ m}^2$ .
- $\lambda_K$  is the conversion factor between the maximum flow coefficient in SI units ( $K_{v,\text{max}}$ ) and the maximum opening area:  $2.7765 \times 10^{-5} \text{ m}^2$ .

The minimum opening area in turn is obtained by multiplying the maximum opening area by the ratio between minimum and maximum flow coefficients:

$$S_{\text{Min}} = \begin{cases} \frac{C_{v,\text{min}}}{C_{v,\text{max}}} S_{\text{max}}, & \text{if } C_v \text{ is used} \\ \frac{K_{v,\text{min}}}{K_{v,\text{max}}} S_{\text{max}}, & \text{if } K_v \text{ is used} \end{cases}$$

## Energy Balance

The valve is modeled as an adiabatic component. No heat exchange can occur between the fluid and the wall that surrounds it. No work is done on or by the fluid as it traverses from inlet to outlet. With these assumptions, energy can flow by advection only, through ports **A** and **B**. By the principle of conservation of energy, the sum of the port energy flows must then always equal zero:

$$\phi_A + \phi_B = 0,$$

where  $\phi$  is defined as the energy flow rate *into* the valve through one of the ports (**A** or **B**).

## Ports

### Input

**L** — Valve control signal, unitless  
physical signal

Port through which to specify the signal that controls the opening of the valve (in certain valve types associated with *stroke* or *lift percent*). The valve is fully closed at a value of 0 and fully open at a value of 1.

### Conserving

**A** — Flow passage  
thermal liquid

Opening through which the flow can enter or exit the flow resistance. Which of the ports serves as inlet and which as outlet depends on the direction of flow.

**B** — Flow passage  
thermal liquid

Opening through which the flow can enter or exit the flow resistance. Which of the ports serves as inlet and which as outlet depends on the direction of flow.

**Parameters**

**Flow coefficient specification** — Parameterization by which to specify the flow coefficient of the valve

`Cv coefficient (USG/min) (default)` | `Kv coefficient (m3/h)`

Choice of flow coefficient to specify.  $C_v$  and  $K_v$  differ in the physical conditions of their measurement and in the physical units of their expression. Generally at least one of these is reported in product data sheets provided by the manufacturer. Select the option for which data is available.

**Cv coefficient at maximum flow** — Flow coefficient expressed in imperial units for a maximally open valve

`1 (default)` | positive scalar in units of USG/min

Flow coefficient expressed in imperial units for a valve opened to full capacity. This is the value reported in the valve data sheets when the  $C_v$  coefficient is provided by the manufacturer.

**Kv coefficient at maximum flow** — Flow coefficient expressed in SI units for a maximally open valve

`1 (default)` | positive scalar in units of m<sup>3</sup>/h

Flow coefficient expressed in SI units for a valve opened to full capacity. This is the value reported in the valve data sheets when the  $K_v$  coefficient is provided by the manufacturer.

**Cv coefficient at minimum flow** — Flow coefficient expressed in imperial units for a maximally closed valve

`1e-4 (default)` | positive scalar in units of USG/min

Flow coefficient expressed in imperial units for a valve that is closed tight and devoid of all flow except for that due to internal leakage between port **A** and port **B**. The primary purpose of this parameter is to ensure the numerical robustness of the model during simulation. Its exact value is less important than its being a very small number greater than zero.

**Kv coefficient at minimum flow** — Flow coefficient expressed in SI units for a maximally closed valve

`1e-4 (default)` | positive scalar in units of m<sup>3</sup>/h

Flow coefficient expressed in SI units for a valve that is closed tight and devoid of all flow except for that due to internal leakage between port **A** and port **B**. The primary purpose of this parameter is to ensure the numerical robustness of the model during simulation. Its exact value is less important than it being a very small number greater than zero.

**Valve opening characteristics** — Parameterization by which to compute the valve opening fraction

`Linear (default)` | `Quick opening` | `Equal percentages`

Choice of valve opening profile to use during simulation. The selection made here determines how the control signal specified at port **L** is converted into a valve opening fraction (and opening area). See the block description for detail on the opening parameterizations.

**Exponent number** — Denominator of the exponent in the quick-opening parameterization  
2 (default) | positive unitless scalar

Number by which to divide the exponent in the governing equation of the quick-opening parameterization. Use a value greater than 1 for a true quick-opening profile, one corresponding to a valve that opens quickly from a maximally closed position but progressively more slowly as it approaches the maximally opened position.

**Valve rangeability** — Base of the exponent in the equal-percentages parameterization  
50 (default) | positive unitless scalar

Number to which the exponent is applied in the governing equation of the equal-percentages parameterization. This number is the ratio between the maximum and minimum flow rates through the valve (the first corresponding obtained when the valve is maximally opened and the second when the valve is maximally closed). Typical values range from 20 to 50.

**Cross-sectional area at ports A and B** — Flow area at the inlet and outlet of the valve  
0.01 m<sup>2</sup> (default) | positive scalar in units of area

Area normal to the flow path at each port. The ports are assumed to be equal in size. The flow area specified here should match those of the inlets of those components to which the valve connects.

**Critical Reynolds number** — Reynolds number at which the flow switches between laminar and turbulent  
150 (default) | positive unitless scalar

Reynolds number at which the fluid in the valve is expected to switch between its laminar and turbulent flow regimes. The switch is assumed to occur at once: the transition region that normally exists between the two flow regimes is ignored.

## Library

Flow Control Valves

## Description

The Flow Divider block simulates a hydraulic two-path flow divider, which consists of a spring-centered spool installed in a case, as shown in the figure.

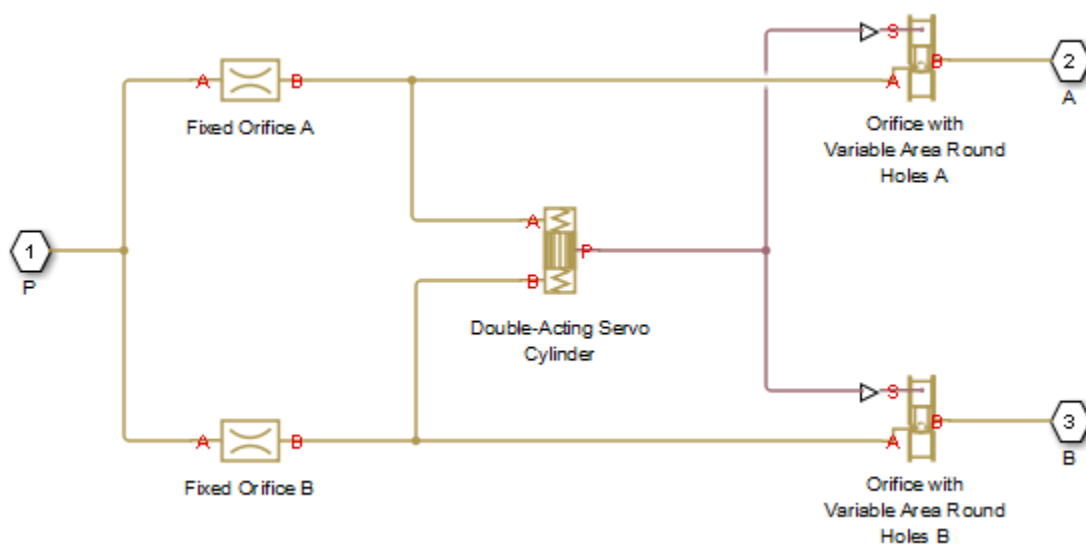

The flow from the source enters the valve through port P and is split into two parts flowing through the P-A and P-B paths. Each path contains a fixed orifice and a variable orifice. The fixed orifices

must be precisely matched to divide flow in equal parts, or arranged in a certain proportion if unequal division is required.

The purpose of variable orifices is to maintain a constant pressure drop across the fixed orifices, regardless of pressure fluctuations at valve outlets. The load increase on any outlet causes the pressure drop across the spool (and across fixed orifices) to change, and thus shift the spool. As a result, the passage areas of variable orifices change until the pressure drop values across the fixed orifices even out.

The model of the flow divider uses the Double-Acting Servo Cylinder, Fixed Orifice, and Orifice with Variable Area Round Holes blocks. The following figure shows the schematic diagram of the model. The Double-Acting Servo Cylinder detects the pressure drop and shifts the variable orifice control member accordingly.

**Note** You cannot use this block as a flow combiner. Use the Flow Divider-Combiner block instead.

## Assumptions and Limitations

- Friction between moving parts is not taken into account.
- Inertia effects are not taken into account.
- Fluid compressibility is not taken into account.
- Leakage flows are assumed to be negligible.
- The hard stops in the Double-Acting Servo Cylinder are assumed to be fully inelastic.

## Parameters

- “Fixed Orifices Tab” on page 1-938
- “Variable Orifices Tab” on page 1-939
- “Servo Cylinder Tab” on page 1-940

## **Fixed Orifices Tab**

### **Fixed orifice A area**

The cross-sectional passage area of the fixed orifice in the P-A path. The default value is  $1e-4$  m<sup>2</sup>.

### **Fixed orifice B area**

The cross-sectional passage area of the fixed orifice in the P-B path. The default value is  $1e-4$  m<sup>2</sup>.

### **Fixed orifice A flow discharge coefficient**

Semi-empirical parameter defining the capacity of the fixed orifice in the P-A path. The value depends on the geometrical properties of the orifice, and usually is provided in textbooks or manufacturer data sheets. The default value is  $0.7$ .

### **Fixed orifice B flow discharge coefficient**

Semi-empirical parameter defining the capacity of the fixed orifice in the P-B path. The value depends on the geometrical properties of the orifice, and usually is provided in textbooks or manufacturer data sheets. The default value is  $0.7$ .

### **Fixed orifice laminar transition specification**

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

### **Fixed orifice A laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes for the fixed orifice in the P-A path. The default value is  $0.999$ . This parameter is visible only if the **Fixed orifice laminar transition specification** parameter is set to **Pressure ratio**.

### **Fixed orifice B laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes for the fixed orifice in the P-B path. The default value is  $0.999$ . This parameter is visible only if the **Fixed orifice laminar transition specification** parameter is set to **Pressure ratio**.

### **Fixed orifice A critical Reynolds number**

The maximum Reynolds number for laminar flow for the fixed orifice in the P-A path. The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches this value. The default value is  $10$ . This parameter is visible only if the **Fixed orifice laminar transition specification** parameter is set to **Reynolds number**.

### **Fixed orifice B critical Reynolds number**

The maximum Reynolds number for laminar flow for the fixed orifice in the P-B path. The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches this value. The default value is  $10$ . This parameter is visible only if the **Fixed orifice laminar transition specification** parameter is set to **Reynolds number**.

## Variable Orifices Tab

### Diameter of round holes

Diameter of the round holes in the two identical Variable Orifice with Round Holes blocks. The default value is 0.005 m.

### Number of round holes

Number of holes in each of the Variable Orifice with Round Holes blocks. The default value is 4.

### Variable orifices flow discharge coefficient

Semi-empirical parameter defining the orifice capacity of the Variable Orifice with Round Holes blocks. The value depends on the geometrical properties of the orifice, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.65.

### Variable orifice A initial opening

Initial opening of the variable orifice in the P-A path. The parameter can be positive (underlapped orifice), negative (overlapped orifice), or 0 for zero-lap configuration. The value of initial opening does not depend on the orifice orientation. The default value is 0.0025 m.

### Variable orifice B initial opening

Initial opening of the variable orifice in the P-B path. The parameter can be positive (underlapped orifice), negative (overlapped orifice), or 0 for zero-lap configuration. The value of initial opening does not depend on the orifice orientation. The default value is 0.0025 m.

### Variable orifice laminar transition specification

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

### Variable orifice A laminar flow pressure ratio

Pressure ratio at which the flow transitions between laminar and turbulent regimes for the fixed orifice in the P-A path. The default value is 0.999. This parameter is visible only if the **Variable orifice laminar transition specification** parameter is set to **Pressure ratio**.

### Variable orifice B laminar flow pressure ratio

Pressure ratio at which the flow transitions between laminar and turbulent regimes for the fixed orifice in the P-B path. The default value is 0.999. This parameter is visible only if the **Variable orifice laminar transition specification** parameter is set to **Pressure ratio**.

### Variable orifice A critical Reynolds number

The maximum Reynolds number for laminar flow through the variable orifice in the P-A path. The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches this value. The default value is 10. This parameter is visible only if the **Variable orifice laminar transition specification** parameter is set to **Reynolds number**.

### Variable orifice B critical Reynolds number

The maximum Reynolds number for laminar flow through the variable orifice in the P-B path. The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches this value. The default value is 10. This parameter is visible only if the **Variable orifice laminar transition specification** parameter is set to **Reynolds number**.

**Variable orifice leakage area**

The total area of possible leaks in each variable orifice when it is completely closed. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from becoming isolated after the orifice is completely closed. The parameter value must be greater than 0. The default value is  $1e-9 \text{ m}^2$ .

**Servo Cylinder Tab****Servo cylinder piston area**

The face area of the piston in the servo cylinder. The default value is  $1.6e-4 \text{ m}^2$ .

**Servo cylinder piston stroke**

The full piston stroke in the servo cylinder, from one hard stop to another. The piston is located initially in the middle of the stroke and can travel half a stroke in the positive and negative direction. The default value is  $0.005 \text{ m}$ .

**Servo cylinder spring rate**

The spring rate of the centering springs in the servo cylinder. The default value is  $1000 \text{ N/m}$ .

**Servo cylinder damping coefficient**

The damping coefficient in the contact between the piston and the case of the servo cylinder. The default value is  $150 \text{ N/(m/s)}$ .

**Servo cylinder stop penetration coefficient**

The penetration property of the piston hard stop in the servo cylinder. The hard stop is represented as absolutely inelastic, and its property is characterized by the penetration coefficient. The default value of the coefficient is  $1e12 \text{ N/m/(m/s)}$ .

**Global Parameters**

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

**Ports**

The block has the following ports:

P

Hydraulic conserving port associated with the inlet port P.

A

Hydraulic conserving port associated with the outlet port A.

B

Hydraulic conserving port associated with the outlet port B.

Flow Control Valves

## Description

The Flow Divider-Combiner block models a hydraulic valve that divides incoming flow through port P (direct flow) between two outlets, and also maintains a specified proportion between return flows through ports A and B in the total flow rate through port P. In other words, the valve works in two distinctive modes: flow divider for direct flow and flow combiner for reverse flow.

The figure shows a schematic for the flow divider-combiner valve: a) in the divider mode, and b) in the combiner mode.

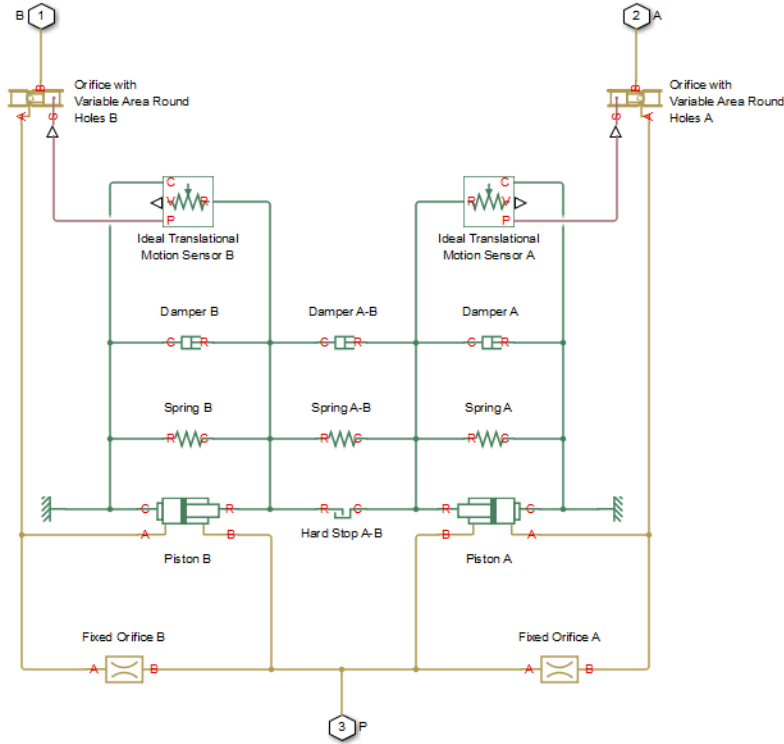

The valve works as a flow divider when fluid is pumped through port P to ports A and B (schematic figure a). In this mode, fluid passes through fixed orifices in pistons 2 and 5 and through variable orifices formed by round holes in the pistons and case. The pressure differential across pistons moves them apart from each other proportionally to the piston areas and the spring 1 and 6 forces. The spring-suspended pistons and the respective variable orifices work as pressure reducing valves maintaining constant pressure drop across fixed orifices and thus keeping flow rates through them practically constant. The flow divider-combiner valve is essentially a combination of two pressure-compensated flow control valves working in parallel.

For reverse flows (schematic figure b), the pressure differential across pistons forces them against each other until the gap in the hard stop is cleared. The pistons settle at a position where pressure drops across fixed orifices are equal, thus maintaining equal flow rates through branches.

The model of the flow divider-combiner uses the Fixed Orifice, Orifice with Variable Area Round Holes, Double-Acting Hydraulic Cylinder (Simple), Translational Hard Stop, Translational Spring, and Translational Damper blocks, as shown in the block diagram.

The table explains the purpose of each model component.

Name in the block diagram	Purpose (numbers refer to the valve schematic)	Name in the actual component file
Fixed Orifice A	Fixed orifice in piston 5	fixed_orifice_A
Fixed Orifice B	Fixed orifice in piston 2	fixed_orifice_B
Piston A	Piston 5	piston_A
Piston B	Piston 2	piston_B
Hard Stop A-B	Hard stop between pistons 2 and 5	hard_stop_A_B
Spring A	Spring 6	spring_A
Spring A-B	Spring 4	spring_A_B
Spring B	Spring 1	spring_B
Damper A	Spring 6 damping	damper_A
Damper A-B	Spring 4 damping	damper_A_B
Damper B	Spring 1 damping	damper_B
Orifice with Variable Area Round Holes A	Variable orifice created by round holes in piston 5 and the case	variable_orifice_A
Orifice with Variable Area Round Holes B	Variable orifice created by round holes in piston 2 and the case	variable_orifice_B

Name in the block diagram	Purpose (numbers refer to the valve schematic)	Name in the actual component file
Ideal Translational Motion Sensor A	Measures piston 5 displacement and exports the measurement to the Orifice with Variable Area Round Holes A	sensor_A
Ideal Translational Motion Sensor B	Measures piston 2 displacement and exports the measurement to the Orifice with Variable Area Round Holes B	sensor_B

The block orientations in the model are explained by the structure section of the underlying component file, reproduced below:

### Fixed Orifices Tab

#### Fixed orifice A area

The cross-sectional passage area of the fixed orifice in piston 5 (the P-A path). The default value is  $1.5e-5 \text{ m}^2$ .

#### Fixed orifice B area

The cross-sectional passage area of the fixed orifice in piston 2 (the P-B path). The default value is  $1.5e-5 \text{ m}^2$ .

**Fixed orifice flow discharge coefficient**

Semi-empirical coefficient for fixed orifice capacity characterization. The value depends on the orifice geometrical properties, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.7.

**Fixed orifice laminar transition specification**

Select how the block transitions between the laminar and turbulent regimes for the fixed orifices:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Fixed orifice laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Fixed orifice critical Reynolds number** parameter.

**Fixed orifice laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Fixed orifice laminar transition specification** parameter is set to **Pressure ratio**.

**Fixed orifice critical Reynolds number**

The maximum Reynolds number for laminar flow in the fixed orifices. The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches this value. The default value is 10. This parameter is visible only if the **Fixed orifice laminar transition specification** parameter is set to **Reynolds number**.

**Pistons Tab****Piston A area**

The face area of Piston A (piston 5). The default value is  $2e-4 \text{ m}^2$ .

**Piston A stroke**

The full stroke of Piston A. The default value is 5 mm.

**Piston A initial extension**

The initial extension of Piston A. The default value is 0 m.

**Piston B area**

The face area of Piston B (piston 2). The default value is  $2e-4 \text{ m}^2$ .

**Piston B stroke**

The full stroke of Piston B. The default value is 5 mm.

**Piston B initial extension**

The initial extension of Piston B. The default value is 0 m.

**Piston stop penetration coefficient**

The penetration property of colliding bodies in the underlying cylinder blocks, which is assumed to be absolutely plastic. The default value is  $1e12 \text{ s}^2/\text{N/m}^2$ .

**Springs/Dampers Tab****Spring A rate**

Spring rate of Spring A (spring 6). The default value is  $1e3 \text{ N/m}$ .

**Spring A preload**

This parameter sets the initial high-priority target value for the **Deformation** variable in the underlying Spring A block. For more information, see “Variable Priority for Model Initialization”. The default value is 0.1 m.

**Damping coefficient A**

Damping coefficient of Damper A (spring 6 damping). The default value is 150 N/(m/s).

**Spring B rate**

Spring rate of Spring B (spring 1). The default value is 1e3 N/m.

**Spring B preload**

This parameter sets the initial high-priority target value for the **Deformation** variable in the underlying Spring B block. For more information, see “Variable Priority for Model Initialization”. The default value is -0.1 m.

**Damping coefficient B**

Damping coefficient of Damper B (spring 1 damping). The default value is 150 N/(m/s).

**Spring A-B rate**

Spring rate of Spring A-B (spring 4). The default value is 1e3 N/m.

**Spring A-B preload**

This parameter sets the initial high-priority target value for the **Deformation** variable in the underlying Spring A-B block. For more information, see “Variable Priority for Model Initialization”. The default value is 0.1 m.

**Damping coefficient A\_B**

Damping coefficient of Damper A-B (spring 4 damping). The default value is 150 N/(m/s).

**Variable Orifices Tab****Variable orifice A hole diameter**

Diameter of the holes in the underlying Orifice with Variable Area Round Holes A block. The default value is 0.0025 m.

**Variable orifice B hole diameter**

Diameter of the holes in the underlying Orifice with Variable Area Round Holes B block. The default value is 0.0025 m.

**Number of hole pairs in the variable orifice**

Number of holes in each of the Orifice with Variable Area Round Holes blocks. The default value is 4.

**Variable orifice flow discharge coefficient**

Semi-empirical parameter defining the orifice capacity of the Orifice with Variable Area Round Holes blocks. The value depends on the geometrical properties of the orifice, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.7.

**Variable orifice A initial center distance**

Initial opening in the underlying Orifice with Variable Area Round Holes A block. The parameter value can be positive (underlapped orifice), negative (overlapped orifice), or equal to zero for zero lap configuration. The default value is 0.0025 m, which corresponds to the position of piston 5 in the valve schematic drawing.

**Variable orifice B initial center distance**

Initial opening in the underlying Orifice with Variable Area Round Holes B block. The parameter value can be positive (underlapped orifice), negative (overlapped orifice), or equal to zero for zero lap configuration. The default value is  $-0.0025$  m, which corresponds to the position of piston 2 in the valve schematic drawing.

**Variable orifice laminar transition specification**

Select how the block transitions between the laminar and turbulent regimes for the variable orifices:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Variable orifice laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Variable orifice critical Reynolds number** parameter.

**Variable orifice laminar flow pressure ratio**

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is  $0.999$ . This parameter is visible only if the **Variable orifice laminar transition specification** parameter is set to **Pressure ratio**.

**Variable orifice critical Reynolds number**

The maximum Reynolds number for laminar flow through the variable orifices. The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches this value. The default value is  $10$ . This parameter is visible only if the **Variable orifice laminar transition specification** parameter is set to **Reynolds number**.

**Variable orifice leakage area**

The total area of possible leaks in each variable orifice when it is completely closed. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from becoming isolated after the orifice is completely closed. The parameter value must be greater than 0. The default value is  $1e-9$  m<sup>2</sup>.

**Hard Stop Between Pistons Tab****Hard stop upper bound**

Gap between the slider and the upper bound in the underlying Hard Stop block. The default value is  $5.1$  mm.

**Hard stop lower bound**

Gap between the slider and the lower bound in the underlying Hard Stop block. The default value is  $1$  mm.

**Hard stop stiffness**

The elastic property of colliding bodies in the hard stop. The default value is  $1e8$  N/m.

**Hard stop damping coefficient**

The dissipating property of colliding bodies in the hard stop. The default value is  $150$  N/(m/s).

**Global Parameters**

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## Ports

The block has the following ports:

P

Hydraulic conserving port associated with the inlet port P.

A

Hydraulic conserving port associated with the outlet port A.

B

Hydraulic conserving port associated with the outlet port B.

## Gas-Charged Accumulator (IL)

Gas-charged accumulator in an isothermal liquid network

### Libraries:

Simscape / Fluids / Isothermal Liquid / Tanks & Accumulators

### Description

The Gas-Charged Accumulator (IL) block represents a gas-charged accumulator in an isothermal liquid network. The accumulator consists of a precharged gas chamber and a liquid chamber. The chambers are separated by a bladder, a piston, or any kind of a diaphragm.

As the liquid pressure at the accumulator inlet becomes greater than the precharge pressure, liquid enters the accumulator and compresses the gas through a polytropic process. A decrease in the liquid pressure causes the gas to decompress and discharge stored liquid into the system. The separator motion is restricted by a hard stop when the liquid volume is zero and when the liquid volume is at the liquid chamber capacity. The liquid chamber capacity is the total accumulator volume minus the minimum gas volume.

Inlet liquid resistance, and separator properties such as inertia and damping are not modeled. The flow rate is positive if liquid flows into the accumulator.

This diagram represents a gas-charged accumulator. The total accumulator volume,  $V_T$ , is divided into the liquid chamber on the left and the gas chamber on the right by the vertical separator. The distance between the left side and the separator defines the liquid volume,  $V_L$ . The distance between the right side and the separator defines the gas volume,  $V_G$ . The liquid chamber capacity,  $V_C$ , is less than the total accumulator volume, so that the gas volume never becomes zero:

$$V_L = V_T - V_G$$

$$V_C = V_T - V_{dead}$$

where:

- $V_T$  is the total volume of the accumulator, including the liquid chamber and the gas chamber.
- $V_L$  is the volume of the liquid in the accumulator.
- $V_G$  is the volume of the gas in the accumulator.
- $V_C$  is the liquid chamber capacity ( $V_T - V_G$ ).
- $V_{dead}$  is the gas chamber dead volume, a small portion of the gas chamber that remains filled with gas when the liquid chamber is at capacity.

The hard stop contact pressure is modeled with a stiffness term and a damping term. The relationship of the gas pressure and gas volume between the current state and the precharge state is polytropic and pressure is balanced at the separator:

$$p_G V_G^{k_{sh}} = p_{pr} V_T^{k_{sh}},$$

where:

- $p_G$  is the gas pressure in the gas chamber.
- $p_{pr}$  is the pressure in the gas chamber when the liquid chamber is empty
- $k_{sh}$  is the specific heat ratio (adiabatic index).

### Conservation of Mass

Conservation of mass is represented by the following equation.

$$\left\{ \begin{array}{ll} \dot{p}_I \frac{d\rho_I}{dp_I} V_L + \rho_I \dot{V}_L = \dot{m}_A, & \text{compressibility on} \\ \rho_I \dot{V}_L = \dot{m}_A, & \text{compressibility of f} \end{array} \right.$$

where:

- $p_I$  is the liquid pressure in the liquid chamber, which is equal to the pressure at the accumulator inlet.
- $\dot{m}_A$  is the mass flow rate of liquid coming into port **A**.
- $\rho_I$  is the density of the liquid in the liquid chamber.

$$\dot{V}_L = \begin{cases} \frac{\dot{p}_I}{k_{sh} \frac{p_G}{V_G}}, & \text{if } 0 < V_L < V_C \\ \frac{\dot{p}_I}{k_{sh} \frac{p_G}{V_G} + K_{stiff}}, & \text{else} \end{cases}$$

where  $K_{stiff}$  is the hard-stop stiffness coefficient.

### Conservation of Momentum

Conservation of momentum is represented by:

$$p_I = p_G + p_{HS}$$

where  $p_{HS}$  is the hard-stop contact pressure.

$$p_{HS} = \begin{cases} (V_L - V_C)K_{stiff}, & \text{if } V_L \geq V_C \\ V_L K_{stiff}, & \text{if } V_L \leq 0 \\ 0, & \text{else} \end{cases}$$

## Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

## Ports

### Conserving

**A** — Liquid port  
isothermal liquid

Isothermal liquid port associated with the accumulator inlet. The flow rate is positive if liquid flows into the accumulator.

## Parameters

**Total accumulator volume** — Accumulator volume  
8e-3 m<sup>3</sup> (default) | positive scalar

Total volume of the accumulator, including the liquid chamber and the gas chamber. It is the sum of the liquid chamber capacity and the minimum gas volume.

**Minimum gas volume** — Gas chamber dead volume  
4e-5 m<sup>3</sup> (default) | positive scalar

Gas chamber dead volume, which is defined as a small portion of the gas chamber that remains filled with gas when the liquid chamber is filled to capacity. The block requires a nonzero value to avoid divide-by-zero when the liquid chamber is at capacity.

**Precharge pressure** — Gas chamber pressure  
1.101325 MPa (default) | positive scalar

Pressure in the gas chamber when the liquid chamber is empty.

**Specific heat ratio** — Specific heat ratio  
1.4 (default) | positive scalar

Specific heat ratio (adiabatic index). To account for heat exchange, set it to a value normally between 1 and 2, depending on the properties of the gas in the gas chamber. For dry air at 20°C, this value is 1 for an isothermal process or 1.4 for an adiabatic (and isentropic) process.

**Hard stop stiffness coefficient** — Proportionality constant  
1e4 MPa/m<sup>3</sup> (default) | positive scalar

Proportionality constant of the hard-stop contact pressure with respect to the liquid volume penetrated into the hard stop. The hard stops are used to restrict the liquid volume between zero and liquid chamber capacity.

**Fluid dynamic compressibility** — Fluid compressibility  
on (default) | off

Whether to model any change in fluid density due to fluid compressibility. When you select **Fluid dynamic compressibility**, changes due to the mass flow rate into the block are calculated in addition to density changes due to changes in pressure. In the Isothermal Liquid Library, all blocks calculate density as a function of pressure.

**Libraries:**

Simscape / Fluids / Hydraulics (Isothermal) / Accumulators

## Description

The Gas-Charged Accumulator block models a gas-charged accumulator that consists of a precharged gas chamber and a fluid chamber. The fluid chamber is connected to a hydraulic system. The chambers are separated by a bladder, a piston, or any kind of a diaphragm.

As the fluid pressure at the accumulator inlet becomes greater than the precharge pressure, fluid enters the accumulator and compresses the gas, storing hydraulic energy. A decrease in the fluid pressure causes the gas to decompress and discharge the stored fluid into the system.

During typical operations, the pressure in the gas chamber is equal to the pressure in the fluid chamber. However, if the pressure at the accumulator inlet drops below the precharge pressure, the gas chamber becomes isolated from the system. In this situation, the fluid chamber is empty and the pressure in the gas chamber remains constant and equal to the precharge pressure. The pressure at the accumulator inlet depends on the hydraulic system to which the accumulator is connected. If the pressure at the accumulator inlet builds up to the precharge pressure or higher, fluid enters the accumulator again.

The motion of the separator between the fluid chamber and the gas chamber is restricted by two hard stops that limit the expansion and contraction of the fluid volume. The fluid volume is limited when the fluid chamber is at capacity and when the fluid chamber is empty. The hard stops are modeled with finite stiffness and damping. This means that it is possible for the fluid volume to become negative or greater than the fluid chamber capacity, depending on the values of the hard-stop stiffness coefficient and the accumulator inlet pressure.

The diagram represents a gas-charged accumulator. The vertical separator divides the total accumulator volume,  $V_T$ , into the fluid chamber on the left and the gas chamber on the right. The distance between the left side and the separator defines the fluid volume,  $V_F$ . The distance between the right side and the separator defines the gas volume,  $V_T - V_F$ . The fluid chamber capacity,  $V_C$ , is less than the total accumulator volume,  $V_T$ , so that the gas volume never becomes zero.

The block models the hard stop contact pressure with a stiffness term and a damping term. The relationship of the gas pressure and gas volume between the current state and the precharge state is given by the polytropic relation, with pressure balanced at the separator

$$(p_G + p_A)(V_T - V_F)^k = (p_{pr} + p_A)V_T^k$$

$$p_F = p_G + p_{HS}$$

$$V_C = V_T - V_{dead}$$

$$p_{HS} = \begin{cases} K_S(V_F - V_C) + K_d q_F^\pm (V_F - V_C) & \text{if } V_F \geq V_C \\ K_S V_F - K_d q_F^- V_F & \text{if } V_F \leq 0 \\ 0 & \text{otherwise} \end{cases}$$

$$q_F^\pm = \begin{cases} q_F & \text{if } q_F \geq 0 \\ 0 & \text{otherwise} \end{cases}$$

$$q_F^- = \begin{cases} q_F & \text{if } q_F \leq 0 \\ 0 & \text{otherwise} \end{cases}$$

where:

$V_T$	Total volume of the accumulator, including the fluid chamber and the gas chamber
$V_F$	Volume of fluid in the accumulator
$V_{init}$	Initial volume of fluid in the accumulator
$V_C$	Fluid chamber capacity, which is the difference between total accumulator volume and the gas chamber dead volume
$V_{dead}$	Gas chamber dead volume, which is a small portion of the gas chamber that remains filled with gas when the fluid chamber is at capacity

$p_F$	Fluid pressure (gauge) in the fluid chamber, which is equal to the pressure at the accumulator inlet
$p_{pr}$	Pressure (gauge) in the gas chamber when the fluid chamber is empty
$p_A$	Atmospheric pressure
$p_G$	Gas pressure (gauge) in the gas chamber
$p_{HS}$	Hard-stop contact pressure
$K_s$	Hard-stop stiffness coefficient
$K_d$	Hard-stop damping coefficient
$k$	Specific heat ratio (adiabatic index)
$q_F$	Fluid flow rate into the accumulator, which is positive if fluid flows into the accumulator

The flow rate into the accumulator is the rate of change of the fluid volume:

$$q_F = \frac{dV_F}{dt}.$$

At  $t = 0$ , the initial condition is  $V_F = V_{init}$ , where  $V_{init}$  is the value you assign to the **Initial fluid volume** parameter.

### Variables

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

### Assumptions and Limitations

- The process in the gas chamber is assumed to be polytropic.
- Loading on the separator, such as inertia or friction, is not considered.
- Inlet hydraulic resistance is not considered.
- Fluid compressibility is not considered.

### Ports

#### Conserving

**A** — Accumulator inlet  
hydraulic

Hydraulic conserving port associated with the accumulator inlet. The flow rate is positive if fluid flows into the accumulator.

## Parameters

**Total accumulator volume** — Accumulator volume, including fluid chamber and gas chamber  
 $8e-3 \text{ m}^3$  (default) | positive scalar

Total volume of the accumulator, including the fluid chamber and the gas chamber. This value is the sum of the fluid chamber capacity and the minimum gas volume.

**Minimum gas volume** — Gas chamber dead volume  
 $4e-5 \text{ m}^3$  (default) | positive scalar

Gas chamber dead volume, a small portion of the gas chamber that remains filled with gas when the fluid chamber is at capacity. A nonzero volume is necessary so that the gas pressure does not become infinite when the fluid chamber is at capacity.

**Precharge pressure (gauge)** — Pressure in gas chamber when fluid chamber is empty  
 $10e5 \text{ Pa}$  (default) | positive scalar

Pressure (gauge) in the gas chamber when the fluid chamber is empty.

**Specific heat ratio** — Adiabatic index  
 $1.4$  (default) | scalar, typically between 1 and 2

Specific heat ratio, also known as the adiabatic index. To account for heat exchange, set this parameter to a value, typically between 1 and 2, depending on the properties of the gas in the gas chamber. For dry air at  $20^\circ\text{C}$ , this value is 1 for an isothermal process and 1.4 for an adiabatic and isentropic process.

**Hard-stop stiffness coefficient** — Proportionality constant for hard-stop stiffness  
 $1e10 \text{ Pa/m}^3$  (default) | nonnegative scalar

Proportionality constant of the hard-stop contact pressure with respect to the fluid volume penetrated into the hard stop. The block uses the hard stops to restrict the fluid volume between zero and fluid chamber capacity.

**Hard-stop damping coefficient** — Proportionality constant for hard-stop damping  
 $1e10 \text{ Pa}\cdot\text{s/m}^6$  (default) | nonnegative scalar

Proportionality constant of the hard-stop contact pressure with respect to the flow rate and the fluid volume penetrated into the hard stop. The block uses the hard stops to restrict the fluid volume between zero and fluid chamber capacity.

## Version History

### **See Also**

Spring-Loaded Accumulator

# Gas-Charged Accumulator (TL)

Gas-charged accumulator in a thermal liquid network

## Libraries:

Simscape / Fluids / Thermal Liquid / Tanks & Accumulators

## Description

The Gas-Charged Accumulator (TL) block represents a pressurized thermal liquid container with a compressed gas charge. The accumulator consists of thermal liquid and gas chambers separated by a hermetic and insulated diaphragm.

## Accumulator Schematic

If the inlet pressure is greater than the gas charge pressure, the liquid chamber volume increases, compressing the gas chamber. If the inlet pressure is lower than the gas charge pressure, the liquid chamber volume decreases, decompressing the gas chamber.

Hard stops limit the diaphragm motion when the liquid chamber is at capacity and when the liquid chamber is empty. If the specified spring stiffness is too low, the liquid volume can momentarily fall below zero or rise above capacity. Use the **Hard stop stiffness coefficient** parameter to correct this.

## Mass Balance

The mass conservation equation in the liquid chamber is

$$V_L \rho_L \left( \frac{1}{\beta_L} \frac{dp_L}{dt} - \alpha_L \frac{dT_L}{dt} \right) + \rho_L \frac{dV_L}{dt} = \dot{m}_A,$$

where:

- $\rho_L$  is the thermal liquid density.
- $\beta_L$  is the isothermal bulk modulus.
- $\alpha_L$  is the isobaric thermal expansion coefficient.
- $p_L$  is the thermal liquid pressure.
- $T_L$  is the thermal liquid temperature.
- $\dot{m}_A$  is the thermal liquid mass flow rate into the accumulator through port **A**.

The block computes the time variation of the liquid chamber volume using the conditional equation

$$\frac{dV_L}{dt} = \begin{cases} \frac{\dot{p}_L}{kp_{pr}V_T^k V_G^{(-k-1)} + K_s + K_d \dot{m}^+ / \rho_L}, & V_L \geq V_C \\ \frac{\dot{p}_L}{kp_{pr}V_T^k V_G^{(-k-1)} + K_s - K_d \dot{m}^- / \rho_L}, & V_L \leq 0 \\ \frac{\dot{p}_L}{kp_{pr}V_T^k V_G^{(-k-1)}}, & \text{Else} \end{cases},$$

where:

- $K_s$  is the **Hard-stop stiffness coefficient** parameter.
- $K_d$  is the **Hard-stop damping coefficient** parameter.
- $\dot{m}^+$  is the mass flow rate into the liquid chamber when the accumulator diaphragm contacts the top hard stop:

$$\dot{m}^+ = \begin{cases} \dot{m}, & \dot{m} > 0 \\ 0, & \text{Else} \end{cases},$$

- $\dot{m}^-$  is the mass flow rate from the liquid chamber when the accumulator diaphragm contacts the bottom hard stop:

$$\dot{m}^- = \begin{cases} \dot{m}, & \dot{m} < 0 \\ 0, & \text{Else} \end{cases},$$

### Momentum Balance

The momentum conservation equation in the accumulator volume is

$$p_L = p_G + p_{HS},$$

where  $p_{HS}$  is the hard-stop contact pressure:

- $$p_{HS} = \begin{cases} (V_L - V_C)(K_s + K_d \dot{m}^+ / \rho), & V_L \geq V_C \\ V_L(K_s - K_d \dot{m}^- / \rho), & V_L \leq 0 \\ 0, & \text{Else} \end{cases},$$

### Energy Balance

The energy conservation equation in the liquid chamber volume is

$$\frac{d}{dt}(\rho_L u_L V_L) = \phi_A + \phi_H,$$

where:

- $u_L$  is the thermal liquid specific internal energy.
- $\Phi_A$  is the energy flow rate into the liquid chamber through the accumulator inlet.
- $\Phi_H$  is the thermal energy flow rate into the liquid chamber through the accumulator wall.

### Chamber Volumes

The liquid chamber volume is the difference between the total accumulator volume and the gas chamber volume:

$$V_L = V_T - V_G,$$

where:

- $V_L$  is the liquid chamber volume.
- $V_T$  is the total accumulator volume.
- $V_G$  is the gas chamber volume.

### Chamber Volumes

The liquid chamber capacity is the difference between the total accumulator volume and the dead volume of gas in the accumulator at full capacity:

$$V_C = V_T - V_{Dead},$$

where:

- $V_C$  is the liquid chamber capacity.
- $V_{Dead}$  is the dead volume of gas at full capacity.

The gas chamber pressure and volume follow from the precharge states as described by the polytropic equation

$$p_G V_G^k = p_{pr} V_T^k,$$

where:

- $p_G$  is the gas chamber pressure at a given time step.
- $V_G$  is the gas chamber volume at a given time step.
- $p_{pr}$  is the precharge gas chamber pressure when the liquid chamber is empty.

- $V_T$  is the total liquid chamber volume.
- $k$  is the polytropic index.

### Initial Targets

To set the priority and initial target values for the block variables prior to simulation, use the **Initial Targets** section in the block dialog box or Property Inspector. For more information, see “Set Priority and Initial Target for Block Variables”.

Nominal values provide a way to specify the expected magnitude of a variable in a model. Using system scaling based on nominal values increases the simulation robustness. Nominal values can come from different sources, one of which is the **Nominal Values** section in the block dialog box or Property Inspector. For more information, see “Modify Nominal Values for a Block Variable”.

### Assumptions and Limitations

- The block treats the gas chamber compression as a polytropic process.
- The block ignores diaphragm loading.
- The block ignores the effects of fluid inertia.

### Ports

#### Conserving

**A** — Liquid port  
thermal liquid

Thermal liquid conserving port associated with the accumulator inlet. The flow rate is positive if liquid flows into the accumulator.

**H** — Heat port  
thermal

Thermal conserving port associated with the thermal mass of the liquid volume.

### Parameters

**Total accumulator volume** — Accumulator volume  
 $8e-3 \text{ m}^3$  (default) | positive scalar

Total volume of the accumulator, including the liquid chamber and the gas chamber. This is the sum of the liquid chamber capacity and the minimum gas volume.

**Minimum gas volume** — Gas chamber dead volume  
 $4e-5 \text{ m}^3$  (default) | positive scalar

Gas chamber dead volume. This is the amount of remaining gas when the liquid chamber is full. A nonzero volume is necessary so that the gas pressure does not become infinite when the liquid chamber is full.

**Precharge pressure (gauge)** — Gas chamber pressure  
0 MPa (default) | nonnegative scalar

Initial gauge pressure of the empty accumulator chamber. Fluid enters the accumulator if the inlet pressure is equal to or greater than the precharge pressure.

**Specific heat ratio** — Specific heat ratio

1.4 (default) | positive scalar

Specific heat ratio for the gas in the chamber. This value is typically 1.4 for air at 20°C.

**Cross-sectional area at port A** — Inlet cross-sectional area

0.01 m<sup>2</sup> positive scalar (default)

Flow cross-sectional area at the accumulator inlet.

**Hard stop stiffness coefficient** — Stiffness coefficient

1e4 MPa/m<sup>3</sup> (default) | positive scalar

Stiffness coefficient of the top and bottom accumulator hard stops. The hard stops restrict diaphragm motion between zero and the maximum liquid chamber level.

**Hard-stop damping coefficient** — Damping coefficient

1e4 MPa\*s/m<sup>6</sup> (default) | positive scalar

Damping coefficients of the top and bottom accumulator hard stops. The hard stops restrict diaphragm motion between zero and the maximum liquid chamber level. The damping coefficients account for the dissipative portion of the hard-stop contact forces.

## Library

Flow Control Valves

## Description

The Gate Valve block models a valve consisting of a round orifice in the valve housing and a flat gate, which moves perpendicular to the orifice axis. The orifice in the gate has the same diameter as the orifice in the housing. As the gate moves, it opens or closes the valve passage (shown as a shaded area in the following illustration).

The flow rate through the valve is proportional to the valve opening and to the pressure differential across the valve. The flow rate is determined according to the following equations:

$$q = C_D \cdot A(h) \sqrt{\frac{2}{\rho} \frac{\Delta p}{(\Delta p^2 + p_{Cr}^2)^{1/4}}}$$

$$\Delta p = p_A - p_B,$$

$$h = x_0 + x$$

$$A(h) = \begin{cases} A_{leak} & \text{for } h \leq 0 \text{ or } h > 2D \\ D^2 \cdot \left( \frac{\alpha}{2} - \frac{\sin(2\alpha)}{4} \right), \alpha = \arccos \left| 1 - \frac{h}{D} \right| & \text{for } 0 < h \leq 2D \end{cases}$$

where

$q$	Flow rate
$p$	Pressure differential
$p_A, p_B$	Gauge pressures at the block terminals
$C_D$	Flow discharge coefficient
$A(h)$	Instantaneous orifice passage area
$x_0$	Initial opening
$x$	Gate displacement from initial position
$h$	Valve opening
$D$	Orifice diameter
$\rho$	Fluid density
$A_{leak}$	Closed valve leakage area
$p_{Cr}$	Minimum pressure for turbulent flow

The minimum pressure for turbulent flow,  $p_{Cr}$ , is calculated according to the laminar transition specification method:

- By pressure ratio — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{Cr} = (p_{avg} + p_{atm})(1 - B_{lam})$$

$$p_{avg} = (p_A + p_B)/2$$

where

$p_{avg}$	Average pressure between the block terminals
$p_{atm}$	Atmospheric pressure, 101325 Pa
$B_{lam}$	Pressure ratio at the transition between laminar and turbulent regimes ( <b>Laminar flow pressure ratio</b> parameter value)

- By Reynolds number — The transition from laminar to turbulent regime is defined by the following equations:

$$p_{cr} = \frac{\rho}{2} \left( \frac{Re_{cr} \cdot \nu}{C_D \cdot D_H} \right)^2$$

$$D_H = \sqrt{\frac{4A}{\pi}}$$

where

$D_H$	Valve instantaneous hydraulic diameter
$\nu$	Fluid kinematic viscosity
$Re_{cr}$	Critical Reynolds number ( <b>Critical Reynolds number</b> parameter value)

Connections A and B are hydraulic conserving ports. Connection S is a physical signal port that controls the gate displacement. The block positive direction is from port A to port B. This means that the flow rate is positive if it flows from A to B, and the pressure differential is determined as  $\Delta p = p_A - p_B$ . Positive signal at the physical signal port S opens the valve.

## Basic Assumptions and Limitations

- No inertial effects are taken into account.

## Parameters

### Valve orifice diameter

The diameter of the valve orifice. The orifices in the valve housing and in the gate have the same diameter. The default value is 0.01 m.

### Initial opening

The initial opening of the valve. The parameter can take both positive and negative values. The default value is 0.

### Flow discharge coefficient

Semi-empirical parameter for valve capacity characterization. Its value depends on the geometrical properties of the orifice, and usually is provided in textbooks or manufacturer data sheets. The default value is 0.65.

### Laminar transition specification

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

### Laminar flow pressure ratio

Pressure ratio at which the flow transitions between laminar and turbulent regimes. The default value is 0.999. This parameter is visible only if the **Laminar transition specification** parameter is set to **Pressure ratio**.

### Critical Reynolds number

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks. The default value is 10. This parameter is visible only if the **Laminar transition specification** parameter is set to Reynolds number.

### Leakage area

The total area of possible leaks in the completely closed valve. The main purpose of the parameter is to maintain numerical integrity of the circuit by preventing a portion of the system from getting isolated after the valve is completely closed. The parameter value must be greater than 0. The default value is  $1e-12 \text{ m}^2$ .

## Global Parameters

Parameters determined by the type of working fluid:

- **Fluid density**
- **Fluid kinematic viscosity**

Use the Hydraulic Fluid block or the Custom Hydraulic Fluid block to specify the fluid properties.

## Ports

The block has the following ports:

A

Hydraulic conserving port associated with the valve inlet.

B

Hydraulic conserving port associated with the valve outlet.

S

Physical signal port that controls the gate displacement. The signal applied to this port is treated as translational motion, in meters.

## Version History

### Introduced in R2011b

#### **R2023a: To be removed**

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Extended Capabilities

### **C/C++ Code Generation**

Generate C and C++ code using Simulink® Coder™.

Ball Valve | Needle Valve | Poppet Valve | Pressure-Compensated Flow Control Valve

## Gate Valve (IL)

Gate valve in an isothermal liquid system

### Libraries:

Simscape / Fluids / Isothermal Liquid / Valves & Orifices / Flow Control Valves

### Description

The Gate Valve (IL) block represents flow control by a gate valve in an isothermal liquid network. The valve comprises a round, sharp-edged orifice and a round gate with the same diameter. The gate opens or closes according to the displacement signal at port **S**. A positive signal retracts the gate and opens the valve.

### Opening Area

### Gate Valve Opening Schematic

The area open to flow as the gate retracts is:

$$A_{open} = \frac{\pi d_0^2}{4} - A_{shielded},$$

where  $d_0$  is the **Valve orifice diameter**. The area shielded by the gate in a partially open valve is:

$$A_{shielded} = \frac{d_0^2}{2} \cos^{-1}\left(\frac{\Delta l}{d_0}\right) - \frac{\Delta l}{2} \sqrt{d_0^2 - (\Delta l)^2},$$

where  $\Delta l$  is the gate displacement, which is the sum of the signal at port **S** and the **Gate position when fully covering orifice**.

If displacement exceeds the **Orifice diameter**, the valve area  $A_{open}$  is the sum of the maximum orifice area and the **Leakage area**:

$$A_{open} = \frac{\pi}{4} d_0^2 + A_{leak}.$$

For any combination of the signal at port **S** and the gate offset that is less than 0, the minimum valve area is the **Leakage area**.

## Numerically Smoothed Displacement

When the valve is in a near-open or near-closed position, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the gate displacement between  $\theta$  and the **Valve orifice diameter** parameter. For more information, see “Numerical Smoothing”.

## Mass Flow Rate Equation

Mass is conserved through the valve:

$$\dot{m}_A + \dot{m}_B = 0.$$

The mass flow rate through the valve is calculated as:

$$\dot{m} = \frac{C_d A_{\text{valve}} \sqrt{2\bar{\rho}}}{\sqrt{PR_{\text{loss}} \left(1 - \left(\frac{A_{\text{valve}}}{A_{\text{port}}}\right)^2\right) [\Delta p^2 + \Delta p_{\text{crit}}^2]^{1/4}}} \Delta p$$

where:

- $C_d$  is the **Discharge coefficient**.
- $A_{\text{valve}}$  is the valve open area.
- $A_{\text{port}}$  is the **Cross-sectional area at ports A and B**.
- $\bar{\rho}$  is the average fluid density.
- $\Delta p$  is the valve pressure difference  $p_A - p_B$ .

The critical pressure difference,  $\Delta p_{\text{crit}}$ , is the pressure differential associated with the **Critical Reynolds number**,  $Re_{\text{crit}}$ , which is the flow regime transition point between laminar and turbulent flow:

$$\Delta p_{\text{crit}} = \frac{\pi \bar{\rho}}{8 A_{\text{valve}}} \left( \frac{\nu Re_{\text{crit}}}{C_d} \right)^2.$$

*Pressure loss* describes the reduction of pressure in the valve due to a decrease in area.  $PR_{\text{loss}}$  is calculated as:

$$PR_{\text{loss}} = \frac{\sqrt{1 - \left(\frac{A_{\text{valve}}}{A_{\text{port}}}\right)^2 (1 - C_d^2)} - C_d \frac{A_{\text{valve}}}{A_{\text{port}}}}{\sqrt{1 - \left(\frac{A_{\text{valve}}}{A_{\text{port}}}\right)^2 (1 - C_d^2)} + C_d \frac{A_{\text{valve}}}{A_{\text{port}}}}.$$

*Pressure recovery* describes the positive pressure change in the valve due to an increase in area. If you do not wish to capture this increase in pressure, clear the **Pressure recovery** check box. In this case,  $PR_{\text{loss}}$  is 1.

## Ports

### Input

**S** — Gate displacement, m  
physical signal

Physical signal port associated with the valve gate displacement, in m. A positive signal retracts the gate and opens the valve.

### Conserving

**A** — Liquid port  
isothermal liquid

Isothermal liquid conserving port associated with valve inlet A.

**B** — Liquid port  
isothermal liquid

Isothermal liquid conserving port associated with valve inlet B.

### Parameters

**Valve orifice diameter** — Orifice diameter  
5e-3 m<sup>2</sup> (default) | positive scalar

Valve open-area diameter.

**Gate position when fully covering orifice** — Gate offset  
0 m (default) | positive scalar

Gate offset when the valve is closed. A positive, nonzero value indicates a partially open valve when the signal at port **S** is 0. A negative, nonzero value indicates an overlapped valve that remains closed for an initial positive displacement set by the physical signal at port **S**.

**Leakage area** — Gap area when in fully closed position  
1e-10 m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the valve is in the fully closed position. Any area smaller than this value is saturated to the specified leakage area. This contributes to numerical stability by maintaining continuity in the flow.

**Cross-sectional area at ports A and B** — Orifice area at conserving ports  
inf m<sup>2</sup> (default) | positive scalar

Areas at the entry and exit ports **A** and **B**, which are used in the pressure-flow rate equation that determines the mass flow rate through the orifice.

**Discharge coefficient** — Discharge coefficient  
0.64 (default) | positive scalar

Correction factor accounting for discharge losses in theoretical flows.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow  
150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

**Smoothing factor** — Numerical smoothing factor  
0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions.

**Pressure recovery** — Whether to account for pressure increase in area expansions  
off (default) | on

Whether to account for pressure increase when fluid flows from a region of smaller cross-sectional area to a region of larger cross-sectional area.

Needle Valve (IL) | Poppet Valve (IL) | Orifice (IL)

## Gate Valve (G)

Gate valve in a gas network

### Libraries:

Simscape / Fluids / Gas / Valves & Orifices / Flow Control Valves

## Description

The Gate Valve (G) block represents an orifice with a translating gate, or *sluice*, as a flow control mechanism. The gate is circular and must slide perpendicular to the flow due to the constraints of the groove of its seat. The seat of the valve is annular. The flow passes through the bore, which is sized to match the gate. The overlap of the gate and the bore determines the opening area of the valve.

This image shows a gate valve with a conical seat.

The flow can be laminar or turbulent, and it can reach up to sonic speeds. The maximum velocity happens at the throat of the valve where the flow is narrowest and fastest. The flow chokes and the velocity saturates when a drop in downstream pressure can no longer increase the velocity. Choking occurs when the back-pressure ratio reaches the critical value characteristic of the valve. The block does not capture supersonic flow.

Gate valves generally open quickly. Gate valves are most sensitive to gate displacement near the closed position, where a small displacement translates into a disproportionately large change in opening area. Consequently, gate valves have too high a gain in that region to effectively throttle or modulate flow. You can use this block as a binary switch to open and close gas circuits.

### Gate Mechanics

In a real valve, the gate connects by a gear mechanism to a handle. When the handle is turned from a fully closed position, the gate rises from the bore and progressively opens the valve up to a maximum. Hard stops keep the disk from breaching its minimum and maximum positions.

The block captures the motion of the disk but not the detail of its mechanics. You specify the motion as a normalized displacement at port **L**. The input physical signal carries the fraction of the instantaneous displacement over its value in the fully open valve.

If you want to model the action of the handle and hard stop, use Simscape mechanical blocks to capture the displacement signal. However, in many cases, it suffices to know what displacement to impart to the disk and you do not need to model the mechanics of the valve.

### Gate Position

The block models the displacement of the gate but not the valve opening or closing dynamics. The signal at port **L** provides the normalized gate position,  $L$ .  $L$  is a normalized distance between 0 and 1, which indicates a fully closed valve and a fully open valve, respectively. If the calculation returns a number outside of this range, the block sets that number to the nearest bound.

### Numerical Smoothing

When the **Smoothing factor** parameter is nonzero, the block applies numerical smoothing to the normalized gate position,  $L$ . Enabling smoothing helps maintain numerical robustness in your simulation.

For more information, see “Numerical Smoothing”.

### Opening Area

The opening area of the valve is the area of the bore adjusted for the instantaneous overlap of the gate

$$S_{open} = \frac{pD^2}{4} - S_C,$$

where:

- $S_{open}$  is the instantaneous valve opening area. The block then smooths this area to remove derivative discontinuities at the limiting valve positions.
- $D$  is the common diameter of the gate and its bore, which are identical. This is the value of the **Orifice diameter** parameter.
- $S_C$  is the area of overlap between the gate and bore, which the block computes as a function of the gate position,  $L$ :

$$S_C = \frac{D^2}{2} \arccos(L) - \frac{LD}{2} \sqrt{D^2 - L^2 D^2}.$$

The figure shows a front view of the valve when maximally closed, partially open, and fully open, from left to right. The figure also shows the parameters and variables in the opening area calculation.

### Valve Parameterizations

The block behavior depends on the **Valve parametrization** parameter:

- **Cv flow coefficient** — The flow coefficient  $C_v$  determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential.
- **Kv flow coefficient** — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization. The flow coefficient measures the ease with which a gas can flow when driven by a certain pressure differential.
- **Sonic conductance** — The sonic conductance of the resistive element at steady state determines the block parameterization. The sonic conductance measures the ease with which a gas can flow when *choked*, which is a condition in which the flow velocity is at the local speed of sound. Choking occurs when the ratio between downstream and upstream pressures reaches a critical value known as the *critical pressure ratio*.
- **Orifice area based on geometry** — The size of the flow restriction determines the block parametrization.

The block scales the specified flow capacity by the fraction of valve opening. As the fraction of valve opening rises from 0 to 1, the measure of flow capacity scales from its specified minimum to its specified maximum.

### Momentum Balance

The block equations depend on the **Orifice parametrization** parameter. When you set **Orifice parametrization** to Cv flow coefficient parameterization, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C_v \frac{S_{open}}{S_{Max}} N_6 Y \sqrt{(p_{in} - p_{out}) \rho_{in}}$$

where:

- $C_v$  is the value of the **Maximum Cv flow coefficient** parameter.
- $S_{open}$  is the valve opening area.
- $S_{Max}$  is the maximum valve area when the valve is fully open.
- $N_6$  is a constant equal to 27.3 for mass flow rate in kg/hr, pressure in bar, and density in kg/m<sup>3</sup>.
- $Y$  is the expansion factor.
- $p_{in}$  is the inlet pressure.
- $p_{out}$  is the outlet pressure.
- $\rho_{in}$  is the inlet density.

The expansion factor is

$$Y = 1 - \frac{p_{in} - p_{out}}{3p_{in}F_\gamma \chi_T}$$

where:

- $F_\gamma$  is the ratio of the isentropic exponent to 1.4.
- $\chi_T$  is the value of the **xT pressure differential ratio factor at choked flow** parameter.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter,  $B_{lam}$ .

$$\dot{m} = C_v \frac{S_{open}}{S_{Max}} N_6 Y_{lam} \sqrt{\frac{\rho_{avg}}{p_{avg}(1 - B_{lam})}} (p_{in} - p_{out}),$$

where:

$$Y_{lam} = 1 - \frac{1 - B_{lam}}{3F_{\gamma} x_T}.$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below  $1 - F_{\gamma} x_T$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = \frac{2}{3} C_v \frac{S_{open}}{S_{Max}} N_6 \sqrt{F_{\gamma} x_T p_{in} \rho_{in}}.$$

When you set **Orifice parametrization** to Kv flow coefficient parameterization, the block uses these same equations, but replaces  $C_v$  with  $K_v$  by using the relation  $K_v = 0.865C_v$ . For more information on the mass flow equations when the **Orifice parametrization** parameter is Kv flow coefficient parameterization or Cv flow coefficient parameterization, [2][3].

When you set **Orifice parametrization** to Sonic conductance parameterization, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C \frac{S_{open}}{S_{Max}} \rho_{ref} p_{in} \sqrt{\frac{T_{ref}}{T_{in}}} \left[ 1 - \left( \frac{\frac{p_{out}}{p_{in}} - B_{crit}}{1 - B_{crit}} \right)^2 \right]^m,$$

where:

- $C$  is the value of the **Maximum sonic conductance** parameter.
- $B_{crit}$  is the critical pressure ratio.
- $m$  is the value of the **Subsonic index** parameter.
- $T_{ref}$  is the value of the **ISO reference temperature** parameter.
- $\rho_{ref}$  is the value of the **ISO reference density** parameter.
- $T_{in}$  is the inlet temperature.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter  $B_{lam}$ ,

$$\dot{m} = C \frac{S_{open}}{S_{Max}} \rho_{ref} \sqrt{\frac{T_{ref}}{T_{avg}}} \left[ 1 - \left( \frac{B_{lam} - B_{crit}}{1 - B_{crit}} \right)^2 \right]^m \left( \frac{p_{in} - p_{out}}{1 - B_{lam}} \right).$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below the critical pressure ratio,  $B_{crit}$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = C \frac{S_{open}}{S_{Max}} \rho_{ref} p_{in} \sqrt{\frac{T_{ref}}{T_{in}}}.$$

For more information on the mass flow equations when the **Orifice parametrization** parameter is Sonic conductance parameterization, see [1].

When you set **Orifice parametrization** to Orifice area based on geometry, the mass flow rate,  $\dot{m}$ , is

$$\dot{m} = C_d S_{open} \sqrt{\frac{2\gamma}{\gamma-1} p_{in} \rho_{in} \left(\frac{p_{out}}{p_{in}}\right)^{\frac{2}{\gamma}} \left[ \frac{1 - \left(\frac{p_{out}}{p_{in}}\right)^{\frac{\gamma-1}{\gamma}}}{1 - \left(\frac{S_{open}}{S}\right)^2 \left(\frac{p_{out}}{p_{in}}\right)^{\frac{2}{\gamma}}}\right]}$$

where:

- $S_{open}$  is the valve opening area.
- $S$  is the value of the **Cross-sectional area at ports A and B** parameter.
- $C_d$  is the value of the **Discharge coefficient** parameter.
- $\gamma$  is the isentropic exponent.

The block smoothly transitions to a linearized form of the equation when the pressure ratio,  $p_{out}/p_{in}$ , rises above the value of the **Laminar flow pressure ratio** parameter,  $B_{lam}$ ,

$$\dot{m} = C_d S_{open} \sqrt{\frac{2\gamma}{\gamma-1} p_{avg}^{\frac{2-\gamma}{\gamma}} \rho_{avg} B_{lam}^{\frac{2}{\gamma}} \left[ \frac{1 - B_{lam}^{\frac{\gamma-1}{\gamma}}}{1 - \left(\frac{S_{open}}{S}\right)^2 B_{lam}^{\frac{2}{\gamma}}}\right] \left( \frac{p_{in}^{\frac{\gamma-1}{\gamma}} - p_{out}^{\frac{\gamma-1}{\gamma}}}{1 - B_{lam}^{\frac{\gamma-1}{\gamma}}}\right)}$$

When the pressure ratio,  $p_{out}/p_{in}$ , falls below  $\left(\frac{2}{\gamma+1}\right)^{\frac{\gamma}{\gamma-1}}$ , the orifice becomes choked and the block switches to the equation

$$\dot{m} = C_d S_{open} \sqrt{\frac{2\gamma}{\gamma+1} p_{in} \rho_{in} \frac{1}{\left(\frac{\gamma+1}{2}\right)^{\frac{2}{\gamma-1}} - \left(\frac{S_{open}}{S}\right)^2}}$$

For more information on the mass flow equations when the **Orifice parametrization** parameter is Orifice area based on geometry, see [4].

### Mass Balance

The block assumes the volume and mass of fluid inside the valve is very small and ignores these values. As a result, no amount of fluid can accumulate in the valve. By the principle of conservation of mass, the mass flow rate into the valve through one port equals that out of the valve through the other port

$$\dot{m}_A + \dot{m}_B = 0,$$

where  $\dot{m}$  is defined as the mass flow rate into the valve through the port indicated by the **A** or **B** subscript.

### Energy Balance

The resistive element of the block is an adiabatic component. No heat exchange can occur between the fluid and the wall that surrounds it. No work is done on or by the fluid as it traverses from inlet to

outlet. Energy can flow only by advection, through ports **A** and **B**. By the principle of conservation of energy, the sum of the port energy flows is always equal to zero

$$\phi_A + \phi_B = 0,$$

where  $\phi$  is the energy flow rate into the valve through ports **A** or **B**.

### Assumptions and Limitations

- The **Sonic conductance** setting of the **Valve parameterization** parameter is for pneumatic applications. If you use this setting for gases other than air, you may need to scale the sonic conductance by the square root of the specific gravity.
- The equation for the **Orifice area** based on geometry parameterization is less accurate for gases that are far from ideal.
- This block does not model supersonic flow.

## Ports

### Input

**L** — Valve control signal, unitless  
physical signal

Input port through which to specify the relative displacement of the gate as a fraction of its maximum. This input specifies the gate position, which the block uses to compute the mass flow rate through the valve. This position should range between 0 for a maximally closed valve to 1 for a fully open valve.

### Conserving

**A** — Valve entrance  
gas

Gas conserving port associated with the opening through which the flow enters or exits the valve. The direction of flow depends on the pressure differential established across the valve. The block allows both forward and backward directions.

**B** — Valve entrance  
gas

Gas conserving port associated with the opening through which the flow enters or exits the valve. The direction of flow depends on the pressure differential established across the valve. The block allows both forward and backward directions.

## Parameters

**Orifice diameter** — Diameter of the bore of the valve  
0.01 m (default) | positive scalar

Diameter of the bore of the valve and of the gate that controls the opening area. The orifice is assumed to be constant in cross section throughout its length from one port to the other.

**Valve parameterization** — Parameterization used to specify flow characteristics of orifice  
Orifice area based on geometry (default) | Cv flow coefficient | Kv flow coefficient | Sonic conductance

Method to calculate the mass flow rate.

- Cv flow coefficient — The flow coefficient  $C_v$  determines the block parameterization.
- Kv flow coefficient — The flow coefficient  $K_v$ , where  $K_v = 0.865C_v$ , determines the block parameterization.
- Sonic conductance — The sonic conductance of the resistive element at steady state determines the block parameterization.
- Orifice area based on geometry — The size of the flow restriction determines the block parameterization.

**Discharge coefficient** — Discharge coefficient  
0.64 (default) | positive scalar in the range of [0,1]

Correction factor that accounts for discharge losses in theoretical flows.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Orifice area based on geometry.

**Maximum Cv flow coefficient** — Cv coefficient that corresponds to maximally open component  
4 (default) | positive scalar

Value of the  $C_v$  flow coefficient when the restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Cv flow coefficient.

**xT pressure differential ratio factor at choked flow** — Ratio of pressure differentials  
0.7 (default) | positive scalar

Ratio between the inlet pressure,  $p_{in}$ , and the outlet pressure,  $p_{out}$ , defined as  $(p_{in} - p_{out})/p_{in}$  where choking first occurs. If you do not have this value, look it up in table 2 in ISA-75.01.01 [3]. Otherwise, the default value of 0.7 is reasonable for many valves.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Cv flow coefficient or Kv flow coefficient.

**Maximum Kv flow coefficient** — Kv coefficient that corresponds to maximally open component  
3.6 (default) | positive scalar

Maximum value of the  $K_v$  flow coefficient when the restriction area available for flow is at a maximum. This parameter measures the ease with which the gas traverses the resistive element when driven by a pressure differential.

#### Dependencies

To enable this parameter, set **Valve parameterization** to Kv flow coefficient.

**Maximum sonic conductance** — Sonic conductance corresponding to maximally open component  
12 l/(bar\*s) (default) | positive scalar

Value of the sonic conductance when the cross-sectional area available for flow is at a maximum.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**Critical pressure ratio** — Ratio of downstream and upstream pressures at which the flow first chokes  
0.3 (default) | positive scalar

Pressure ratio at which flow first begins to choke and the flow velocity reaches its maximum, given by the local speed of sound. The pressure ratio is the outlet pressure divided by inlet pressure.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**Subsonic index** — Exponent used to characterize mass flow in subsonic flow regime  
0.5 (default) | positive scalar

Empirical value used to more accurately calculate the mass flow rate in the subsonic flow regime.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**ISO reference temperature** — ISO 8778 reference temperature  
293.15 K (default) | scalar

Temperature at standard reference atmosphere, defined as 293.15 K in ISO 8778.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**ISO reference density** — ISO 8778 reference density  
1.185 kg/m<sup>3</sup> (default) | positive scalar

Density at standard reference atmosphere, defined as 1.185 kg/m<sup>3</sup> in ISO 8778.

**Dependencies**

To enable this parameter, set **Valve parameterization** to Sonic conductance.

**Leakage flow fraction** — Ratio of flow rates  
1e-6 (default) | positive scalar

Ratio of the flow rate of the orifice when it is closed to when it is open.

**Smoothing factor** — Numerical smoothing factor  
0.01 (default) | positive scalar in the range [0,1]

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the orifice is in near-open or near-closed positions. Set this parameter to a nonzero value less than one to increase the stability of your simulation in these regimes.

**Laminar flow pressure ratio** — Pressure ratio at which flow transitions between laminar and turbulent regimes

0.999 (default) | positive scalar

Pressure ratio at which flow transitions between laminar and turbulent flow regimes. The pressure ratio is the outlet pressure divided by inlet pressure. Typical values range from 0.995 to 0.999.

**Cross-sectional area at ports A and B** — Flow area at gas ports

0.01 m<sup>2</sup> (default) | positive scalar

Area normal to the flow path at each port. The ports are equal in size. The value of this parameter should match the inlet area of the components to which the resistive element connects.

## Version History

Introduced in R2018b

### R2022b: Model gas systems using improved flow computations

In previous versions, the blocks in the gas library used a conversion factor to implement different orifice parameterizations in terms of sonic conductance. You can use the **Valve parameterization** parameter to specify the parameterization.

The new parameterizations also include new parameters:

- **xT pressure differential ratio factor at choked flow**
- **Discharge coefficient**
- **Leakage flow fraction.** This parameter replaces the **Cv coefficient (USCS) at leakage flow**, **Kv coefficient (SI) at leakage flow**, **Sonic conductance at leakage flow**, and **Restriction area at leakage flow** parameters.

To improve clarity:

- The **Opening parameterization** parameter has been renamed to **Opening characteristic**.
- The **Reference temperature** and **Reference density** parameters have been renamed to **ISO reference temperature** and **ISO reference density**, respectively.
- The **Cv coefficient (USCS) at maximum flow** and **Kv coefficient (USCS) at maximum flow** parameters have been renamed to **Maximum Cv coefficient** and **Maximum Kv coefficient**, respectively.
- The **Sonic conductance at maximum flow** parameter has been renamed to **Maximum sonic conductance**.

### R2022b: Offset parameter removed

The block no longer has a **Gate displacement fraction offset** parameter and the block no longer offsets the input signal. This change does not impact compatibility.

Orifice (G) | Poppet Valve (G)

# Gate Valve (TL)

Gate valve in a thermal liquid system

## Libraries:

Simscape / Fluids / Thermal Liquid / Valves & Orifices / Flow Control Valves

## Description

The Gate Valve (TL) block represents a gate valve in a thermal liquid network. The valve comprises a round, sharp-edged orifice and a round gate with the same diameter. The gate opens or closes according to the displacement signal at port **S**. A positive signal lifts the gate to open the valve. The diagram shows the relationship between the opening area and the net displacement of the gate.

A smoothing function allows the valve opening area to change smoothly between the fully closed and fully open positions. The smoothing function reduces the abrupt opening area changes at the zero and maximum gate positions.

## Mass Balance

The mass conservation equation in the valve is

$$\dot{m}_A + \dot{m}_B = 0,$$

where:

- $\dot{m}_A$  is the mass flow rate into the valve through port **A**.
- $\dot{m}_B$  is the mass flow rate into the valve through port **B**.

## Momentum Balance

The momentum conservation equation in the valve is

$$p_A - p_B = \frac{\dot{m}\sqrt{\dot{m}^2 + \dot{m}_{cr}^2}}{2\rho_{Avg}C_d^2S^2} \left[ 1 - \left( \frac{S_R}{S} \right)^2 \right] PR_{Loss},$$

where:

- $p_A$  and  $p_B$  are the pressures at port **A** and port **B**.
- $\dot{m}$  is the mass flow rate.
- $\dot{m}_{cr}$  is the critical mass flow rate:

$$\dot{m}_{cr} = Re_{cr} \mu_{Avg} \sqrt{\frac{\pi}{4}} S_R.$$

- $\rho_{Avg}$  is the average liquid density.
- $C_d$  is the discharge coefficient.
- $S$  is the valve inlet area.
- $PR_{Loss}$  is the pressure ratio:

$$PR_{Loss} = \frac{\sqrt{1 - (S_R/S)^2(1 - C_d^2)} - C_d(S_R/S)}{\sqrt{1 - (S_R/S)^2(1 - C_d^2)} + C_d(S_R/S)}.$$

### Energy Balance

The energy conservation equation in the valve is

$$\phi_A + \phi_B = 0,$$

where:

- $\phi_A$  is the energy flow rate into the valve through port **A**.
- $\phi_B$  is the energy flow rate into the valve through port **B**.

### Valve Opening Area

The block computes the valve opening area by using the expression

$$A = \frac{\pi d_0^2}{4} - A_{Covered} + A_{leak},$$

where:

- $A$  is the valve opening area.
- $A_{leak}$  is the value of the **Leakage area** parameter.
- $d_0$  is the valve orifice diameter.
- $A_{Covered}$  is the portion of the valve orifice area covered by the gate:

$$A_{Covered} = \frac{d_0^2}{2} \arccos\left(\frac{\Delta l}{d_0}\right) - \frac{\Delta l}{2} \sqrt{d_0^2 - (\Delta l)^2}.$$

- $\Delta l$  is the net displacement of the gate center relative to the orifice center.

$$\Delta l = \begin{cases} 0, & (S_d - S_{min}) \leq 0 \\ d_0, & (S_d - S_{min}) \geq d_0 \\ (S_d - S_{min}), & \text{Else} \end{cases}$$

- $S_{min}$  is value of the **Gate position when fully covering orifice** parameter specified in the block dialog box.

- $S_a$  is the gate displacement specified through physical signal input port S.

### Numerically Smoothed Displacement

When the valve is in a near-open or near-closed position, you can maintain numerical robustness in your simulation by adjusting the **Smoothing factor** parameter. If the **Smoothing factor** parameter is nonzero, the block smoothly saturates the gate displacement between  $\theta$  and the **Valve orifice diameter** parameter. For more information, see “Numerical Smoothing”.

## Ports

### Input

**S** — Gate displacement, m  
physical signal

Physical signal port associated with the valve gate displacement, in m. A positive signal retracts the gate and opens the valve.

### Conserving

**A** — Liquid port  
thermal liquid

Thermal liquid conserving port associated with valve inlet A.

**B** — Liquid port  
thermal liquid

Thermal liquid conserving port associated with valve inlet B.

## Parameters

**Orifice diameter** — Orifice diameter  
 $0.01$  m (default) | positive scalar

Valve open-area diameter.

**Gate position when fully covering orifice** — Gate offset  
 $0$  m (default) | nonnegative scalar

Gate offset when the valve is closed. A positive, nonzero value indicates a partially open valve when the signal at port **S** is 0. A negative, nonzero value indicates an overlapped valve that remains closed for an initial positive displacement set by the physical signal at port **S**.

**Leakage area** — Gap area when in fully shut position  
 $1e-10$  m<sup>2</sup> (default) | positive scalar

Sum of all gaps when the valve is in the fully shut position. The block saturates smaller numbers to this value. This parameter contributes to numerical stability by maintaining continuity in the flow.

**Smoothing factor** — Numerical smoothing factor  
 $0.01$  (default) | scalar in the range  $[0,1]$

Continuous smoothing factor that introduces a layer of gradual change to the flow response when the valve is in near-open or near-closed positions.

**Cross-sectional area at ports A and B** — Orifice area at conserving ports

0.01 m<sup>2</sup> (default) | positive scalar

Areas at the entry and exit ports **A** and **B**, which are used in the pressure-flow rate equation that determines the mass flow rate through the orifice.

**Discharge coefficient** — Discharge coefficient

0.64 (default) | positive scalar

Correction factor that accounts for discharge losses in theoretical flows.

**Critical Reynolds number** — Upper Reynolds number limit for laminar flow

150 (default) | positive scalar

Upper Reynolds number limit for laminar flow through the valve.

# Gradual Area Change

(To be removed) Gradual enlargement or contraction

**Note** The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

For more information on updating your models, see “Upgrading Hydraulic Models to Use Isothermal Liquid Blocks”.

## Libraries:

Simscape / Fluids / Hydraulics (Isothermal) / Local Hydraulic Resistances

## Description

The Gradual Area Change block represents a local hydraulic resistance, such as a gradual cross-sectional area change. The resistance represents a gradual enlargement (diffuser) if fluid flows from inlet to outlet, or a gradual contraction if fluid flows from outlet to inlet. The block is based on the Local Resistance block. It determines the pressure loss coefficient and passes its value to the underlying Local Resistance block. The block offers two methods of parameterization: by applying semi-empirical formulas (with a constant value of the pressure loss coefficient) or by table lookup for the pressure loss coefficient based on the Reynolds number.

If you choose to apply the semi-empirical formulas, you provide geometric parameters of the resistance, and the pressure loss coefficient is determined according to the A.H. Gibson equations (see [1] and [2]):

$$K_{GE} = \begin{cases} K_{cor} \left(1 - \frac{A_s}{A_L}\right)^2 \cdot 2.6 \sin \frac{\alpha}{2} & \text{for } 0 < \alpha \leq 45^\circ \\ K_{cor} \left(1 - \frac{A_s}{A_L}\right)^2 & \text{for } 45^\circ < \alpha < 180^\circ \end{cases}$$

$$K_{GC} = \begin{cases} K_{cor} \cdot 0.5 \left(1 - \frac{A_s}{A_L}\right)^{0.75} \cdot 1.6 \sin \frac{\alpha}{2} & \text{for } 0 < \alpha \leq 45^\circ \\ K_{cor} \cdot 0.5 \left(1 - \frac{A_s}{A_L}\right)^{0.75} \cdot \sqrt{\sin \frac{\alpha}{2}} & \text{for } 45^\circ < \alpha < 180^\circ \end{cases}$$

where

$K_{GE}$	Pressure loss coefficient for the gradual enlargement, which takes place if fluid flows from inlet to outlet
$K_{GC}$	Pressure loss coefficient for the gradual contraction, which takes place if fluid flows from outlet to inlet

$K_{cor}$	Correction factor
$A_S$	Small area
$A_L$	Large area
$\alpha$	Enclosed angle

If you choose to specify the pressure loss coefficient by a table, you have to provide a tabulated relationship between the loss coefficient and the Reynolds number. In this case, the loss coefficient is determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods.

The pressure loss coefficient, determined by either of the two methods, is then passed to the underlying Local Resistance block, which computes the pressure loss according to the formulas explained in the reference documentation for that block. The flow regime is checked in the underlying Local Resistance block by comparing the Reynolds number to the specified critical Reynolds number value, and depending on the result, the appropriate formula for pressure loss computation is used.

The Gradual Area Change block is bidirectional and computes pressure loss for both the direct flow (gradual enlargement) and return flow (gradual contraction). If the loss coefficient is specified by a table, the table must cover both the positive and the negative flow regions.

The block positive direction is from port A to port B. This means that the flow rate is positive if fluid flows from A to B, and the pressure loss is determined as  $p = p_A - p_B$ .

## Assumptions and Limitations

- Fluid inertia is not taken into account.
- If you select parameterization by the table-specified relationship  $K=f(Re)$ , the flow is assumed to be turbulent.

## Ports

### Conserving

**A** — Hydraulic conserving port associated with the resistance inlet  
hydraulic

Hydraulic conserving port associated with the resistance inlet. This is the port with the smaller cross-sectional area.

**B** — Hydraulic conserving port associated with the resistance outlet  
hydraulic

Hydraulic conserving port associated with the resistance outlet. This is the port with the larger cross-sectional area.

## Parameters

**Model parameterization** — Select method of block parameterization

Semi-empirical correlation (default) | Tabulated data – loss coefficient vs. Reynolds number

Select one of the following methods for block parameterization:

- Semi-empirical correlation — Provide geometrical parameters of the resistance.
- Tabulated data – loss coefficient vs. Reynolds number — Provide tabulated relationship between the loss coefficient and the Reynolds number. The loss coefficient is determined by one-dimensional table lookup. You have a choice of two interpolation methods and two extrapolation methods. The table must cover both the positive and the negative flow regions.

**Small diameter** — Internal diameter at the inlet port

0.01 m (default) | positive scalar

Internal diameter at the small port, **A**.

**Large diameter** — Internal diameter at the outlet port

0.02 m (default) | positive scalar

Internal diameter at the large port, **B**.

### Dependencies

To enable this parameter, set **Model parameterization** to Semi-empirical correlation.

**Cone angle** — Enclosed angle

30 deg (default) | scalar in the range of (0,180 deg)

The enclosed angle.

### Dependencies

To enable this parameter, set **Model parameterization** to Semi-empirical correlation.

**Correction coefficient** — Correction factor for computation of the loss coefficient

1 (default) | positive scalar

Correction factor used in the formula for computation of the loss coefficient.

### Dependencies

To enable this parameter, set **Model parameterization** to Semi-empirical correlation.

**Laminar transition specification** — Select how block transitions between the laminar and turbulent regimes

Pressure ratio (default) | Reynolds number

Select how the block transitions between the laminar and turbulent regimes:

- **Pressure ratio** — The transition from laminar to turbulent regime is smooth and depends on the value of the **Laminar flow pressure ratio** parameter. This method provides better simulation robustness.
- **Reynolds number** — The transition from laminar to turbulent regime is assumed to take place when the Reynolds number reaches the value specified by the **Critical Reynolds number** parameter.

#### **Dependencies**

To enable this parameter, set **Model parameterization** to `Semi-empirical correlation`.

**Laminar flow pressure ratio** — Pressure ratio at which the flow transitions between laminar and turbulent regimes

0.999 (default) | scalar in the range of (0,1)

Pressure ratio at which the flow transitions between laminar and turbulent regimes.

#### **Dependencies**

To enable this parameter, set **Laminar transition specification** to `Pressure ratio`.

**Critical Reynolds number** — Maximum Reynolds number for laminar flow

350 (default) | scalar

The maximum Reynolds number for laminar flow. The value of the parameter depends on the orifice geometrical profile. You can find recommendations on the parameter value in hydraulics textbooks.

#### **Dependencies**

To enable this parameter, set **Laminar transition specification** to `Reynolds number`.

**Reynolds number vector** — Vector of input values for Reynolds numbers

[-4000, -3000, -2000, -1000, -500, -200, -100, -50, -40, -30, -20, -15, -10, 10, 20, 30, 40, 50, 100, 200, 500, 1000, 2000, 4000, 5000, 10000] (default) | 1-by-*n* vector

Specify the vector of input values for Reynolds numbers as a one-dimensional array. The input values vector must be strictly increasing. The values can be nonuniformly spaced. The minimum number of values depends on the interpolation method: you must provide at least two values for linear interpolation, at least three values for smooth interpolation.

#### **Dependencies**

To enable this parameter, set **Model parameterization** to `Tabulated data – loss coefficient vs. Reynolds number`.

**Loss coefficient vector** — Vector of the loss coefficient values

[0.25, 0.3, 0.65, 0.9, 0.65, 0.75, 0.90, 1.15, 1.35, 1.65, 2.3, 2.8, 3.10, 5, 2.7, 1.8, 1.46, 1.3, 0.9, 0.65, 0.42, 0.3, 0.20, 0.40, 0.42, 0.25] (default) | 1-by-*n* vector

Specify the vector of the loss coefficient values as a one-dimensional array. The loss coefficient vector must be of the same size as the Reynolds numbers vector.

#### Dependencies

To enable this parameter, set **Model parameterization** to `Tabulated data – loss coefficient vs. Reynolds number`.

**Interpolation method** — Select the interpolation method  
Linear (default) | Smooth

Select one of the following interpolation methods for approximating the output value when the input value is between two consecutive grid points:

- **Linear** — Select this option to get the best performance.
- **Smooth** — Select this option to produce a continuous curve with continuous first-order derivatives.

For more information on interpolation algorithms, see PS Lookup Table (1D).

#### Dependencies

To enable this parameter, set **Model parameterization** to `Tabulated data – loss coefficient vs. Reynolds number`.

**Extrapolation method** — Select the extrapolation method  
Linear (default) | Nearest

Select one of the following extrapolation methods for determining the output value when the input value is outside the range specified in the argument list:

- **Linear** — Select this option to produce a curve with continuous first-order derivatives in the extrapolation region and at the boundary with the interpolation region.
- **Nearest** — Select this option to produce an extrapolation that does not go above the highest point in the data or below the lowest point in the data.

For more information on extrapolation algorithms, see PS Lookup Table (1D).

#### Dependencies

To enable this parameter, set **Model parameterization** to `Tabulated data – loss coefficient vs. Reynolds number`.

## Version History

### Introduced in R2006b

### R2023a: To be removed

*Not recommended starting in R2023a*

The Hydraulics (Isothermal) library will be removed in a future release. Use the Isothermal Liquid library instead.

# Heat Exchanger (G)

Heat exchanger for systems with gas and controlled flows

## Libraries:

Simscape / Fluids / Fluid Network Interfaces / Heat Exchangers

## Description

The Heat Exchanger (G) block models heat exchange between a gas, which flows between ports **A1** and **B1**, and an external, *controlled* fluid via a physical signal. The physical signal ports **C2** and **HC2** are exposed when heat exchange is calculated according to the E-NTU model. The physical signal ports **CP2** and **M2** are exposed when heat exchange is calculated according to the Simple model.

You can set the E-NTU or Simple block variant by using the **Modeling option** parameter to set your preferred heat exchange model.

## The E-NTU Model

The default variant. Its heat transfer model derives from the Effectiveness-NTU method. Heat transfer in the steady state then proceeds at a fraction of the ideal rate which the flows, if kept each at its inlet temperature, and if cleared of every thermal resistance in between, could in theory support:

$$Q_{\text{Act}} = \epsilon Q_{\text{Max}}$$

where  $Q_{\text{Act}}$  the actual heat transfer rate,  $Q_{\text{Max}}$  is the ideal heat transfer rate, and  $\epsilon$  is the fraction of the ideal rate actually observed in a real heat exchanger encumbered with losses. The fraction is the heat exchanger effectiveness, and it is a function of the number of transfer units, or NTU, a measure of the ease with which heat moves between flows, relative to the ease with which the flows absorb that heat:

$$NTU = \frac{1}{RC_{\text{Min}}}$$

where the fraction is the overall thermal conductance between the flows and  $C_{\text{Min}}$  is the smallest of the heat capacity rates from among the flows—that belonging to the flow least capable of absorbing

heat. The heat capacity rate of a flow depends on the specific heat of the fluid ( $c_p$ ) and on its mass flow rate through the exchanger ( $\dot{m}$ ):

$$C = c_p \dot{m}.$$

The effectiveness depends also on the relative disposition of the flows, the number of passes between them, and the mixing condition for each. This dependence reflects in the effectiveness expression used, with different flow arrangements corresponding to different expressions. For a list of the effectiveness expressions, see the E-NTU Heat Transfer block.

### Flow Arrangement

Use the **Flow arrangement** block parameter to set how the flows meet in the heat exchanger. The flows can run parallel to each other, counter to each other, or across each other. They can also run in a pressurized shell, one through tubes enclosed in the shell, the other around those same tubes. The figure shows an example. The tube flow can make one pass through the shell flow (shown right) or, for greater exchanger effectiveness, multiple passes (left).

Other flow arrangements are possible through a generic parameterization based on tabulated effectiveness data and requiring little detail about the heat exchanger. Flow arrangement, mixing condition, and number of shell or tube passes, if relevant to the heat exchanger, are assumed to manifest in the tabulated data.

### Mixing Condition

Use the **Cross flow type** parameter to mix each of the flows, one of the flows, or none of the flows. Mixing in this context is the lateral movement of fluid in channels that have no internal barriers, normally guides, baffles, fins, or walls. Such movement serves to even out temperature variations in the transverse plane. Mixed flows have variable temperature in the longitudinal plane alone. Unmixed flows have variable temperature in both the transverse and longitudinal planes. The figure shows a mixed flow (i) and an unmixed flow (ii).

The distinction between mixed and unmixed flows is considered only in cross flow arrangements. There, longitudinal temperature variation in one fluid produces transverse temperature variation in the second fluid that mixing can even out. In counter and parallel flow arrangements, longitudinal temperature variation in one fluid produces longitudinal temperature variation in the second fluid and mixing, as it is of little effect here, is ignored.

#### Effectiveness Curves

Shell-and-tube exchangers with multiple passes (**iv.b-e** in the figure for 2, 3, and 4 passes) are most effective. Of exchangers with a single pass, those with counter flows (**ii**) are most effective and those with parallel flows (**i**) are least.

Cross-flow exchangers are intermediate in effectiveness, with mixing condition playing a factor. They are most effective when both flows are unmixed (**iii.a**) and least effective when both flows are mixed (**iii.b**). Mixing just the flow with the smallest heat capacity rate (**iii.c**) lowers the effectiveness more than mixing just the flow with the largest heat capacity rate (**iii.d**).

**Thermal Resistance**

The overall thermal resistance,  $R$ , is the sum of the local resistances lining the heat transfer path. The local resistances arise from convection at the surfaces of the wall, conduction through the wall, and, if the wall sides are fouled, conduction through the layers of fouling. Expressed in order from the gas side (subscript 1) to the controlled fluid side (subscript 2):

$$R = \frac{1}{U_1 A_{Th,1}} + \frac{F_1}{A_{Th,1}} + R_{Wall} + \frac{F_2}{A_{Th,2}} + \frac{1}{U_2 A_{Th,2}}$$

where  $U$  is the convective heat transfer coefficient,  $F$  is the fouling factor, and  $A_{Th}$  is the heat transfer surface area, each for the flow indicated in the subscript.  $R_W$  is the thermal resistance of the wall.

The wall thermal resistance and fouling factors are simple constants obtained from block parameters. The heat transfer coefficients are elaborate functions of fluid properties, flow geometry, and wall friction, and derive from standard empirical correlations between Reynolds, Nusselt, and Prandtl

numbers. The correlations depend on flow arrangement and mixing condition, and are detailed for each in the E-NTU Heat Transfer block on which the E-NTU Model variant is based.

### Composite Structure

The E-NTU Model variant is a composite component built from simpler blocks. A Heat Exchanger Interface (G) block models the gas flow. Physical signals for the heat capacity rate and heat transfer coefficient, along with a thermal port for temperature, capture the controlled flow. An E-NTU Heat Transfer block models the heat exchanged across the wall between the flows. The figure shows the block connections for the E-NTU Model block variant.

### The Simple Model

The alternative variant. Its heat transfer model depends on the concept of *specific dissipation*, a measure of the heat transfer rate observed when gas and controlled fluid inlet temperatures differ by one degree. Its product with the inlet temperature difference gives the expected heat transfer rate:

$$Q = \xi(T_{In,1} - T_{In,2}),$$

where  $\xi$  is specific dissipation and  $T_{In}$  is inlet temperature for gas (subscript 1) or controlled fluid (subscript 2). The specific dissipation is a tabulated function of the mass flow rates into the exchanger through the gas and controlled fluid inlets:

$$\xi = f(\dot{m}_1, \dot{m}_2)$$

To accommodate reverse flows, the tabulated data can extend over positive and negative flow rates, in which case the inlets can also be thought of as outlets. The data normally derives from measurement of heat transfer rate against temperature in a real prototype:

$$\xi = \frac{Q}{T_{In,1} - T_{In,2}}$$

The heat transfer model, as it relies almost entirely on tabulated data, and as that data normally derives from experiment, requires little detail about the exchanger. Flow arrangement, mixing condition, and number of shell or tube passes, if relevant to the heat exchanger modeled, are assumed to manifest entirely in the tabulated data.

### Composite Structure

The Simple Model variant is a composite component. A Simple Heat Exchanger Interface (G) block models the gas flow. Physical signals for the heat transfer coefficient and mass flow rate, along with a thermal port for temperature, capture the controlled flow. A Specific Dissipation Heat Transfer block models the heat exchanged across the wall between the flows.

## Ports

### Conserving

**A1** — Gas port  
gas

Opening for gas to enter and exit its side of the heat exchanger.

**B1** — Gas port  
gas

Opening for gas to enter and exit its side of the heat exchanger.

### Input

**C2** — Heat capacity rate  
physical signal

Instantaneous value of the heat capacity rate for the controlled flow.

### Dependencies

This port is active only for the block variant of E-NTU Model.

**HC2** — Heat transfer coefficient  
physical signal

Instantaneous value of the heat transfer coefficient between the controlled flow and the wall.

### Dependencies

This port is active only for the block variant of E-NTU Model.

**CP2** — Isobaric specific heat of controlled fluid  
physical signal

Instantaneous value of the isobaric specific heat for the controlled fluid.

### Dependencies

This port is active only for the block variant of Simple Model.

**M2** — Mass flow rate of controlled fluid  
physical signal

Instantaneous value of the mass flow rate of the controlled fluid.

## Dependencies

This port is active only for the block variant of Simple Model.

## Parameters

**Modeling option** — Heat transfer model  
E-NTU Model | Simple model

Set the heat transfer model for the block.

### Block Variant: Simple Model

#### Heat Transfer Tab

**Gas mass flow rate vector** — Mass flow rate of gas at each breakpoint in lookup table for specific heat dissipation table  
numerical array with units of mass over time

Mass flow rate of gas at each breakpoint in the lookup table for the specific heat dissipation table. The block inter- and extrapolates the breakpoints to obtain the specific heat dissipation of the heat exchanger at any mass flow rate. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The mass flow rates can be positive, zero, or negative, but they must increase monotonically from left to right. Their number must equal the number of columns in the **Specific heat dissipation table** parameter. If the table has  $m$  rows and  $n$  columns, the mass flow rate vector must be  $n$  elements long.

**Controlled fluid mass flow rate vector** — Mass flow rate of controlled fluid at each breakpoint in lookup table for specific heat dissipation table  
numerical array with units of mass over time

Mass flow rate of controlled fluid at each breakpoint in the lookup table for the specific heat dissipation table. The block inter- and extrapolates the breakpoints to obtain the specific heat dissipation of the heat exchanger at any mass flow rate. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The mass flow rates can be positive, zero, or negative, but they must increase monotonically from left to right. Their number must equal the number of columns in the **Specific heat dissipation table** parameter. If the table has  $m$  rows and  $n$  columns, the mass flow rate vector must be  $n$  elements long.

**Specific heat dissipation table** — Specific heat dissipation at each breakpoint in lookup table over mass flow rates of gas and controlled fluid  
numerical array with units of power over temperature

Specific heat dissipation at each breakpoint in its lookup table over the mass flow rates of gas and controlled fluid. The block inter- and extrapolates the breakpoints to obtain the effectiveness at any pair of gas and controlled fluid mass flow rates. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The specific heat dissipation values must be not be negative. They must align from top to bottom in order of increasing mass flow rate in the gas channel, and from left to right in order of increasing mass flow rate in the controlled fluid channel. The number of rows must equal the size of the **Gas mass flow rate vector** parameter, and the number of columns must equal the size of the **Controlled fluid mass flow rate vector** parameter.

**Check if violating maximum specific dissipation** — Warning condition for specific heat dissipation in excess of minimum heat capacity rate

Warning (default) | None

Warning condition for specific heat dissipation in excess of minimum heat capacity rate. Heat capacity rate is the product of mass flow rate and specific heat, and its minimum value is the lowest between the flows. This minimum gives the specific dissipation for a heat exchanger with maximum effectiveness and cannot be exceeded. See the Specific Dissipation Heat Transfer block for more detail.

#### **Pressure Loss Tab**

**Mass flow rate vector** — Mass flow rate at each breakpoint in lookup table for pressure drop  
numerical array with units of mass per unit time

Mass flow rate at each breakpoint in the lookup table for the pressure drop. The block inter- and extrapolates the breakpoints to obtain the pressure drop at any mass flow rate. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The mass flow rates can be positive, zero, or negative and they can span across laminar, transient, and turbulent zones. They must, however, increase monotonically from left to right. Their number must equal the size of the **Pressure drop vector** parameter, with which they are to combine to complete the tabulated breakpoints.

**Pressure drop vector** — Pressure drop at each breakpoint in lookup table over mass flow rate  
numerical array with units of pressure

Pressure drop at each breakpoint in its lookup table over the mass flow rate. The block inter- and extrapolates the breakpoints to obtain the pressure drop at any mass flow rate. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The pressure drops can be positive, zero, or negative, and they can span across laminar, transient, and turbulent zones. They must, however, increase monotonically from left to right. Their number must equal the size of the **Mass flow rate vector** parameter, with which they are to combine to complete the tabulated breakpoints.

**Reference inflow temperature** — Absolute inlet temperature assumed in tabulated data  
293.15 K (default) | scalar with units of temperature

Absolute temperature established at the inlet in the gathering of the tabulated pressure drops. The reference inflow temperature and pressure determine the fluid density assumed in the tabulated data. During simulation, the ratio of reference to actual fluid densities multiplies the tabulated pressure drop to obtain the actual pressure drop.

**Reference inflow pressure** — Absolute inlet pressure assumed in tabulated data  
0.101325 MPa (default) | scalar with units of pressure

Absolute pressure established at the inlet in the gathering of the tabulated pressure drops. The reference inflow temperature and pressure determine the fluid density assumed in the tabulated data. During simulation, the ratio of reference to actual fluid densities multiplies the tabulated pressure drop to obtain the actual pressure drop.

**Mass flow rate threshold for flow reversal** — Upper bound of numerically smooth region for mass flow rate

1e-3 kg/s (default) | scalar with units of mass/time

Mass flow rate below which its value is numerically smoothed to avoid discontinuities known to produce simulation errors at zero flow. See the Simple Heat Exchanger Interface (G) block (on which the Simple Model variant is based) for detail on the calculations for the gas side of the exchanger.

**Gas volume** — Volume of fluid in the gas flow channel  
`0.01 m^3 (default) | scalar with units of length cubed`

Volume of fluid in the gas flow channel.

**Cross-sectional area at ports A1 and B1** — Flow area at the inlet and outlet of the flow channel  
`0.01 m^2 (default) | scalar with units of length squared`

Flow area at the inlet and outlet of the gas flow channel. The ports are of the same size.

### Block Variant: E-NTU Model

#### Common Tab

**Flow arrangement** — Manner in which the flows align in the heat exchanger  
`Parallel or counter flow (default) | Shell and tube | Cross flow | Generic - effectiveness table`

Manner in which the flows align in the heat exchanger. The flows can run parallel to each other, counter to each other, or across each other. They can also run in a pressurized shell, one through tubes enclosed in the shell, the other around those tubes. Other flow arrangements are possible through a generic parameterization based on tabulated effectiveness data and requiring little detail about the heat exchanger.

**Number of shell passes** — Number of times the flow traverses the shell before exiting  
`1 (default) | unitless scalar`

Number of times the flow traverses the shell before exiting.

#### Dependencies

This parameter applies solely to the **Flow arrangement** setting of Shell and tube.

**Cross flow type** — Mixing condition in each of the flow channels  
`Both fluids mixed (default) | Both fluids unmixed | Gas mixed & Controlled Fluid unmixed | Gas unmixed & Controlled Fluid mixed`

Mixing condition in each of the flow channels. Mixing in this context is the lateral movement of fluid as it proceeds along its flow channel toward the outlet. The flows remain separate from each other. Unmixed flows are common in channels with plates, baffles, or fins. This setting reflects in the effectiveness of the heat exchanger, with unmixed flows being most effective and mixed flows being least.

#### Dependencies

This parameter applies solely to the **Flow arrangement** setting of Shell and tube.

**Number of heat transfer units vector, NTU** — Number of transfer units at each breakpoint in lookup table for heat exchanger effectiveness  
`unitless numerical array`

Number of transfer units at each breakpoint in the lookup table for the heat exchanger effectiveness number. The table is two-way, with both the number of transfer units and the thermal capacity ratio

serving as independent coordinates. The block inter- and extrapolates the breakpoints to obtain the effectiveness at any number of transfer units. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The numbers specified must be greater than zero and increase monotonically from left to right. The size of the vector must equal the number of rows in the **Effectiveness table** parameter. If the table has  $m$  rows and  $n$  columns, the vector for the number of transfer units must be  $m$  elements long.

#### Dependencies

This parameter applies solely to the **Flow arrangement** setting of `Generic - effectiveness table`.

**Thermal capacity ratio vector, CR** — Thermal capacity ratio at each breakpoint in lookup table for heat exchanger effectiveness  
unitless numerical array

Thermal capacity ratio at each breakpoint in lookup table for heat exchanger effectiveness. The table is two-way, with both the number of transfer units and the heat capacity rate ratio serving as independent coordinates. The block inter- and extrapolates the breakpoints to obtain the effectiveness at any thermal capacity ratio. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The thermal capacity ratios must be greater than zero and increase monotonically from left to right. The size of the vector must equal the number of columns in the **Nusselt number table** parameter. If the table has  $m$  rows and  $n$  columns, the vector for the thermal capacity ratio must be  $n$  elements long. The thermal capacity ratio is the fraction of minimum over maximum heat capacity rates.

#### Dependencies

This parameter applies solely to the **Flow arrangement** setting of `Generic - effectiveness table`.

**Effectiveness table, E(NTU,CR)** — Heat exchanger effectiveness at each breakpoint in lookup table over the number of transfer units and thermal capacity ratio  
unitless numerical array

Heat exchanger effectiveness at each breakpoint in its lookup table over the number of transfer units and thermal capacity ratio. The block inter- and extrapolates the breakpoints to obtain the effectiveness at any pair of number of transfer units and thermal capacity ratio. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The effectiveness values must be not be negative. They must align from top to bottom in order of increasing number of transfer units and from left to right in order of increasing thermal capacity ratio. The number of rows must equal the size of the **Number of heat transfer units vector** parameter, and the number of columns must equal the size of the **Thermal capacity ratio vector** parameter.

#### Dependencies

This parameter applies solely to the **Flow arrangement** setting of `Generic - effectiveness table`.

**Wall thermal resistance** — Resistance of the wall to heat flow by thermal conduction  
 $1.6e-4$  K/W (default) | scalar with units of temperature over power

Resistance of the wall to heat flow by thermal conduction, and the inverse of thermal conductance, or the product of thermal conductivity with the ratio of surface area to length. Wall resistance adds to convective and fouling resistances to determine the overall heat transfer coefficient between the flows.

### Gas Tab

**Minimum free-flow area** — Cross-sectional area of the flow channel at its narrowest point  
 $0.01 \text{ m}^2$  (default) | scalar with units of length squared

Cross-sectional area of the flow channel at its narrowest point. If the channel is a collection of ducts, tubes, slots, or grooves, the area is the sum of the areas in the collection—minus the occlusion due to walls, ridges, plates, or other barriers.

**Gas volume** — Total volume of fluid in the gas flow channel  
 $0.01 \text{ m}^3$  (default) | scalar with units of length squared

Total volume of fluid contained in the gas flow channel.

**Hydraulic diameter for pressure loss** — Effective diameter of the flow channel at its narrowest point  
 $0.1 \text{ m}$  (default) | scalar with units of length

Effective inner diameter of the flow at its narrowest point. For channels not circular in cross section, that diameter is of an imaginary circle equal in area to the flow cross section. Its value is the ratio of the minimum free-flow area to a fourth of its gross perimeter.

If the channel is a collection of ducts, tubes, slots, or grooves, the gross perimeter is the sum of the perimeters in the collection. If the channel is a single pipe or tube and it is circular in cross section, the hydraulic diameter is the same as the true diameter.

**Laminar flow upper Reynolds number limit** — Start of transition between laminar and turbulent zones  
 $2000$  (default) | unitless scalar

Start of transition between laminar and turbulent zones. Above this number, inertial forces take hold and the flow grows progressively turbulent. The default value is characteristic of circular pipes and tubes with smooth surfaces.

**Turbulent flow lower Reynolds number limit** — End of transition between laminar and turbulent zones  
 $4000$  (default) | unitless scalar

End of transition between laminar and turbulent zones. Below this number, viscous forces take hold and the flow grows progressively laminar. The default value is characteristic of circular pipes and tubes with smooth surfaces.

**Pressure loss parameterization** — Mathematical model for pressure loss by viscous friction  
 constant loss coefficient (default) | correlations for tubes | Tabulated data - Darcy friction factor vs. Reynolds number | Tabulated data - Euler number vs. Reynolds number

Mathematical model for pressure loss by viscous friction. This setting determines which expressions to use for calculation and which block parameters to specify as input. See the Heat Exchanger Interface (G) block for the calculations by parameterization.

**Pressure loss coefficient** — Aggregate loss coefficient for all flow resistances between the ports  
0.1 (default) | unitless scalar

Aggregate loss coefficient for all flow resistances in the flow channel—including the wall friction responsible for major loss and the local resistances, due to bends, elbows, and other geometry changes, responsible for minor loss.

The loss coefficient is an empirical dimensionless number commonly used to express the pressure loss due to viscous friction. It can be calculated from experimental data or, in some cases, obtained from product data sheets.

#### **Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of Constant loss coefficient.

**Length of flow path from inlet to outlet** — Distance traveled from port to port  
1 m (default) | unitless scalar with units of length

Total distance the flow must travel to reach across the ports. In multi-pass shell-and-tube exchangers, the total distance is the sum over all shell passes. In tube bundles, corrugated plates, and other channels in which the flow is split into parallel branches, it is the distance covered in a single branch. The longer the flow path, the steeper the major pressure loss due to viscous friction at the wall.

#### **Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of Correlations for tubes and Tabulated data - Darcy friction factor vs Reynolds number.

**Aggregate equivalent length of local resistances** — Aggregate minor pressure loss expressed as a length  
0.1 m (default) | scalar with units of length

Aggregate minor pressure loss expressed as a length. This length is that which all local resistances, such as elbows, tees, and unions, would add to the flow path if in their place was a simple wall extension. The larger the equivalent length, the steeper the minor pressure loss due to the local resistances.

#### **Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of Correlations for tubes.

**Internal surface absolute roughness** — Mean height of surface protrusions behind wall friction  
15e-6 m (default) | scalar with units of length

Mean height of the surface protrusions from which wall friction arises. Higher protrusions mean a rougher wall for more friction and so a steeper pressure loss. Surface roughness features in the Haaland correlation from which the Darcy friction factor derives and on which the pressure loss calculation depends.

#### **Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of Correlations for tubes.

**Laminar friction constant for Darcy friction factor** — Pressure loss correction for flow cross section in laminar flow conditions

64 (default) | unitless scalar

Pressure loss correction for flow cross section in laminar flow conditions. This parameter is commonly referred to as the shape factor. Its ratio to the Reynolds number gives the Darcy friction factor for the pressure loss calculation in the laminar zone. The default value belongs to cylindrical pipes and tubes.

The shape factor derives for certain shapes from the solution of the Navier-Stokes equations. A square duct has a shape factor of 56, a rectangular duct with aspect ratio of 2:1 has a shape factor of 62, and an annular tube has a shape factor of 96, as does a slender conduit between parallel plates.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of Correlations for tubes.

**Reynolds number vector for Darcy friction factor** — Reynolds number at each breakpoint in lookup table for Darcy friction factor

unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Darcy friction factor. The block interpolates the breakpoints to obtain the Darcy friction factor at any Reynolds number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. Their number must equal the size of the **Darcy friction factor vector** parameter, with which they are to combine to complete the tabulated breakpoints.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of Tabulated data - Darcy friction factor vs. Reynolds number.

**Darcy friction factor vector** — Darcy friction factor at each breakpoint in lookup table over Reynolds number

unitless numerical array

Darcy friction factor at each breakpoint in its lookup table over the Reynolds number. The block interpolates the breakpoints to obtain the Darcy friction factor at any Reynolds number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Darcy friction factors must not be negative and they must align from left to right in order of increasing Reynolds number. Their number must equal the size of the **Reynolds number vector for Darcy friction factor** parameter, with which they are to combine to complete the tabulated breakpoints.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of Tabulated data - Darcy friction factor vs. Reynolds number.

**Reynolds number vector for Euler number** — Reynolds number at each breakpoint in lookup table for Euler number

unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Euler number. The block inter- and extrapolates the breakpoints to obtain the Euler number at any Reynolds number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. Their number must equal the size of the **Euler number vector** parameter, with which they are to combine to complete the tabulated breakpoints.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of `Tabulated data - Euler number vs. Reynolds number`.

**Euler number vector** — Euler number at each breakpoint in lookup table over Reynolds number

unitless numerical array

Euler number at each breakpoint in its lookup table over the Reynolds number. The block inter- and extrapolates the breakpoints to obtain the Euler number at any Reynolds number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Euler numbers must not be negative and they must align from left to right in order of increasing Reynolds number. Their number must equal the size of the **Reynolds number vector for Euler number** parameter, with which they are to combine to complete the tabulated breakpoints.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of `Tabulated data - Euler number vs. Reynolds number`.

**Heat transfer parameterization** — Mathematical model for heat transfer between fluid and wall  
Constant heat transfer coefficient (default) | Correlations for tubes | Tabulated data - Colburn factor vs. Reynolds number | Tabulated data - Nusselt number vs. Reynolds number & Prandtl number

Mathematical model for heat transfer between fluid and wall. The choice of model determines which expressions to apply and which parameters to specify for heat transfer calculation. See the E-NTU Heat Transfer block for the calculations by parameterization.

**Heat transfer surface area** — Effective surface area used in heat transfer between fluid and wall

0.4 m<sup>2</sup> (default) | scalar with units of length squared

Effective surface area used in heat transfer between fluid and wall. The effective surface area is the sum of primary and secondary surface areas, or those of the wall, where it is exposed to fluid, and of the fins, if any are used. Fin surface area is normally scaled by a fin efficiency factor.

**Gas-wall heat transfer coefficient** — Heat transfer coefficient for convection between fluid and wall

0.4 m<sup>2</sup> (default) | unitless scalar

Heat transfer coefficient for convection between fluid and wall. Resistance due to fouling is captured separately in the **Fouling factor** parameter.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Constant heat transfer coefficient.

**Length of flow path for heat transfer** — Characteristic length traversed in heat transfer between fluid and wall

1 m (default) | scalar with units of length

Characteristic length traversed in heat transfer between fluid and wall. This length factors in the calculation of the hydraulic diameter from which the heat transfer coefficient and the Reynolds number, as defined in the tabulated heat transfer parameterizations, derives.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Colburn factor vs. Reynolds number or Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Nusselt number for laminar flow heat transfer** — Constant assumed for Nusselt number in laminar flow

3.66 (default) | positive unitless scalar

Constant assumed for Nusselt number in laminar flow. The Nusselt number factors in the calculation of the heat transfer coefficient between fluid and wall, on which the heat transfer rate depends. The default value belongs to cylindrical pipes and tubes.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Correlations for tubes.

**Reynolds number vector for Colburn factor** — Values of the Reynolds number at which to specify the Colburn factor data

unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Colburn factor. The block inter- and extrapolates the breakpoints to obtain the Colburn factor at any Reynolds number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. Their number must equal the size of the **Colburn factor vector** parameter, with which they are to combine to complete the tabulated breakpoints.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Colburn factor vs. Reynolds number.

**Colburn factor vector** — Colburn factor at each breakpoint in lookup table over Reynolds number

unitless numerical array

Colburn factor at each breakpoint in its lookup table over the Reynolds number. The block inter- and extrapolates the breakpoints to obtain the Euler number at any Reynolds number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Colburn factors must not be negative and they must align from left to right in order of increasing Reynolds number. Their number must equal the size of the **Reynolds number vector for Colburn factor** parameter, with which they are to combine to complete the tabulated breakpoints.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Colburn factor vs. Reynolds number.

**Reynolds number vector for Nusselt number** — Reynolds number at each breakpoint in lookup table for Nusselt number

unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Nusselt number. The table is two-way, with both Reynolds and Prandtl numbers serving as independent coordinates. The block inter- and extrapolates the breakpoints to obtain the Nusselt number at any Reynolds number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. The size of the vector must equal the number of rows in the **Nusselt number table** parameter. If the table has  $m$  rows and  $n$  columns, the Reynolds number vector must be  $m$  elements long.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Prandtl number vector for Nusselt number** — Prandtl number at each breakpoint in lookup table for Nusselt number

unitless numerical array

Prandtl number at each breakpoint in the lookup table for the Nusselt number. The table is two-way, with both Reynolds and Prandtl numbers serving as independent coordinates. The block inter- and extrapolates the breakpoints to obtain the Nusselt number at any Prandtl number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Prandtl numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. The size of the vector must equal the number of columns in the **Nusselt number table** parameter. If the table has  $m$  rows and  $n$  columns, the Prandtl number vector must be  $n$  elements long.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Nusselt number table, Nu (Re,Pr)** — Nusselt number at each breakpoint in lookup table over Reynolds and Prandtl numbers

unitless numerical array

Nusselt number at each breakpoint in its lookup table over the Reynolds and Prandtl numbers. The block inter- and extrapolates the breakpoints to obtain the Nusselt number at any pair of Reynolds and Prandtl numbers. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`. By determining the Nusselt number, the table feeds the calculation from which the heat transfer coefficient between fluid and wall derives.

The Nusselt numbers must be greater than zero. They must align from top to bottom in order of increasing Reynolds number and from left to right in order of increasing Prandtl numbers. The number of rows must equal the size of the **Reynolds number vector for Nusselt number** parameter, and the number of columns must equal the size of the **Prandtl number vector for Nusselt number** parameter.

### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Fouling factor** — Measure of thermal resistance due to fouling deposits

1.6e-4 K/W (default) | scalar with units of temperature over power

Measure of thermal resistance due to fouling deposits which over time tend to build on the exposed surfaces of the wall. The deposits, as they impose between the fluid and wall a new solid layer through which heat must traverse, add to the heat transfer path an extra thermal resistance. Fouling deposits grow slowly and the resistance due to them is accordingly assumed constant during simulation.

**Minimum fluid-wall heat transfer coefficient** — Lower bound for the heat transfer coefficient

100 W/(m<sup>2</sup> \* K) (default) | scalar with units of power/area/temperature

Lower bound for the heat transfer coefficient between fluid and wall. If calculation returns a lower heat transfer coefficient, this bound replaces the calculated value.

### Controlled Fluid Tab

**Heat transfer surface area** — Aggregate heat transfer surface area on the controlled fluid side

0.4 m<sup>2</sup> (default) | scalar with units of length squared

Aggregate heat transfer surface area on the controlled fluid side

**Fouling factor** — Measure of thermal resistance due to fouling deposits

1e-4 K/W (default) | scalar with units of length squared times temperature over power

Measure of thermal resistance due to fouling deposits which over time tend to build on the exposed surfaces of the wall. The deposits, as they impose between the controlled fluid and wall a new solid layer through which heat must traverse, add to the heat transfer path an extra thermal resistance. Fouling deposits grow slowly and the resistance due to them is accordingly assumed constant during simulation.

**Minimum fluid-wall heat transfer coefficient** — Lower bound for the heat transfer coefficient

100 W/(m<sup>2</sup> \* K) (default) | scalar with units of power/area/temperature

Lower bound for the heat transfer coefficient between the controlled fluid and wall. If calculation returns a lower heat transfer coefficient, this bound replaces the calculated value.

### Effects and Initial Conditions

**Gas initial temperature** — Temperature in the gas channel at the start of simulation

293.15 K (default) | scalar with units of temperature

Temperature in the gas channel at the start of simulation.

**Gas initial pressure** — Pressure in the gas channel at the start of simulation  
0.101325 MPa (default) | scalar with units of pressure

Pressure in the gas channel at the start of simulation.

# Heat Exchanger (G-G)

Heat exchanger for systems with two gas flows

## Libraries:

Simscape / Fluids / Fluid Network Interfaces / Heat Exchangers

## Description

The Heat Exchanger (G-G) block models a gas-gas heat exchanger. The wall can store heat in its bounds, adding to the heat transfer a slight transient delay that scales in proportion to its thermal mass. The fluids are single phase—each a gas. Neither fluid can switch phase and so, as latent heat is never released, the exchange is strictly one of sensible heat.

## Block Variants

The heat transfer model depends on the choice of block variant. The block has two variants: E-NTU Model and Simple Model. Use the **Modeling option** parameter to change the variant.

### E-NTU Model

The default variant. Its heat transfer model derives from the Effectiveness-NTU method. Heat transfer in the steady state then proceeds at a fraction of the ideal rate which the flows, if kept each at its inlet temperature, and if cleared of every thermal resistance in between, could in theory support:

$$Q_{\text{Act}} = \epsilon Q_{\text{Max}}$$

where  $Q_{\text{Act}}$  the actual heat transfer rate,  $Q_{\text{Max}}$  is the ideal heat transfer rate, and  $\epsilon$  is the fraction of the ideal rate actually observed in a real heat exchanger encumbered with losses. The fraction is the heat exchanger effectiveness, and it is a function of the number of transfer units, or NTU, a measure of the ease with which heat moves between flows, relative to the ease with which the flows absorb that heat:

$$NTU = \frac{1}{RC_{\text{Min}}}$$

where the fraction is the overall thermal conductance between the flows and  $C_{\text{Min}}$  is the smallest of the heat capacity rates from among the flows—that belonging to the flow least capable of absorbing heat. The heat capacity rate of a flow depends on the specific heat of the fluid ( $c_p$ ) and on its mass flow rate through the exchanger ( $\dot{m}$ ):

$$C = c_p \dot{m}.$$

The effectiveness depends also on the relative disposition of the flows, the number of passes between them, and the mixing condition for each. This dependence reflects in the effectiveness expression used, with different flow arrangements corresponding to different expressions. For a list of the effectiveness expressions, see the E-NTU Heat Transfer block.

### Flow Arrangement

Use the **Flow arrangement** block parameter to set how the flows meet in the heat exchanger. The flows can run parallel to each other, counter to each other, or across each other. They can also run in a pressurized shell, one through tubes enclosed in the shell, the other around those same tubes. The figure shows an example. The tube flow can make one pass through the shell flow (shown right) or, for greater exchanger effectiveness, multiple passes (left).

Other flow arrangements are possible through a generic parameterization based on tabulated effectiveness data and requiring little detail about the heat exchanger. Flow arrangement, mixing condition, and number of shell or tube passes, if relevant to the heat exchanger, are assumed to manifest in the tabulated data.

### Mixing Condition

Use the **Cross flow type** parameter to mix each of the flows, one of the flows, or none of the flows. Mixing in this context is the lateral movement of fluid in channels that have no internal barriers, normally guides, baffles, fins, or walls. Such movement serves to even out temperature variations in the transverse plane. Mixed flows have variable temperature in the longitudinal plane alone. Unmixed flows have variable temperature in both the transverse and longitudinal planes. The figure shows a mixed flow (i) and an unmixed flow (ii).

The distinction between mixed and unmixed flows is considered only in cross flow arrangements. There, longitudinal temperature variation in one fluid produces transverse temperature variation in the second fluid that mixing can even out. In counter and parallel flow arrangements, longitudinal temperature variation in one fluid produces longitudinal temperature variation in the second fluid and mixing, as it is of little effect here, is ignored.

#### Effectiveness Curves

Shell-and-tube exchangers with multiple passes (**iv.b-e** in the figure for 2, 3, and 4 passes) are most effective. Of exchangers with a single pass, those with counter flows (**ii**) are most effective and those with parallel flows (**i**) are least.

Cross-flow exchangers are intermediate in effectiveness, with mixing condition playing a factor. They are most effective when both flows are unmixed (**iii.a**) and least effective when both flows are mixed (**iii.b**). Mixing just the flow with the smallest heat capacity rate (**iii.c**) lowers the effectiveness more than mixing just the flow with the largest heat capacity rate (**iii.d**).

**Thermal Resistance**

The overall thermal resistance,  $R$ , is the sum of the local resistances lining the heat transfer path. The local resistances arise from convection at the surfaces of the wall, conduction through the wall, and, if the wall sides are fouled, conduction through the layers of fouling. Expressed in order from gas side 1 to gas side 2:

$$R = \frac{1}{U_1 A_{Th,1}} + \frac{F_1}{A_{Th,1}} + R_{Wall} + \frac{F_2}{A_{Th,2}} + \frac{1}{U_2 A_{Th,2}}$$

where  $U$  is the convective heat transfer coefficient,  $F$  is the fouling factor, and  $A_{Th}$  is the heat transfer surface area, each for the flow indicated in the subscript.  $R_W$  is the thermal resistance of the wall.

The wall thermal resistance and fouling factors are simple constants obtained from block parameters. The heat transfer coefficients are elaborate functions of fluid properties, flow geometry, and wall friction, and derive from standard empirical correlations between Reynolds, Nusselt, and Prandtl

numbers. The correlations depend on flow arrangement and mixing condition, and are detailed for each in the E-NTU Heat Transfer block on which the E-NTU Model variant is based.

### Thermal Mass

The wall is more than a thermal resistance for heat to pass through. It is also a thermal mass and, like the flows it divides, it can store heat in its bounds. The storage slows the transition between steady states so that a thermal perturbation on one side does not promptly manifest on the side across. The lag persists for the short time that it takes the heat flow rates from the two sides to balance each other. That time interval scales with the thermal mass of the wall:

$$C_{Q,W} = c_{p,W}M_W,$$

where  $c_{p,W}$  is the specific heat capacity and  $M_W$  the inertial mass of the wall. Their product gives the energy required to raise wall temperature by one degree. Use the **Wall thermal mass** block parameter to specify that product. The parameter is active when the **Wall thermal dynamics** setting is **On**.

Thermal mass is often negligible in low-pressure systems. Low pressure affords a thin wall with a transient response so fast that, on the time scale of the heat transfer, it is virtually instantaneous. The same is not true of high-pressure systems, common in the production of ammonia by the Haber process, where pressure can break 200 atmospheres. To withstand the high pressure, the wall is often thicker, and, as its thermal mass is heftier, so its transient response is slower.

Set the **Wall thermal dynamics** parameter to **Off** to ignore the transient lag, cut the differential variables that produce it, and, in reducing calculations, speed up the rate of simulation. Leave it **On** to capture the transient lag where it has a measurable effect. Experiment with the setting if necessary to determine whether to account for thermal mass. If simulation results differ to a considerable degree, and if simulation speed is not a factor, keep the setting **On**.

The wall, if modeled with thermal mass, is considered in halves. One half sits on gas side 1 and the other half sits on gas side 2. The thermal mass divides evenly between the pair:

$$C_{Q,1} = C_{Q,2} = \frac{C_{Q,W}}{2}.$$

Energy is conserved in the wall. In the simple case of a wall half at steady state, heat gained from the fluid equals heat lost to the second half. The heat flows at the rate predicted by the E-NTU method for a wall without thermal mass. The rate is positive for heat flows directed from side 1 of the heat exchanger to side 2:

$$Q_1 = -Q_2 = \epsilon Q_{\text{Max}}.$$

In the transient state, the wall is in the course of storing or losing heat, and heat gained by one half no longer equals that lost to the second half. The difference in the heat flow rates varies over time in proportion to the rate at which the wall stores or loses heat. For side 1 of the heat exchanger:

$$Q_1 = \epsilon Q_{\text{Max}} + C_{Q,1}\dot{T}_{W,1},$$

where  $\dot{T}_{W,1}$  is the rate of change in temperature in the wall half. Its product with the thermal mass of the wall half gives the rate at which heat accumulates there. That rate is positive when temperature rises and negative when it drops. The closer the rate is to zero the closer the wall is to steady state.

For side 2 of the heat exchanger:  $Q_2 = -\epsilon Q_{\text{Max}} + C_{Q,2}\dot{T}_{W,2}$ ,

### Composite Structure

The E-NTU Model variant is a composite component built from simpler blocks. A Heat Exchanger Interface (G) block models the gas flow on side 1 of the heat exchanger. Another models the gas flow on side 2. An E-NTU Heat Transfer block models the heat exchanged across the wall between the flows. The figure shows the block connections for the E-NTU Model block variant.

### Simple Model

The alternative variant. Its heat transfer model depends on the concept of *specific dissipation*, a measure of the heat transfer rate observed when gas 1 and gas 2 inlet temperatures differ by one degree. Its product with the inlet temperature difference gives the expected heat transfer rate:

$$Q = \xi(T_{In,1} - T_{In,2}),$$

where  $\xi$  is specific dissipation and  $T_{In}$  is inlet temperature for gas 1 (subscript 1) or gas 2 (subscript 2). The specific dissipation is a tabulated function of the mass flow rates into the exchanger through the gas 1 and gas 2 inlets:

$$\xi = f(\dot{m}_1, \dot{m}_2)$$

To accommodate reverse flows, the tabulated data can extend over positive and negative flow rates, in which case the inlets can also be thought of as outlets. The data normally derives from measurement of heat transfer rate against temperature in a real prototype:

$$\xi = \frac{Q}{T_{In,1} - T_{In,2}}$$

The heat transfer model, as it relies almost entirely on tabulated data, and as that data normally derives from experiment, requires little detail about the exchanger. Flow arrangement, mixing condition, and number of shell or tube passes, if relevant to the heat exchanger modeled, are assumed to manifest entirely in the tabulated data.

See the Specific Dissipation Heat Transfer block for more detail on the heat transfer calculations.

### Composite Structure

The Simple Model variant is a composite component. A Simple Heat Exchanger Interface (G) block models the gas flow on side 1 of the heat exchanger. Another models the gas flow on side 2. A Specific Dissipation Heat Transfer block captures the heat exchanged across the wall between the flows.

## Ports

### Conserving

**A1** — Gas 1 port  
gas

Opening for gas 1 to enter and exit its side of the heat exchanger.

**B1** — Gas 1 port  
gas

Opening for gas 1 to enter and exit its side of the heat exchanger.

**A2** — Gas 2 port  
gas

Opening for gas 2 to enter and exit its side of the heat exchanger.

**B2** — Gas 2 port  
gas

Opening for gas 2 to enter and exit its side of the heat exchanger.

## Parameters

**Modeling option** — Heat transfer model  
E-NTU Model | Simple model

Set the heat transfer model for the block.

### Block Variant: Simple Model

#### Heat Transfer Tab

**Gas 1 mass flow rate vector** — Mass flow rate of gas 1 at each breakpoint in lookup table for specific heat dissipation table  
numerical array with units of mass over time

Mass flow rate of gas 1 at each breakpoint in the lookup table for the specific heat dissipation table. The block inter- and extrapolates the breakpoints to obtain the specific heat dissipation of the heat exchanger at any mass flow rate. Interpolation is the MATLAB linear type and extrapolation is nearest.

The mass flow rates can be positive, zero, or negative, but they must increase monotonically from left to right. Their number must equal the number of columns in the **Specific heat dissipation table** parameter. If the table has  $m$  rows and  $n$  columns, the mass flow rate vector must be  $n$  elements long.

**Gas 2 mass flow rate vector** — Mass flow rate of gas 2 at each breakpoint in lookup table for specific heat dissipation table  
numerical array with units of mass over time

Mass flow rate of gas 2 at each breakpoint in the lookup table for the specific heat dissipation table. The block inter- and extrapolates the breakpoints to obtain the specific heat dissipation of the heat exchanger at any mass flow rate. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The mass flow rates can be positive, zero, or negative, but they must increase monotonically from left to right. Their number must equal the number of columns in the **Specific heat dissipation table** parameter. If the table has  $m$  rows and  $n$  columns, the mass flow rate vector must be  $n$  elements long.

**Specific heat dissipation table** — Specific heat dissipation at each breakpoint in lookup table over mass flow rates of gas 1 and gas 2  
numerical array with units of power over temperature

Specific heat dissipation at each breakpoint in its lookup table over the mass flow rates of gas 1 and gas 2. The block inter- and extrapolates the breakpoints to obtain the effectiveness at any pair of gas 1 and gas 2 mass flow rates. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The specific heat dissipation values must not be negative. They must align from top to bottom in order of increasing mass flow rate in the gas 1 channel, and from left to right in order of increasing mass flow rate in the gas 2 channel. The number of rows must equal the size of the **Gas 1 mass flow rate vector** parameter, and the number of columns must equal the size of the **Gas 2 mass flow rate vector** parameter.

**Check if violating maximum specific dissipation** — Warning condition for specific heat dissipation in excess of minimum heat capacity rate  
Warning (default) | None

Warning condition for specific heat dissipation in excess of minimum heat capacity rate. Heat capacity rate is the product of mass flow rate and specific heat, and its minimum value is the lowest between the flows. This minimum gives the specific dissipation for a heat exchanger with maximum effectiveness and cannot be exceeded. See the Specific Dissipation Heat Transfer block for more detail.

### Gas 1|2 Tab

**Mass flow rate vector** — Mass flow rate at each breakpoint in lookup table for pressure drop  
numerical array with units of mass per unit time

Mass flow rate at each breakpoint in the lookup table for the pressure drop. The block inter- and extrapolates the breakpoints to obtain the pressure drop at any mass flow rate. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The mass flow rates can be positive, zero, or negative and they can span across laminar, transient, and turbulent zones. They must, however, increase monotonically from left to right. Their number must equal the size of the **Pressure drop vector** parameter, with which they are to combine to complete the tabulated breakpoints.

**Pressure drop vector** — Pressure drop at each breakpoint in lookup table over mass flow rate  
numerical array with units of pressure

Pressure drop at each breakpoint in its lookup table over the mass flow rate. The block inter- and extrapolates the breakpoints to obtain the pressure drop at any mass flow rate. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The pressure drops can be positive, zero, or negative, and they can span across laminar, transient, and turbulent zones. They must, however, increase monotonically from left to right. Their number must equal the size of the **Mass flow rate vector** parameter, with which they are to combine to complete the tabulated breakpoints.

**Reference inflow temperature** — Absolute inlet temperature assumed in tabulated data  
293.15 K (default) | scalar with units of temperature

Absolute temperature established at the inlet in the gathering of the tabulated pressure drops. The reference inflow temperature and pressure determine the fluid density assumed in the tabulated data. During simulation, the ratio of reference to actual fluid densities multiplies the tabulated pressure drop to obtain the actual pressure drop.

**Reference inflow pressure** — Absolute inlet pressure assumed in tabulated data  
0.101325 MPa (default) | scalar with units of pressure

Absolute pressure established at the inlet in the gathering of the tabulated pressure drops. The reference inflow temperature and pressure determine the fluid density assumed in the tabulated data. During simulation, the ratio of reference to actual fluid densities multiplies the tabulated pressure drop to obtain the actual pressure drop.

**Threshold mass flow rate for flow reversal** — Upper bound of numerically smooth region for mass flow rate  
1e-3 kg/s (default) | scalar with units of mass/time

Mass flow rate below which its value is numerically smoothed to avoid discontinuities known to produce simulation errors at zero flow. See the Simple Heat Exchanger Interface (G) block (on which the Simple Model variant is based) for detail on the calculations.

**Fluid volume** — Volume of fluid in the gas 1 or gas 2 flow channel  
0.01 m<sup>3</sup> (default) | scalar with units of length cubed

Volume of fluid in the gas 1 or gas 2 flow channel.

**Cross-sectional area at ports A and B** — Flow area at the inlet and outlet of the flow channel  
0.01 m<sup>2</sup> (default) | scalar with units of length squared

Flow area at the inlet and outlet of the gas 1 or gas 2 flow channel. Ports in the same flow channel are of the same size.

### Block Variant: E-NTU Model

#### Common Tab

**Flow arrangement** — Manner in which the flows align in the heat exchanger  
Parallel or counter flow (default) | Shell and tube | Cross flow | Generic - effectiveness table

Manner in which the flows align in the heat exchanger. The flows can run parallel to each other, counter to each other, or across each other. They can also run in a pressurized shell, one through tubes enclosed in the shell, the other around those tubes. Other flow arrangements are possible through a generic parameterization based on tabulated effectiveness data and requiring little detail about the heat exchanger.

**Number of shell passes** — Number of times the flow traverses the shell before exiting  
1 (default) | unitless scalar

Number of times the flow traverses the shell before exiting.

#### **Dependencies**

This parameter applies solely to the **Flow arrangement** setting of Shell and tube.

**Cross flow type** — Mixing condition in each of the flow channels  
Both fluids mixed (default) | Both fluids unmixed | Gas 1 mixed & Gas 2 unmixed | Gas 1 unmixed & Gas 2 mixed

Mixing condition in each of the flow channels. Mixing in this context is the lateral movement of fluid as it proceeds along its flow channel toward the outlet. The flows remain separate from each other. Unmixed flows are common in channels with plates, baffles, or fins. This setting reflects in the effectiveness of the heat exchanger, with unmixed flows being most effective and mixed flows being least.

#### **Dependencies**

This parameter applies solely to the **Flow arrangement** setting of Shell and tube.

**Number of heat transfer units vector, NTU** — Number of transfer units at each breakpoint in lookup table for heat exchanger effectiveness  
unitless numerical array

Number of transfer units at each breakpoint in the lookup table for the heat exchanger effectiveness number. The table is two-way, with both the number of transfer units and the thermal capacity ratio serving as independent coordinates. The block inter- and extrapolates the breakpoints to obtain the effectiveness at any number of transfer units. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The numbers specified must be greater than zero and increase monotonically from left to right. The size of the vector must equal the number of rows in the **Effectiveness table** parameter. If the table has  $m$  rows and  $n$  columns, the vector for the number of transfer units must be  $m$  elements long.

#### **Dependencies**

This parameter applies solely to the **Flow arrangement** setting of Generic - effectiveness table.

**Thermal capacity ratio vector, CR** — Thermal capacity ratio at each breakpoint in lookup table for heat exchanger effectiveness  
unitless numerical array

Thermal capacity ratio at each breakpoint in lookup table for heat exchanger effectiveness. The table is two-way, with both the number of transfer units and the heat capacity rate ratio serving as independent coordinates. The block inter- and extrapolates the breakpoints to obtain the

effectiveness at any thermal capacity ratio. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The thermal capacity ratios must be greater than zero and increase monotonically from left to right. The size of the vector must equal the number of columns in the **Nusselt number table** parameter. If the table has  $m$  rows and  $n$  columns, the vector for the thermal capacity ratio must be  $n$  elements long. The thermal capacity ratio is the fraction of minimum over maximum heat capacity rates.

#### Dependencies

This parameter applies solely to the **Flow arrangement** setting of `Generic - effectiveness table`.

**Effectiveness table, E(NTU,CR)** — Heat exchanger effectiveness at each breakpoint in lookup table over the number of transfer units and thermal capacity ratio  
unitless numerical array

Heat exchanger effectiveness at each breakpoint in its lookup table over the number of transfer units and thermal capacity ratio. The block inter- and extrapolates the breakpoints to obtain the effectiveness at any pair of number of transfer units and thermal capacity ratio. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The effectiveness values must be not be negative. They must align from top to bottom in order of increasing number of transfer units and from left to right in order of increasing thermal capacity ratio. The number of rows must equal the size of the **Number of heat transfer units vector** parameter, and the number of columns must equal the size of the **Thermal capacity ratio vector** parameter.

#### Dependencies

This parameter applies solely to the **Flow arrangement** setting of `Generic - effectiveness table`.

**Wall thermal dynamics** — Modeling assumption for transient response of wall to thermal changes  
`Off` (default) | `On`

Modeling assumption for the transient response of the wall to thermal changes. Set to `On` to impart a thermal mass to the wall and to capture the delay in its transient response to changes in temperature or heat flux. Such delays are relevant in thick walls, such as those required to sustain high pressures. The default setting assumes a wall thin enough for its transient response to be virtually instantaneous on the time scale of the heat transfer.

**Wall thermal mass** — Heat required to raise wall temperature by one degree  
`447 J/K` (default) | scalar with units of energy over temperature

Heat required to raise wall temperature by one degree. Thermal mass is the product of mass with specific heat and a measure of the ability to absorb heat. A wall with thermal mass has a transient response to sudden changes in surface temperature or heat flux. The larger the thermal mass, the slower that response, and the longer the time to steady state. The default value corresponds to a wall of stainless steel with a mass of approximately 1 kg.

#### Dependencies

This parameter applies solely to the **Wall thermal dynamics** setting of `On`.

**Wall thermal resistance** — Resistance of the wall to heat flow by thermal conduction

1.6e-4 K/W (default) | scalar with units of temperature over power

Resistance of the wall to heat flow by thermal conduction, and the inverse of thermal conductance, or the product of thermal conductivity with the ratio of surface area to length. Wall resistance adds to convective and fouling resistances to determine the overall heat transfer coefficient between the flows.

### Gas 1|2 Tab

**Minimum free-flow area** — Cross-sectional area of the flow channel at its narrowest point

0.01 m<sup>2</sup> (default) | scalar with units of length squared

Cross-sectional area of the flow channel at its narrowest point. If the channel is a collection of ducts, tubes, slots, or grooves, the area is the sum of the areas in the collection—minus the occlusion due to walls, ridges, plates, or other barriers.

**Fluid volume** — Total volume of fluid in the gas 1 or gas 2 flow channel

0.01 m<sup>3</sup> (default) | scalar with units of length squared

Total volume of fluid contained in the gas 1 or gas 2 flow channel.

**Hydraulic diameter for pressure loss** — Effective diameter of the flow channel at its narrowest point

0.1 m (default) | scalar with units of length

Effective inner diameter of the flow at its narrowest point. For channels not circular in cross section, that diameter is of an imaginary circle equal in area to the flow cross section. Its value is the ratio of the minimum free-flow area to a fourth of its gross perimeter.

If the channel is a collection of ducts, tubes, slots, or grooves, the gross perimeter is the sum of the perimeters in the collection. If the channel is a single pipe or tube and it is circular in cross section, the hydraulic diameter is the same as the true diameter.

**Laminar flow upper Reynolds number limit** — Start of transition between laminar and turbulent zones

2000 (default) | unitless scalar

Start of transition between laminar and turbulent zones. Above this number, inertial forces take hold and the flow grows progressively turbulent. The default value is characteristic of circular pipes and tubes with smooth surfaces.

**Turbulent flow lower Reynolds number limit** — End of transition between laminar and turbulent zones

4000 (default) | unitless scalar

End of transition between laminar and turbulent zones. Below this number, viscous forces take hold and the flow grows progressively laminar. The default value is characteristic of circular pipes and tubes with smooth surfaces.

**Pressure loss parameterization** — Mathematical model for pressure loss by viscous friction

constant loss coefficient (default) | correlations for tubes | Tabulated data - Darcy friction factor vs. Reynolds number | Tabulated data - Euler number vs. Reynolds number

Mathematical model for pressure loss by viscous friction. This setting determines which expressions to use for calculation and which block parameters to specify as input. See the Heat Exchanger Interface (G) block for the calculations by parameterization.

**Pressure loss coefficient** — Aggregate loss coefficient for all flow resistances between the ports  
0.1 (default) | unitless scalar

Aggregate loss coefficient for all flow resistances in the flow channel—including the wall friction responsible for major loss and the local resistances, due to bends, elbows, and other geometry changes, responsible for minor loss.

The loss coefficient is an empirical dimensionless number commonly used to express the pressure loss due to viscous friction. It can be calculated from experimental data or, in some cases, obtained from product data sheets.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of Constant loss coefficient.

**Length of flow path from inlet to outlet** — Distance traveled from port to port  
1 m (default) | unitless scalar with units of length

Total distance the flow must travel to reach across the ports. In multi-pass shell-and-tube exchangers, the total distance is the sum over all shell passes. In tube bundles, corrugated plates, and other channels in which the flow is split into parallel branches, it is the distance covered in a single branch. The longer the flow path, the steeper the major pressure loss due to viscous friction at the wall.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of Correlations for tubes and Tabulated data - Darcy friction factor vs Reynolds number.

**Aggregate equivalent length of local resistances** — Aggregate minor pressure loss expressed as a length  
0.1 m (default) | scalar with units of length

Aggregate minor pressure loss expressed as a length. This length is that which all local resistances, such as elbows, tees, and unions, would add to the flow path if in their place was a simple wall extension. The larger the equivalent length, the steeper the minor pressure loss due to the local resistances.

#### Dependencies

This parameter applies solely to the **Pressure loss parameterization** setting of Correlations for tubes.

**Internal surface absolute roughness** — Mean height of surface protrusions behind wall friction  
15e-6 m (default) | scalar with units of length

Mean height of the surface protrusions from which wall friction arises. Higher protrusions mean a rougher wall for more friction and so a steeper pressure loss. Surface roughness features in the Haaland correlation from which the Darcy friction factor derives and on which the pressure loss calculation depends.

**Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of **Correlations for tubes**.

**Laminar friction constant for Darcy friction factor** — Pressure loss correction for flow cross section in laminar flow conditions  
64 (default) | unitless scalar

Pressure loss correction for flow cross section in laminar flow conditions. This parameter is commonly referred to as the shape factor. Its ratio to the Reynolds number gives the Darcy friction factor for the pressure loss calculation in the laminar zone. The default value belongs to cylindrical pipes and tubes.

The shape factor derives for certain shapes from the solution of the Navier-Stokes equations. A square duct has a shape factor of 56, a rectangular duct with aspect ratio of 2:1 has a shape factor of 62, and an annular tube has a shape factor of 96, as does a slender conduit between parallel plates.

**Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of **Correlations for tubes**.

**Reynolds number vector for Darcy friction factor** — Reynolds number at each breakpoint in lookup table for Darcy friction factor  
unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Darcy friction factor. The block interpolates and extrapolates the breakpoints to obtain the Darcy friction factor at any Reynolds number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. Their number must equal the size of the **Darcy friction factor vector** parameter, with which they are to combine to complete the tabulated breakpoints.

**Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of **Tabulated data - Darcy friction factor vs. Reynolds number**.

**Darcy friction factor vector** — Darcy friction factor at each breakpoint in lookup table over Reynolds number  
unitless numerical array

Darcy friction factor at each breakpoint in its lookup table over the Reynolds number. The block interpolates and extrapolates the breakpoints to obtain the Darcy friction factor at any Reynolds number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Darcy friction factors must not be negative and they must align from left to right in order of increasing Reynolds number. Their number must equal the size of the **Reynolds number vector for Darcy friction factor** parameter, with which they are to combine to complete the tabulated breakpoints.

**Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of Tabulated data - Darcy friction factor vs. Reynolds number.

**Reynolds number vector for Euler number** — Reynolds number at each breakpoint in lookup table for Euler number  
unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Euler number. The block inter- and extrapolates the breakpoints to obtain the Euler number at any Reynolds number. Interpolation is the MATLAB linear type and extrapolation is nearest.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. Their number must equal the size of the **Euler number vector** parameter, with which they are to combine to complete the tabulated breakpoints.

**Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of Tabulated data - Euler number vs. Reynolds number.

**Euler number vector** — Euler number at each breakpoint in lookup table over Reynolds number  
unitless numerical array

Euler number at each breakpoint in its lookup table over the Reynolds number. The block inter- and extrapolates the breakpoints to obtain the Euler number at any Reynolds number. Interpolation is the MATLAB linear type and extrapolation is nearest.

The Euler numbers must not be negative and they must align from left to right in order of increasing Reynolds number. Their number must equal the size of the **Reynolds number vector for Euler number** parameter, with which they are to combine to complete the tabulated breakpoints.

**Dependencies**

This parameter applies solely to the **Pressure loss parameterization** setting of Tabulated data - Euler number vs. Reynolds number.

**Heat transfer parameterization** — Mathematical model for heat transfer between fluid and wall  
Constant heat transfer coefficient (default) | Correlations for tubes | Tabulated data - Colburn factor vs. Reynolds number | Tabulated data - Nusselt number vs. Reynolds number & Prandtl number

Mathematical model for heat transfer between fluid and wall. The choice of model determines which expressions to apply and which parameters to specify for heat transfer calculation. See the E-NTU Heat Transfer block for the calculations by parameterization.

**Heat transfer surface area** — Effective surface area used in heat transfer between fluid and wall  
0.4 m<sup>2</sup> (default) | scalar with units of length squared

Effective surface area used in heat transfer between fluid and wall. The effective surface area is the sum of primary and secondary surface areas, or those of the wall, where it is exposed to fluid, and of the fins, if any are used. Fin surface area is normally scaled by a fin efficiency factor.

**Gas-wall heat transfer coefficient** — Heat transfer coefficient for convection between fluid and wall  
0.4 m<sup>2</sup> (default) | unitless scalar

Heat transfer coefficient for convection between fluid and wall. Resistance due to fouling is captured separately in the **Fouling factor** parameter.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Constant heat transfer coefficient.

**Length of flow path for heat transfer** — Length of pipe or channel  
1 m (default) | scalar with units of length

Length of the pipe or channel from inlet to outlet.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Colburn factor vs. Reynolds number or Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Nusselt number for laminar flow heat transfer** — Constant assumed for Nusselt number in laminar flow  
3.66 (default) | positive unitless scalar

Constant assumed for Nusselt number in laminar flow. The Nusselt number factors in the calculation of the heat transfer coefficient between fluid and wall, on which the heat transfer rate depends. The default value belongs to cylindrical pipes and tubes.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Correlations for tubes.

**Reynolds number vector for Colburn factor** — Values of the Reynolds number at which to specify the Colburn factor data  
unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Colburn factor. The block inter- and extrapolates the breakpoints to obtain the Colburn factor at any Reynolds number. Interpolation is the MATLAB linear type and extrapolation is nearest.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. Their number must equal the size of the **Colburn factor vector** parameter, with which they are to combine to complete the tabulated breakpoints.

**Dependencies**

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Colburn factor vs. Reynolds number.

**Colburn factor vector** — Colburn factor at each breakpoint in lookup table over Reynolds number  
unitless numerical array

Colburn factor at each breakpoint in its lookup table over the Reynolds number. The block inter- and extrapolates the breakpoints to obtain the Euler number at any Reynolds number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Colburn factors must not be negative and they must align from left to right in order of increasing Reynolds number. Their number must equal the size of the **Reynolds number vector for Colburn factor** parameter, with which they are to combine to complete the tabulated breakpoints.

#### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Colburn factor vs. Reynolds number.

**Reynolds number vector for Nusselt number** — Reynolds number at each breakpoint in lookup table for Nusselt number  
unitless numerical array

Reynolds number at each breakpoint in the lookup table for the Nusselt number. The table is two-way, with both Reynolds and Prandtl numbers serving as independent coordinates. The block inter- and extrapolates the breakpoints to obtain the Nusselt number at any Reynolds number. Interpolation is the MATLAB `linear` type and extrapolation is `nearest`.

The Reynolds numbers must be greater than zero and increase monotonically from left to right. They can span across laminar, transient, and turbulent zones. The size of the vector must equal the number of rows in the **Nusselt number table** parameter. If the table has  $m$  rows and  $n$  columns, the Reynolds number vector must be  $m$  elements long.

#### Dependencies

This parameter applies solely to the **Heat transfer parameterization** setting of Tabulated data - Nusselt number vs. Reynolds number & Prandtl number.

**Prandtl number vector for Nusselt number** — Prandtl number at each breakpoint in lookup table for Nusselt number  
unitless numerical array
