You can specify the following modifiers in parentheses after the specified criterion to alter the behavior of the `SELECT=` option:

GLOBAL	specifies that a global minimum be found within the range of smoothing parameter values examined. This modifier has no effect if you also specify the <code>SMOOTH=</code> option in the MODEL statement.
STEPS	specifies that all models evaluated in the selection process be displayed.
RANGE(<i>lower,upper</i>)	specifies that only smoothing parameter values greater than or equal to <i>lower</i> and less than or equal to <i>upper</i> be examined.

For models with one dependent variable, if you specify neither the `SELECT=` nor the `SMOOTH=` options in the MODEL statement, then PROC LOESS uses `SELECT=AICC`.

The following table summarizes how the smoothing parameter values are chosen for various combinations of the `SMOOTH=` option, the `SELECT=` option, and the `SELECT=` option modifiers.

Table 41.2. Smoothing Parameter Value(s) Used for Combinations of `SMOOTH=` and `SELECT=` OPTIONS for Models with One Dependent Variable

Syntax	Search Method	Search Domain
<i>default</i>	golden section using AICC	(0, 1]
<code>SMOOTH=list</code>	no selection	values in <i>list</i>
<code>SMOOTH=list SELECT=criterion</code>	global	values in <i>list</i>
<code>SMOOTH=list SELECT=criterion (RANGE(<i>l,u</i>))</code>	global	values in <i>list</i> within [<i>l,u</i>]
<code>SELECT=criterion</code>	golden section	(0, 1]
<code>SELECT=criterion (RANGE(<i>l,u</i>))</code>	golden section	[<i>l,u</i>]
<code>SELECT=criterion (GLOBAL)</code>	global	(0, 1]
<code>SELECT=criterion (GLOBAL RANGE(<i>l,u</i>))</code>	global	[<i>l,u</i>]

Some examples of using the SELECT= option are

SELECT=GCV	specifies selection using the GCV <i>criterion</i> .
SELECT=DF1(6.3)	specifies selection using the DF1 <i>DFCriterion</i> with target value 6.3.
SELECT=AICC(STEPS)	specifies selection using the AICC <i>criterion</i> showing all step details.
SELECT=DF2(7 GLOBAL)	specifies selection using the DF2 <i>DFCriterion</i> with target value 7 using a global search algorithm.

Note: The SELECT= option cannot be used for models with more than one dependent variable.

SMOOTH=value-list

specifies a list of positive smoothing parameter values. If you do not SELECT= option in the MODEL statement, then a separate fit is obtained for each SMOOTH= value specified. If you do specify the SELECT= option, then models with all values specified in the SMOOTH= list are examined, and PROC LOESS selects the value that minimizes the criterion specified in the SELECT= option.

For models with two or more dependent variables, if the SMOOTH= option is not specified in the MODEL statement, then SMOOTH=0.5 is used as a default.

STD

specifies that standardized errors are to be included in the “Output Statistics” table.

T

specifies that *t* statistics are to be included in the “Output Statistics” table.

TRACEL

specifies that the trace of the prediction matrix as well as the GCV and AICC statistics are to be included in the “FIT Summary” table. The use of any of the MODEL statement options ALL, CLM, DFMETHOD=EXACT, DIRECT, SELECT=, or T implicitly selects the TRACEL option.

SCORE Statement

SCORE <DATA=SAS-data-set> <ID=(variable list) > </options > ;

The fitted loess model is used to score the data in the specified SAS data set. This data set must contain all the regressor variables specified in the MODEL statement. Furthermore, when a BY statement is used, the score data set must also contain all the BY variables sorted in the order of the BY variables. A SCORE statement is optional, and more than one SCORE statement can be used. SCORE statements cannot be used if the DIRECT option is specified in the MODEL statement. The optional ID=(variable list) specifies ID variables to be included in the “Score Results” table.

You find the results of the SCORE statement in the “Score Results” table. This table contains all the data in the data set named in the SCORE statement, including observations with missing values. However, only those observations with nonmissing regressor variables are scored. If no data set is named in the SCORE statement, the data set named in the PROC LOESS statement is scored. You use the PRINT option in the SCORE statement to request that the “Score Results” table be displayed. You can place the “Score Results” table in an output data set using an ODS OUTPUT statement even if this table is not displayed.

The following options are available in the SCORE statement after a slash (/).

CLM

requests that $100(1 - \alpha)$ confidence limits on the mean predicted value be added to the “Score Results” table. By default the 95% limits are computed; the ALPHA= option in the MODEL statement can be used to change the α -level. The use of this option implicitly selects the model option DFMETHOD=EXACT if the DFMETHOD= option has not been explicitly used.

PRINT < (variables) >

specifies that the “Score Results” table is to be displayed. By default only the variables named in the MODEL statement, the variables listed in the ID list in the SCORE statement, and the scored dependent variables are displayed. The optional list in the PRINT option specifies additional variables in the score data set that are to be included in the displayed output. Note however that all columns in the SCORE data set are placed in the SCORE results table, even if you do not request that they be included in the displayed output.

SCALEDINDEP

specifies that scaled regressor coordinates be included in the SCORE results table. This option is ignored if the SCALE= model option is not used or if SCALE=NONE is specified.

STEPS

requests that all models evaluated during smoothing parameter value selection be scored, provided that the SELECT= option together with the STEPS modifier is specified in the MODEL statement. By default only the selected model is scored.

WEIGHT Statement

WEIGHT *variable* ;

The WEIGHT statement specifies a variable in the input data set that contains values to be used as a priori weights for a loess fit.

The values of the weight variable must be nonnegative. If an observation’s weight is zero, negative, or missing, the observation is deleted from the analysis.

Details

Missing Values

PROC LOESS deletes any observation with missing values for any variable specified in the MODEL statement. This enables the procedure to reuse the kd tree for all the dependent variables that appear in the MODEL statement. If you have multiple dependent variables with different missing value structures for the same set of independent variables, you may want to use separate PROC LOESS steps for each dependent variable.

Output Data Sets

PROC LOESS assigns a name to each table it creates. You can use the ODS OUTPUT statement to place one or more of these tables in output data sets. See the section “[ODS Table Names](#)” on page 2248 for a list of the table names created by PROC LOESS. For detailed information on ODS, see [Chapter 14, “Using the Output Delivery System.”](#)

For example, the following statements create an output data set named MyOutStats containing the OutputStatistics table and an output data set named MySummary containing the FitSummary table.

```
proc loess data=Melanoma;
  model Incidences=Year;
  ods output OutputStatistics = MyOutStats
             FitSummary       = MySummary;
run;
```

Often, a single MODEL statement describes more than one model. For example, the following statements fit eight different models (4 smoothing parameter values for each dependent variable).

```
proc loess data=notReal;
  model y1 y2 = x1 x2 x3/smooth =0.1 to 0.7 by 0.2;
  ods output OutputStatistics = MyOutStats;
run;
```

The eight OutputStatistics tables for these models are stacked in a single data set called MyOutStats. The data set contains a column named DepVarName and a column named SmoothingParameter that distinguish each model (see [Figure 41.4](#) on page 2224 for an example). If you want the OutputStatistics table for each model to be in its own data set, you can do so by using the MATCH_ALL option in the ODS OUTPUT statement. The following statements create eight data sets named MyOutStats, MyOutStats1, ..., MyOutStats7.

```
proc loess data=notReal;
  model y1 y2 = x1 x2 x3/smooth =0.1 to 0.7 by 0.2;
  ods output OutputStatistics(match_all) = MyOutStats;
run;
```

For further options available in the ODS OUTPUT statement, see [Chapter 14, “Using the Output Delivery System.”](#)

Only the ScaleDetails and FitSummary tables are displayed by default. The other tables are optionally displayed by using the DETAILS option in the MODEL statement and the PRINT option in the SCORE statement. Note that it is not necessary to display a table in order for that table to be used in an ODS OUTPUT statement. For example, the following statements display the OutputStatistics and kdTree tables but place the OutputStatistics and PredAtVertices tables in output data sets.

```
proc loess data=Melanoma;
  model Incidences=Year/details(OutputStatistics kdTree);
  ods output OutputStatistics = MyOutStats
             PredAtVertices   = MyVerticesOut;
run;
```

Using the DETAILS option alone causes all tables to be displayed.

The MODEL statement options CLM, RESIDUAL, STD, SCALEDINDEP, and T control which optional columns are added to the OutputStatistics table. For example, to obtain an OutputStatistics output data set containing residuals and confidence limits in addition to the model variables and predicted value, you need to specify the RESIDUAL and CLM options in the MODEL statement as in the following example:

```
proc loess data=Melanoma;
  model Incidences=Year/residual clm;
  ods output OutputStatistics = MyOutStats;
run;
```

Finally, note that the ALL option in the MODEL statement includes all optional columns in the output. Also, ID columns can be added to the OutputStatistics table by using the ID statement.

Data Scaling

The loess algorithm to obtain a predicted value at a given point in the predictor space proceeds by doing a least squares fit using all data points that are close to the given point. Thus the algorithm depends critically on the metric used to define closeness. This has the consequence that if you have more than one predictor variable and these predictor variables have significantly different scales, then closeness depends almost entirely on the variable with the largest scaling. It also means that merely changing the units of one of your predictors can significantly change the loess model fit.

To circumvent this problem, it is necessary to standardize the scale of the independent variables in the loess model. The SCALE= option in the MODEL statement is provided for this purpose. PROC LOESS uses a symmetrically trimmed standard deviation as the scale estimate for each independent variable of the loess model. This is a robust scale estimator in that extreme values of a variable are discarded before

estimating the data scaling. For example, to compute a 10% trimmed standard deviation of a sample, you discard the smallest and largest 5% of the data and compute the standard deviation of the remaining 90% of the data points. In this case, the trimming fraction is 0.1.

For example, the following statements specify that the variables `Temperature` and `Catalyst` are scaled before performing the loess fitting. In this case, because the trimming fraction is 0.1, the scale estimate used for each of these variables is a 10% trimmed standard deviation.

```
model Yield=Temperature Catalyst / scale = SD(0.1);
```

The default trimming fraction used by PROC LOESS is 0.1 and need not be specified by the `SCALE=` option. Thus the following MODEL statement is equivalent to the previous MODEL statement.

```
model Yield=Temperature Catalyst / scale = SD;
```

If the `SCALE=` option is not specified, no scaling of the independent variables is done. This is appropriate when there is only a single independent variable or when all the independent variables are a priori scaled similarly.

When the `SCALE=` option is specified, the scaling details for each independent variable are added to the `ScaleDetails` table (see [Output 41.3.2](#) on page 2265 for an example). By default, this table contains only the minimum and maximum values of each independent variable in the model. Finally, note that when the `SCALE=` option is used, specifying the `SCALEDINDEP` option in the MODEL statement adds the scaled values of the independent variables to the `OutputStatistics` and `PredAtVertices` tables. If the `SCALEDINDEP` option is specified in the SCORE statement then scaled values of the independent variables are included in the `ScoreResults` table. By default, only the unscaled values are placed in these tables.

Direct versus Interpolated Fitting

Local regression to obtain a predicted value at a given point in the predictor space is done by doing a least squares fit using all data points in a local neighborhood of the given point. This method is computationally expensive because a local neighborhood must be determined and a least squares problem solved for each point at which a fitted value is required. A faster method is to obtain such fits at a representative sample of points in the predictor space and to obtain fitted values at all other points by interpolation.

PROC LOESS can fit models using either of these two paradigms. By default, PROC LOESS uses fitting at a sample of points and interpolation. The method fitting a local model at every data point is selected by specifying the `DIRECT` option in the MODEL statement.

kd Trees and Blending

PROC LOESS uses a kd tree to divide the box (also called the *initial cell* or *bucket*) enclosing all the predictor data points into rectangular cells. The vertices of these cells are the points at which local least squares fitting is done.

Starting from the initial cell, the direction of the longest cell edge is selected as the split direction. The median of this coordinate of the data in the cell is the split value. The data in the starting cell are partitioned into two child cells. The left child consists of all data from the parent cell whose coordinate in the split direction is less than the split value. The above procedure is repeated for each child cell that has more than a prespecified number of points, called the *bucket size* of the kd tree.

You can specify the bucket size with the BUCKET= option in the MODEL statement. If you do not specify the BUCKET= option, the default value used is the largest integer less than or equal to $ns/5$, where n is the number of observations and s is the value of the smoothing parameter. Note that if fitting is being done for a range of smoothing parameter values, the bucket size may change for each value.

The set of vertices of all the cells of the kd tree are the points at which PROC LOESS performs its local fitting. The fitted value at an original data point (or at any other point within the original data cell) is obtained by blending the fitted values at the vertices of the kd tree cell that contains that data point.

The univariate blending methods available in PROC LOESS are linear and cubic polynomial interpolation, with linear interpolation being the default. You can request cubic interpolation by specifying the INTERP=CUBIC option in the MODEL statement. In this case, PROC LOESS uses the unique cubic polynomial whose values and first derivatives match those of the fitted local polynomials evaluated at the two endpoints of the kd tree cell edge.

In the multivariate case, such univariate interpolating polynomials are computed on each edge of the kd-tree cells, and are combined using blending functions (Gordon 1971). In the case of two regressors, if you specify INTERP=CUBIC in the MODEL statement, PROC LOESS uses Hermite cubic polynomials as blending functions. If you do not specify INTERP=CUBIC, or if you specify a model with more than two regressors, then PROC LOESS uses linear polynomials as blending functions. In these cases, the blending method reduces to tensor product interpolation from the 2^p vertices of each kd tree cell, where p is the number of regressors.

While the details of the kd tree and the fitted values at the vertices of the kd tree are implementation details that seldom need to be examined, PROC LOESS does provide options for their display. Each kd tree subdivision of the data used by PROC LOESS is placed in the “kdTree” table. The predicted values at the vertices of each kd tree are placed in the “PredAtVertices” table. You can request these tables using the DETAILS option in the MODEL statement.

Local Weighting

The size of the local neighborhoods that PROC LOESS uses in performing local fitting is determined by the smoothing parameter value s . When $s < 1$, the local neighborhood used at a point x contains the s fraction of the data points closest to the point x . When $s \geq 1$, all data points are used.

Suppose q denotes the number of points in the local neighborhoods and d_1, d_2, \dots, d_q denote the distances in increasing order of the q points closest to x . The point at distance d_i from x is given a weight w_i in the local regression that decreases as the distance from x increases. PROC LOESS uses a tricube weight function to define

$$w_i = \frac{32}{5} \left(1 - \left(\frac{d_i}{d_q} \right)^3 \right)^3$$

If $s > 1$, then d_q is replaced by $d_q s^{1/p}$ in the previous formula, where p is the number of predictors in the model.

Finally, note that if a weight variable has been specified using a WEIGHT statement, then w_i is multiplied by the corresponding value of the specified weight variable.

Iterative Reweighting

PROC LOESS can do iterative reweighting to improve the robustness of the fit in the presence of outliers in the data. Iterative reweighting is also appropriate when statistical inference is requested and the error distribution is symmetric but not Gaussian.

The number of iterations is specified by the ITERATIONS= option in the MODEL statement. The default is ITERATIONS=1, which corresponds to no reweighting.

At iterations beyond the first iteration, the local weights w_i of the previous section are replaced by $r_i w_i$ where r_i is a weight that decreases as the residual of the fitted value at the previous iteration at the point corresponding to d_i increases. Refer to Cleveland and Grosse (1991) and Cleveland, Grosse, and Shyu (1992) for details.

Specifying the Local Polynomials

PROC LOESS uses linear or quadratic polynomials in doing the local least squares fitting. The option DEGREE = in the MODEL statement is used to specify the degree of the local polynomials used by PROC LOESS, with DEGREE = 1 being the default. In addition, when DEGREE = 2 is specified, the MODEL statement DROPSQUARE= option can be used to exclude specific monomials during the least squares fitting.

For example, the following statements use the monomials 1, x1, x2, x1*x2, and x2*x2 for the local least squares fitting.

```
proc loess data=notReal;
  model y= x1 x2/ degree=2 dropsquare=(x1);
run;
```

Statistical Inference

If you denote the i th measurement of the response by y_i and the corresponding measurement of predictors by x_i , then

$$y_i = g(x_i) + \epsilon_i$$

where g is the regression function and ϵ_i are independent random errors with mean zero. If the errors are normally distributed with constant variance, then you can obtain confidence intervals for the predictions from PROC LOESS. You can also obtain confidence limits in the case where ϵ_i is heteroscedastic but $a_i\epsilon_i$ has constant variance and a_i are a priori weights that are specified using the WEIGHT statement of PROC LOESS. You can do inference in the case in which the error distribution is symmetric by using iterative reweighting.

Formulae for doing statistical inference under the preceding conditions can be found in Cleveland and Grosse (1991) and Cleveland, Grosse, and Shyu (1992). The main result of their analysis is that a standardized residual for a loess model follows a t distribution with ρ degrees of freedom, where ρ is called the “lookup degrees of freedom.” ρ is a function of the smoothing matrix L , which defines the linear relationship between the fitted and observed dependent variable values of a loess model.

The determination of ρ is computationally expensive and is not done by default. It is computed if you specify the DFMETHOD=EXACT or DFMETHOD=APPROX option in the MODEL statement. It is also computed if you specify any of the options CLM, STD, or T in the MODEL statement.

If you specify the CLM option in the MODEL statement, confidence limits are added to the OutputStatistics table. By default, 95% limits are computed, but you can change this by using the ALPHA= option in the MODEL statement.

Automatic Smoothing Parameter Selection

There are several methodologies for automatic smoothing parameter selection. One class of methods chooses the smoothing parameter value to minimize a criterion that incorporates both the tightness of the fit and model complexity. Such a criterion can usually be written as a function of the error mean square, $\hat{\sigma}^2$, and a penalty function designed to decrease with increasing smoothness of the fit. This penalty function is usually defined in terms of the matrix L such that

$$\hat{y} = Ly$$

where y is the vector of observed values and \hat{y} is the corresponding vector of predicted values of the dependent variable. Examples of specific criteria are generalized cross-validation (Craven and Wahba 1979) and the Akaike information criterion (Akaike 1973). These classical selectors have two undesirable properties when used with local polynomial and kernel estimators: they tend to undersmooth and tend to be non-robust in the sense that small variations of the input data can change the choice

of smoothing parameter value significantly. Hurvich, Simonoff, and Tsai (1998) obtained several bias-corrected AIC criteria that limit these unfavorable properties and perform comparably with the *plug-in selectors* (Ruppert, Sheather, and Wand 1995). PROC LOESS provides automatic smoothing parameter selection using two of these bias-corrected AIC criteria, named AIC_{C_1} and AIC_C in Hurvich, Simonoff, and Tsai (1998), and generalized cross-validation, denoted by the acronym GCV.

The relevant formulae are

$$\begin{aligned} AIC_{C_1} &= n \log(\hat{\sigma}^2) + n \frac{\delta_1/\delta_2(n + \nu_1)}{\delta_1^2/\delta_2 - 2} \\ AIC_C &= \log(\hat{\sigma}^2) + 1 + \frac{2(\text{Trace}(L) + 1)}{n - \text{Trace}(L) - 2} \\ GCV &= \frac{n\hat{\sigma}^2}{(n - \text{Trace}(L))^2} \end{aligned}$$

where n is the number of observations and

$$\begin{aligned} \delta_1 &\equiv \text{Trace}(I - L)^T(I - L) \\ \delta_2 &\equiv \text{Trace}((I - L)^T(I - L))^2 \\ \nu_1 &\equiv \text{Equivalent Number of Parameters} \\ &\equiv \text{Trace}(L^T L) \end{aligned}$$

Note that the values of δ_1 , δ_2 , and the “Equivalent Number of Parameters” are reported in the “Fit Summary” table.

You invoke these methods for automatic smoothing parameter selection by specifying the `SELECT=criterion` option in the MODEL statement, where *criterion* is one of AICC1, AICC, or GCV. PROC LOESS evaluates the specified criterion for a sequence of smoothing parameter values and selects the value in this sequence that minimizes the specified criterion. If multiple values yield the optimum, then the largest of these values is selected.

A second class of methods seeks to set an approximate measure of model degrees of freedom to a specified target value. These methods are useful for making meaningful comparisons between loess fits and other nonparametric and parametric fits. The approximate model degrees of freedom in a nonparametric fit is a number that is analogous to the number of free parameters in a parametric model. There are three commonly used measures of model degrees of freedom in nonparametric models. These criteria are $\text{Trace}(L)$, $\text{Trace}(L^T L)$, and $2\text{Trace}L - \text{Trace}(L^T L)$. A discussion of their properties can be found in Hastie and Tibshirani (1990). You invoke these

methods by specifying the `SELECT=DFCriterion(target)` option in the MODEL statement, where *DFCriterion* is one of DF1, DF2, or DF3. The criterion that is minimized is given in the following table:

Table 41.3. Minimization Criteria for Degree of Freedom Based Smoothing Parameter Value Selection

Syntax	Minimization Criterion
<code>SELECT=DF1(target)</code>	$ \text{Trace}(L) - \text{target} $
<code>SELECT=DF2(target)</code>	$ \text{Trace}(L^T L) - \text{target} $
<code>SELECT=DF3(target)</code>	$ 2\text{Trace}(L) - \text{Trace}(L^T L) - \text{target} $

The results are summarized in the “Smoothing Criterion” table. This table is displayed whenever automatic smoothing parameter selection is performed. You can obtain details of the sequence of models examined by specifying the `DETAILS(MODELSUMMARY)` option in the model statement to display the “Model Summary” table.

There are several ways in which you can control the sequence of models examined by PROC LOESS. If you specify the `SMOOTH=value-list` option in the MODEL statement, then only the values in this list are examined in performing the selection. For example, the following statements select the model that minimizes the AICC1 criterion among the three models with smoothing parameter values 0.1, 0.3, and 0.4:

```
proc loess data=notReal;
  model y= x1/ smooth=0.1 0.3 0.4 select=AICC1;
run;
```

If you do not specify the `SMOOTH=` option in the model statement, then by default PROC LOESS uses a golden section search method to find a local minimum of the specified criterion in the range (0, 1]. You can use the `RANGE(lower,upper)` modifier in the `SELECT=` option to change the interval in which the golden section search is performed. For example, the following statements request a golden section search to find a local minimizer of the GCV criterion for smoothing parameter values in the interval [0.1,0.5]:

```
proc loess data=notReal;
  model y= x1/select=GCV( range(0.1,0.5) );
run;
```

If you want to be sure of obtaining a global minimum in the range of smoothing parameter values examined, you can specify the `GLOBAL` modifier in the `SELECT=` option. For example, the following statements request that a global minimizer of the AICC criterion be obtained for smoothing parameter values in the interval [0.2, 0.8]:

```
proc loess data=notReal;
  model y= x1/select=AICC( global range(0.2,0.8) );
run;
```

Note that even though the smoothing parameter is a continuous variable, a given range of smoothing parameter values corresponds to a finite set of local models. For example, for a data set with 100 observations, the range $[0.2, 0.4]$ corresponds to models with 20, 21, 22, . . . , 40 points in the local neighborhoods. If the GLOBAL modifier is specified, all possible models in the range are evaluated sequentially.

Note that by default PROC LOESS displays a “Fit Summary” and other optionally requested tables only for the selected model. You can request that these tables be displayed for all models in the selection process by adding the STEPS modifier in the SELECT= option. Also note that by default scoring requested with SCORE statements is done only for the selected model. However, if you specify the STEPS in both the MODEL and SCORE statements, then all models evaluated in the selection process are scored.

In terms of computation, AIC_C , GCV , and DF1 depend on the smoothing matrix L only through its trace. In the direct method, this trace can be computed efficiently. In the interpolated method using kd trees, there is some additional computational cost but the overall work is not significant compared to the rest of the computation. In contrast, the quantities δ_1 , δ_2 , and ν_1 , which appear in the AIC_{C_1} criterion, and the DF2 and DF3 criteria, depend on the entire L matrix and for this reason, the time needed to compute these quantities dominates the time required for the model fitting. Hence SELECT=AICC1, SELECT=DF2, and SELECT=DF3 are much more computationally expensive than SELECT=AICC, SELECT=GCV, and SELECT=DF1, especially when combined with the GLOBAL modifier. Hurvich, Simonoff, and Tsai (1998) note that AIC_C can be regarded as an approximation of AIC_{C_1} and that “the AIC_C selector generally performs well in all circumstances.”

For models with one dependent variable, PROC LOESS uses SELECT=AICC as its default, if you specify neither the SMOOTH= nor SELECT= options in the MODEL statement. With two or more dependent variables, automatic smoothing parameter selection needs to be done separately for each dependent variable. For this reason automatic smoothing parameter selection is not available for models with multiple dependent variables. In such cases you should use a separate PROC LOESS step for each dependent variable, if you want to use automatic smoothing parameter selection.

Sparse and Approximate Degrees of Freedom Computation

As noted in the “Statistical Inference” section on page 2243, obtaining confidence limits in loess models requires the computation of the “lookup degrees of freedom.” This in turn requires the computation of

$$\delta_2 \equiv \text{Trace} \left((I - L)^T (I - L) \right)^2$$

where L is the LOESS smoothing matrix (see the “Automatic Smoothing Parameter Selection” section on page 2243).

The work in a direct implementation of this formula grows as n^3 , where n is the number of observations in analysis. For large n , this work dominates the time needed to fit the loess model itself. To alleviate this computational bottleneck, Cleveland

and Grosse (1991) and Cleveland, Grosse, and Shyu (1992) developed approximate methods for estimating this quantity in terms of more readily computable statistics. A different approach to obtaining a computationally cheap estimate of δ_2 has been implemented in PROC LOESS.

For large data sets with significant local structure, the LOESS model is often used with small values of the smoothing parameter. Recalling that the smoothing parameter defines the fraction of the data used in each local regression, this means that the loess fit at any point in regressor space depends on only a small fraction of the data. This is reflected in the smoothing matrix L whose (i, j) th entry is nonzero only if the i th and j th observations lie in at least one common local neighborhood. Hence the smoothing matrix is a sparse matrix (has mostly zero entries) in such cases. By exploiting this sparsity PROC LOESS now computes δ_2 orders of magnitude faster than in previous implementations.

When each local neighborhood contains a large subset of the data, i.e., when the smoothing parameter is large, then it is no longer true that the smoothing matrix is sparse. However, since a point in a local neighborhood is given a local weight that decreases with its distance from the center of the neighborhood, many of the coefficients in the smoothing matrix turn out to be nonzero but with orders of magnitude smaller than that of the larger coefficients in the matrix. The approximate method for computing δ_2 that has been implemented in PROC LOESS exploits these disparities in magnitudes of the elements in the smoothing matrix by setting the small elements to zero. This creates a sparse approximation of the smoothing matrix to which the fast sparse methods can be applied.

In order to decide the threshold at which elements in the smoothing matrix are set to zero, PROC LOESS samples the elements in the smoothing matrix to obtain the value of the element in a specified lower quantile in this sample. The magnitude of the element at this quantile is used as a cutoff value, and all elements in the smoothing matrix whose magnitude is less than this cutoff are set to zero for the approximate computation. By default all elements in the lower 90th percentile are set to zero. You can use the `DFMETHOD=APPROX(QUANTILE=)` option in the MODEL statement to change this value. As you increase the value for the quantile to be zeroed, you speed up the degrees of freedom computation at the expense of increasing approximation errors. You can also use the `DFMETHOD=APPROX(CUTOFF=)` option in the MODEL statement to specify the cutoff value directly.

For small data sets, the approximate computation is not needed and would be rougher than for larger data sets. Hence PROC LOESS performs the exact computation for analyses with less than 500 points, even if `DFMETHOD=APPROX` is specified in the model statement. Also, for small values of the smoothing parameter, elements in the lower specified quantile may already all be zero. In such cases the approximate method is the same as the exact method. PROC LOESS labels as approximate any statistics that depend on the approximate computation of δ_2 only in the cases where the approximate computation was used and is different from the exact computation.

Scoring Data Sets

One or more SCORE statements can be used with PROC LOESS. A data set that includes all the variables specified in the MODEL and BY statements must be specified in each SCORE statement. Score results are placed in the ScoreResults table. This table is not displayed by default, but specifying the PRINT option in the SCORE statement produces this table. If you specify the CLM option in the SCORE statement, confidence intervals are included in the ScoreResults table.

Note that scoring is not supported when the DIRECT option is specified in the MODEL statement. Scoring at a point specified in a score data set is done by first finding the cell in the kd tree containing this point and then interpolating the scored value from the predicted values at the vertices of this cell. This methodology precludes scoring any points that are not contained in the box that surrounds the data used in fitting the loess model.

ODS Table Names

PROC LOESS assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

Table 41.4. ODS Tables Produced by PROC LOESS

ODS Table Name	Description	Statement	Option
FitSummary	Specified fit parameters and fit summary		default
kdTree	Structure of kd tree used	MODEL	DETAILS(kdTree)
ModelSummary	Summary of all models evaluated	MODEL	DETAILS(ModelSummary)
OutputStatistics	Coordinates and fit results at input data points	MODEL	DETAILS(OutputStatistics)
PredAtVertices	Coordinates and fitted values at kd tree vertices	MODEL	DETAILS(PredAtVertices)
ScaleDetails	Extent and scaling of the independent variables		default
ScoreResults	Coordinates and fit results at scoring points	SCORE	PRINT
SmoothingCriterion	Criterion value and selected smoothing parameter	MODEL	SELECT

ODS Graphics (Experimental)

This section describes the use of ODS for creating statistical graphs with the LOESS procedure. These graphics are experimental in this release, meaning that both the

graphical results and the syntax for specifying them are subject to change in a future release.

To request these graphs you must specify the ODS GRAPHICS statement. For more information on the ODS GRAPHICS statement, see [Chapter 15, “Statistical Graphics Using ODS.”](#)

When the ODS GRAPHICS are in effect, the LOESS procedure produces a variety of plots. For models with multiple dependent variables, separate plots are produced for each dependent variable. For models where multiple smoothing parameters are requested with the SMOOTH= option in the MODEL statement and smoothing parameter value selection is not requested, then separate plots are produced for each smoothing parameter. If smoothing parameter value selection is requested with the SELECT=option in the MODEL statement, then the plots are produced for the selected model only. However, if the STEPS qualifier is included with the SELECT= option, then plots are produced for all smoothing parameters examined in the selection process.

The plots available are as follows:

- When smoothing parameter value selection is performed, the procedure displays a scatterplot of the value of SELECTION= criterion versus the smoothing parameter value for all smoothing parameter values examined in the selection process.
- With a single regressor, the procedure displays a scatterplot of the input data with the fitted LOESS curve overlaid. If the CLM option is specified in the model statement, then a confidence band at the significance level specified in the ALPHA= option is included in the plot. For each SCORE statement a scatterplot of the scored LOESS fit at the requested points is displayed.
- When you specify the RESIDUAL option in the MODEL statement, the procedure displays a panel containing plots of the residual versus each of the regressors in the model, and also a summary panel of fit diagnostics:
 - residuals versus the predicted values
 - histogram of the residuals
 - a normal quantile plot of the residuals
 - a “Residual-Fit” (or RF) plot consisting of side-by-side quantile plots of the centered fit and the residuals. This plot “shows how much variation in the data is explained by the fit and how much remains in the residuals” (Cleveland 1993).
 - dependent variable values versus the predicted values

Note that plots in the Fit Diagnostics panel can be requested individually by specifying the PLOTS(UNPACKPANELS) option in the PROC LOESS statement.

PLOTS (*general-plot-options*)

specifies characteristics of the graphics produced when you use the experimental ODS GRAPHICS statement. You can specify the following *general-plot-options* in parentheses after the PLOTS option:

UNPACK|UNPACKPANELS specifies that plots in the Fit Diagnostics Panel should be displayed separately. Use this option if you want to access individual diagnostic plots within the panel.

MAXPOINTS=*number*|NONE specifies that plots with elements that require processing more than *number* points are suppressed. The default is MAXPOINTS=5000. This cutoff is ignored if you specify MAXPOINTS=NONE.

ODS Graph Names

PROC LOESS assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in [Table 41.5](#).

To request these graphs you must specify the ODS GRAPHICS statement. For more information on the ODS GRAPHICS statement, see [Chapter 15](#), “Statistical Graphics Using ODS.”

Table 41.5. ODS Graphics Produced by PROC LOESS

ODS Graph Name	Plot Description	PLOTS Option
ActualByPredicted	Dependent variable versus LOESS fit	UNPACKPANELS
DiagnosticsPanel	Panel of fit diagnostics	
FitPlot	Loess curve overlaid on scatterplot of data	
QQPlot	Normal quantile plot residuals	UNPACKPANELS
ResidualByPredicted	Residuals versus LOESS fit	UNPACKPANELS
ResidualHistogram	Histogram of fit residuals	UNPACKPANELS
ResidualPanel <i>i</i>	Panel <i>i</i> of residuals versus regressors	
RFPlot	Side-by-side plots of quantiles of centered fit and residuals	UNPACKPANELS
ScorePlot	Loess fit evaluated at scoring points	
SelectionCriterionPlot	Selection criterion versus smoothing parameter	

Examples

Example 41.1. Engine Exhaust Emissions

Investigators studied the exhaust emissions of a one cylinder engine (Brinkman 1981). The SAS data set `Gas` contains the results data. The dependent variable, `NOx`, measures the concentration, in micrograms per joule, of nitric oxide and nitrogen dioxide normalized by the amount of work of the engine. The independent variable, `E`, is a measure of the richness of the air and fuel mixture.

```
data Gas;
  input NOx E;
  format NOx f3.1;
  format E f3.1;
datalines;
4.818 0.831
2.849 1.045
3.275 1.021
4.691 0.97
4.255 0.825
5.064 0.891
2.118 0.71
4.602 0.801
2.286 1.074
0.97 1.148
3.965 1
5.344 0.928
3.834 0.767
1.99 0.701
5.199 0.807
5.283 0.902
3.752 0.997
0.537 1.224
1.64 1.089
5.055 0.973
4.937 0.98
1.561 0.665
;
```

The following PROC GPLOT statements produce the simple scatter plot of these data, displayed in [Output 41.1.1](#).

```
symbol1 color=black value=dot ;
proc gplot data=Gas;
  plot NOx*E;
run;
```

Output 41.1.1. Scatter Plot of Gas Data

The following statements fit two loess models for these data. Because this is a small data set, it is reasonable to do direct fitting at every data point. As there is substantial curvature in the data, quadratic local polynomials are used. An ODS OUTPUT statement creates two output data sets containing the “Output Statistics” and “Fit Summary” tables.

```
proc loess data=Gas;
  ods output OutputStatistics = GasFit
             FitSummary=Summary;
  model NOx = E / degree=2 direct smooth = 0.6 1.0
             alpha=.01 all details;
run;
```

The “Fit Summary” table for smoothing parameter value 0.6, shown in [Output 41.1.2](#), records the fitting parameters specified and some overall fit statistics.

Output 41.1.2. Fit Summary Table

The LOESS Procedure	
Smoothing Parameter: 0.6	
Dependent Variable: NOx	
Fit Summary	
Fit Method	Direct
Number of Observations	22
Degree of Local Polynomials	2
Smoothing Parameter	0.60000
Points in Local Neighborhood	13
Residual Sum of Squares	1.71852
Trace[L]	6.42184
GCV	0.00708
AICC	-0.45637
AICC1	-9.39715
Delta1	15.12582
Delta2	14.73089
Equivalent Number of Parameters	5.96950
Lookup Degrees of Freedom	15.53133
Residual Standard Error	0.33707

The matrix L referenced in the “Fit Summary” table is the smoothing matrix. This matrix satisfies

$$\hat{y} = Ly$$

where y is the vector of observed values and \hat{y} is the corresponding vector of predicted values of the dependent variable. The quantities

$$\begin{aligned} \delta_1 &\equiv \text{Trace}(I - L)^T(I - L) \\ \delta_2 &\equiv \text{Trace}((I - L)^T(I - L))^2 \\ \rho &\equiv \text{Lookup Degrees of Freedom} \\ &\equiv \delta_1^2/\delta_2 \end{aligned}$$

in the “Fit Summary” table are used in doing statistical inference.

The equivalent number of parameters and residual standard error in the “Fit Summary” table are defined by

$$\begin{aligned} \text{Equivalent Number of Parameters} &\equiv \text{Trace}L^T L \\ \text{Residual Standard Error} &\equiv \sqrt{\text{Residual SS}/\delta_1} \end{aligned}$$

The “Output Statistics” table for smoothing parameter value 0.6 is shown in [Output 41.1.3](#). Note that, as the ALL option in the MODEL statement is specified, this table includes all the relevant optional columns. Furthermore, because the ALPHA=0.01 option is specified in the MODEL statement, the confidence limits in this table are 99% limits.

Output 41.1.3. Output Statistics Table

proc greplay nofs tc=sashelp.templt template=h2;
    igout gseg;
    treplay 1:fitGas 2:fitGas1;
run; quit;
```

Output 41.1.4. Loess Fits with 99% Confidence Bands for Gas Data

It is evident from the preceding figure that the better fit is obtained with smoothing parameter value 0.6. Scatter plots of the fit residuals confirm this observation. Note also that PROC LOESS is again used to produce the Residual variable on these plots.

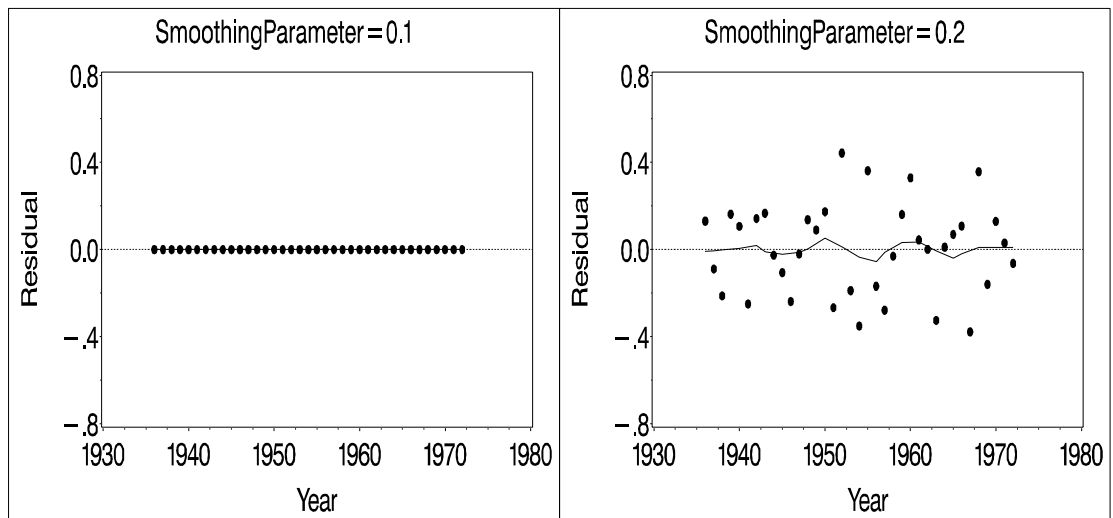

```

proc loess data=GasFit;
  by SmoothingParameter;
  ods output OutputStatistics=residout;
  model Residual=E;
run;

axis1 label = (angle=90 rotate=0)
      order = (-1 to 1 by 0.5);
goptions nodisplay hsize=3.75;
proc gplot data=residout;
  by SmoothingParameter;
  format DepVar 3.1;
  plot DepVar*E Pred*E/ &opts vref=0 lv=2 vm=1
      name='resGas';
run; quit;

goptions display hsize=0 hpos=0;
proc greplay nofs tc=sashelp.templt template=h2;
  igout gseg;
  treplay 1:resGas 2:resGas1;
run; quit;

```

Output 41.1.5. Scatter Plots of Loess Fit Residuals

The residual plots show that with smoothing parameter value 1, the loess model exhibits a lack of fit. Analysis of variance can be used to compare the model with smoothing parameter value 1, which serves as the null model, to the model with smoothing parameter value 0.6.

The statistic

$$F = \frac{(\text{rss}^{(n)} - \text{rss}) / (\delta_1^{(n)} - \delta_1)}{\text{rss} / \delta_1}$$

has a distribution that is well approximated by an F distribution with

$$\nu = \frac{(\delta_1^{(n)} - \delta_1)^2}{\delta_2^{(n)} - \delta_2}$$

numerator degrees of freedom and ρ denominator degrees of freedom (Cleveland and Grosse 1991). Here quantities with superscript n refer to the null model, rss is the residual sum of squares, and δ_1 , δ_2 , and ρ are as previously defined.

The “Fit Summary” tables contain the information needed to carry out such an analysis. These tables have been captured in the output data set named `Summary` using an ODS OUTPUT statement. The following statements extract the relevant information from this data set and carry out the analysis of variance:

```

data h0 h1;
  set Summary(keep=SmoothingParameter Label1 nValue1
              where=(Label1 in ('Residual Sum of Squares','Delta1',
                                'Delta2','Lookup Degrees of Freedom')));
  if SmoothingParameter = 1 then output h0;
  else output h1;
run;

proc transpose data=h0(drop=SmoothingParameter Label1) out=h0;

data h0(drop=_NAME_); set h0;
  rename Col1 = RSSNull
         Col2 = delta1Null
         Col3 = delta2Null;

proc transpose data=h1(drop=SmoothingParameter Label1) out=h1;

data h1(drop=_NAME_); set h1;
  rename Col1 = RSS      Col2 = delta1
         Col3 = delta2  Col4 = rho;

data ftest; merge h0 h1;
  nu = (delta1Null - delta1)**2 / (delta2Null - delta2);
  Numerator = (RSSNull - RSS)/(delta1Null - delta1);
  Denominator = RSS/delta1;
  FValue = Numerator / Denominator;
  PValue = 1 - ProbF(FValue, nu, rho);
  label nu = 'Num DF'
        rho = 'Den DF'
        FValue = 'F Value'
        PValue = 'Pr > F';

proc print data=ftest label;
  var nu rho Numerator Denominator FValue PValue;
  format nu rho FValue 7.2 PValue 6.4;
run;

```

The results are shown in [Output 41.1.6](#).

Output 41.1.6. Test ANOVA for LOESS MODELS of Gas Data

Obs	Num DF	Den DF	Numerator	Denominator	F Value	Pr > F
1	2.67	15.53	1.05946	0.11362	9.32	0.0012

The highly significant p -value confirms that the loess model with smoothing parameter value 0.6 provides a better fit than the model with smoothing parameter value 1.

Example 41.2. Sulfate Deposits in the USA for 1990

The following data set contains measurements in grams per square meter of sulfate (SO_4) deposits during 1990 at 179 sites throughout the 48 states.

```
data SO4;
  input Latitude Longitude SO4 @@;
datalines;
32.45833 87.24222 1.403 34.28778 85.96889 2.103
33.07139 109.86472 0.299 36.07167 112.15500 0.304
31.95056 112.80000 0.263 33.60500 92.09722 1.950
.
.      more data lines
.
42.92889 109.78667 0.182 43.22278 109.99111 0.161
43.87333 104.19222 0.306 44.91722 110.42028 0.210
45.07611 72.67556 2.646
;
```

The following statements produce the two scatter plots of the SO_4 data shown in [Output 41.2.1](#) and [Output 41.2.2](#):

```
symbol1 color=black value=dot ;
proc gplot data=SO4;
  plot Latitude*Longitude/hreverse;
run;

proc g3d data=SO4;
  format SO4 f4.1;
  scatter Longitude*Latitude=SO4 /
    shape='balloon'
    size=0.35
    rotate=80
    tilt=60;
run;
```

Output 41.2.1. Locations of Sulfate Measurements

Output 41.2.2. Scatter Plot of SO4 Data

From these scatter plots, it is clear that the largest concentrations are in the northeastern United States. These plots also indicate that a nonparametric surface, such as a loess fit, is appropriate for these data.

The sulfate measurements are irregularly spaced. The following statements create a SAS data set containing a regular grid of points that will be used in the SCORE statement:

```
data PredPoints;
  do Latitude = 26 to 46 by 1;
    do Longitude = 79 to 123 by 1;
      output;
    end;
  end;
end;
```

The following statements fit loess models for two values of the smoothing parameter and save the results in output data sets:

```
proc loess data=S04;
  ods Output ScoreResults=ScoreOut
        OutputStatistics=StatOut;
  model S04=Latitude Longitude/smooth=0.15 0.4 residual;
  score data=PredPoints;
run;
```

Notice that even though there are two predictors in the model, the SCALE= option is not appropriate because the predictors (Latitude and Longitude) are identically scaled.

[Output 41.2.3](#) shows scatter plots of the fit residuals versus each of the predictors for the two smoothing parameter values specified. A loess fit of the residuals is also shown on these scatter plots and is obtained using PROC LOESS with the StatOut data set generated by the previous PROC LOESS step.

```
proc loess data=StatOut;
  by SmoothingParameter;
  ods output OutputStatistics=ResidLatOut;
  model residual=Latitude;
run;
proc loess data=StatOut;
  by SmoothingParameter;
  ods output OutputStatistics=ResidLongOut;
  model residual=Longitude;
run;
proc sort data=ResidLatOut;
  by SmoothingParameter Latitude;
run;
proc sort data=ResidLongOut;
  by SmoothingParameter Longitude;
run;
```

```

goptions nodisplay;
symbol1 color=black value=dot ;
symbol2 color=black interpol=join value=none;
%let opts = vaxis=axis1 overlay vref=0 lv=2;
axis1 label = (angle=90 rotate=0);

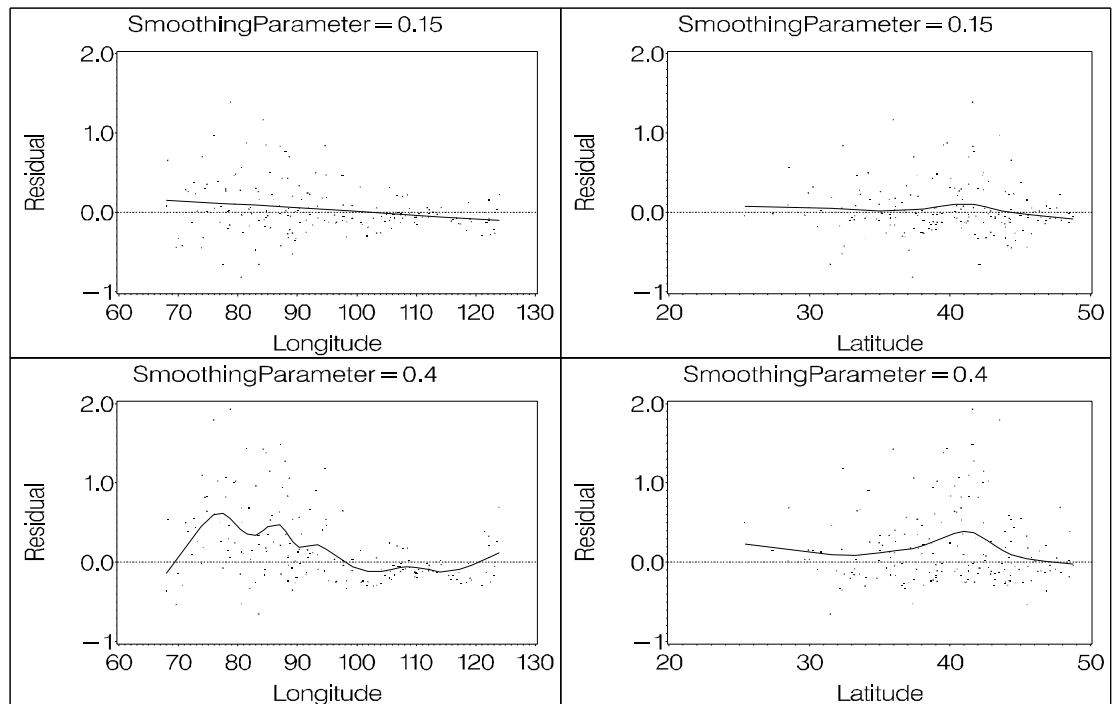

proc gplot data=ResidLatOut;
  by smoothingParameter;
  format DepVar 3.1;
  plot (DepVar Pred) * Latitude / &opts name='lat';
run;

proc gplot data=ResidLongOut;
  by smoothingParameter;
  format DepVar 3.1;
  plot (DepVar Pred) * Longitude / &opts name='long';
run;

goptions display;
proc greplay nofs tc=sashelp.templt template=l2r2;
  igout gseg;
  treplay 1:long 2:long1 3:lat 4:lat1;
run; quit ;

```

Output 41.2.3. Scatter Plots of Loess Fit Residuals

The scatter plots in [Output 41.2.3](#) reveal that, with smoothing parameter value 0.4, there is significant information in the data that is not being captured by the loess model. By contrast, the residuals for the more localized smoothing parameter value 0.15 show a better fit.

The ScoreOut data set contains the model predictions at the grid defined in the PredPoints data set. The following statements request a fitted surface and a contour plot of this surface with a smoothing parameter value 0.15:

```
proc g3d data=ScoreOut(where= (smoothingParameter=0.15));
  format Latitude f4.0;
  format Longitude f4.0;
  format p_SO4 f4.1;
  plot Longitude*Latitude=p_SO4/tilt=60 rotate=80;
run;

proc gcontour data=ScoreOut(where= (smoothingParameter=0.15));
  format latitude f4.0;
  format longitude f4.0;
  format p_SO4 f4.1;
  plot Latitude*Longitude = p_SO4/hreverse;
run;
```

Output 41.2.4. LOESS Fit of SO4 Data

Output 41.2.5. Contour Plot of LOESS Fit of SO4 Data

Example 41.3. Catalyst Experiment

The following data set records the results of an experiment to determine how the yield of a chemical reaction varies with temperature and amount of a catalyst used.

```

data Experiment;
  input Temperature Catalyst Yield;
datalines;
  80      0.000      6.842
  80      0.002      7.944
  .
  .      more data lines
  .
  140     0.078      4.012
  140     0.080      5.212
;

```

Researchers know that about 10% of the yield measurements are corrupted due to an intermittent equipment problem. This can be seen in the surface plot of raw data shown in [Output 41.3.1](#).

```

proc g3d data=Experiment;
  plot Temperature*Catalyst=Yield/zmin=0 zmax=25 zticknum=6;
run;

```

Output 41.3.1. Surface Plot of Experiment Data

A robust fitting method is needed to estimate the underlying surface in the presence of data outliers. The following statements invoke PROC LOESS with iterative reweighting to fit a surface to these data:

```
proc loess data=Experiment;
  ods output OutputStatistics=Results;
  model Yield = Temperature Catalyst /
    scale=sd(0.1)
    iterations=3;
run;
```

The ITERATIONS=3 option in the MODEL statement requests two iteratively reweighted iterations. Note the use of the SCALE=SD(0.1) option in the MODEL statement. This specifies that the independent variables in the model are to be divided by their respective 10% trimmed standard deviations before the fitted model is computed. This is appropriate as the independent variables *Temperature* and *Catalyst* are not similarly scaled. The “Scale Details” table produced by PROC LOESS is shown in [Output 41.3.2](#).

Output 41.3.2. Scale Details Table

The LOESS Procedure		
Independent Variable Scaling		
Scaling applied: 10% trimmed standard deviation		
Statistic	Temperature	Catalyst
Minimum Value	80	0.000
Maximum Value	140	0.080
Trimmed Mean	110	0.040
Trimmed Standard Deviation	14	0.019

The following statements use the G3D procedure to plot the fitted surface shown in [Output 41.3.3.](#)

```
proc g3d data=Results;
  format Temperature f4.0;
  format Catalyst f6.3;
  format pred f5.2;
  plot Temperature*Catalyst=pred/zmin=0 zmax=10 zticknum=3;
run;
```

Output 41.3.3. Fitted Surface Plot for Experiment Data

Example 41.4. Automatic Smoothing Parameter Selection

The following data set contains measurements of monthly averaged atmospheric pressure differences between Easter Island and Darwin, Australia, for a period of 168 months (National Institute of Standards and Technology 1998):

```

data ENSO;
  input Pressure @@;
  Month=_N_;
  format Pressure 4.1;
  format Month 3.0;
datalines;

```

The following PROC Gplot statements produce the simple scatter plot of these data, displayed in [Output 41.4.1](#):

```

symbol1 color=black value=dot ;
proc gplot data=ENSO;
  plot Pressure*Month /
    hminor = 0
    vminor = 0
    vaxis = axis1
    frame;
    axis1 label = ( r=0 a=90 ) order=(0 to 20 by 4);;
run;

```

Output 41.4.1. Scatter Plot of ENSO Data

You can compute a loess fit and plot the results for these data using the following statements:

```
ods output OutputStatistics=ENSOSTATS;

proc loess data=ENSO;
  model Pressure=Month ;
run;

symbol1 color=black value=dot h=2.5 pct;
symbol2 color=black interpol=join value=none width=2;
proc gplot data=ENSOSTATS;
  plot (depvar pred)*Month / overlay
      hminor = 0
      vminor = 0
      vaxis  = axis1
      frame;
  axis1 label = ( r=0 a=90 ) order=(0 to 20 by 4);
run; quit;
```

The “Smoothing Criterion” and “Fit Summary” tables are shown in [Output 41.4.2](#) and the fit is plotted in [Output 41.4.3](#).

Output 41.4.2. Output from PROC LOESS

The LOESS Procedure	
Dependent Variable: Pressure	
Optimal Smoothing Criterion	
AICC	Smoothing Parameter
3.41105	0.22321
The LOESS Procedure	
Selected Smoothing Parameter: 0.223	
Dependent Variable: Pressure	
Fit Summary	
Fit Method	kd Tree
Blending	Linear
Number of Observations	168
Number of Fitting Points	33
kd Tree Bucket Size	7
Degree of Local Polynomials	1
Smoothing Parameter	0.22321
Points in Local Neighborhood	37
Residual Sum of Squares	1654.27725
Trace[L]	8.74180
GCV	0.06522
AICC	3.41105

The smoothing parameter value used for the loess fit shown in [Output 41.4.3](#) was chosen using the default method of PROC LOESS, namely a golden section minimization of the AICC criterion over the interval $(0, 1]$. The fit seems to be oversmoothed. What accounts for this poor fit?

Output 41.4.3. Oversmoothed Loess Fit for the ENSO Data

One possibility is that the golden section search has found a local rather than a global minimum of the AICC criterion. You can test this by redoing the fit requesting a global minimum. It is also helpful to plot the AICC criterion as a function of the smoothing parameter value used. You do this with the following statements:

```
ods output ModelSummary=ENSOSummary;

proc loess data=ENSO;
  model Pressure=Month/select=AICC(global);
run;

proc sort data=ENSOSummary;
  by smooth;
run;

symbol1 color=black interpol=join value=none width=2;
proc gplot data=ENSOSummary;
  format AICC f4.1; format smooth f4.1;
  plot AICC*Smooth /
    hminor = 0 vminor = 0 vaxis = axis1 frame;
    axis1 label = ( r=0 a=90 );
run; quit;
```

The results are shown in [Output 41.4.4](#).

Output 41.4.4. AICC versus Smoothing Parameter Showing Local Minima

The explanation for the oversmoothed fit in [Output 41.4.3](#) is now apparent. The golden section search algorithm found the local minimum that occurs near the value 0.22 of the smoothing parameter rather than the global minimum that occurs near 0.06. Note that if you restrict the range of smoothing parameter values examined to lie below 0.2, then the golden section search finds the global minimum as the following statements demonstrate:

```
ods output OutputStatistics=ENSStats;

proc loess data=ENSO;
  model Pressure=Month/select=AICC( range(0.03,0.2) );
run;

symbol1 color=black value=dot h=2.5 pct;
symbol2 color=black interpol=join value=none width=2;
proc gplot data=ENSStats;
  plot (depvar pred)*Month / overlay
      hminor = 0
      vminor = 0
      vaxis  = axis1
      frame;
      axis1 label = ( r=0 a=90 ) order=(0 to 20 by 4);
run; quit;
```

The fit obtained is shown in [Output 41.4.5](#).

Output 41.4.5. Loess Fit for the ENSO Data

The loess fit shown in [Output 41.4.5](#) clearly shows an annual cycle in the data. An interesting question is whether there is some phenomenon captured in the data that would explain the presence of the local minimum near 0.22 in the AICC curve. Note that there is some evidence of a cycle of about 42 months in the oversmoothed fit in [Output 41.4.3](#). You can see this cycle because the strong annual cycle in [Output 41.4.5](#) has been smoothed out. The physical phenomenon that accounts for the existence of this cycle has been identified as the periodic warming of the Pacific Ocean known as “El Niño.”

Example 41.5. ODS Graphics

This example highlights the use of ODS for creating statistical graphs with the LOESS procedure. The ENSO example is revisited to show how these graphics can be used to enrich the analysis and simplify the process for obtaining functionally equivalent plots to those previously presented with this example.

To request these plots you need to specify the experimental ODS GRAPHICS statement. For general information about ODS graphics see [Chapter 15](#), “Statistical Graphics Using ODS.” The following statements produce the default plots:

```
ods html;
ods graphics on;

proc loess data=ENSO;
  model Pressure=Month/select=AICC( range(0.03,0.4) global) clm
      alpha=0.01;
run;

ods graphics off;
ods html close;
```

Output 41.5.1. Smoothing Parameter Selection (Experimental)

Note that [Output 41.5.1](#) has points corresponding to all models with smoothing parameters between 0.03 and 0.4, as these models were requested in the `SELECT=` option. By default, only the models evaluated in the golden section search for the optimal smoothing parameter appear on this plot.

Output 41.5.2. LOESS Fit of ENSO Data (Experimental)

The fit plot shown in [Output 41.5.2](#) is produced for models with a single regressor. Note that [Output 41.5.2](#) includes the 99% confidence band that was requested in the MODEL statement using the CLM and ALPHA= options.

Diagnostic plots are produced when the RESIDUAL option is included in the model statement. The following statements produce these diagnostic plots:

```
ods html;
ods graphics on;

proc loess data=ENSO;
  model Pressure=Month/smooth = 0.0565 residual;
run;

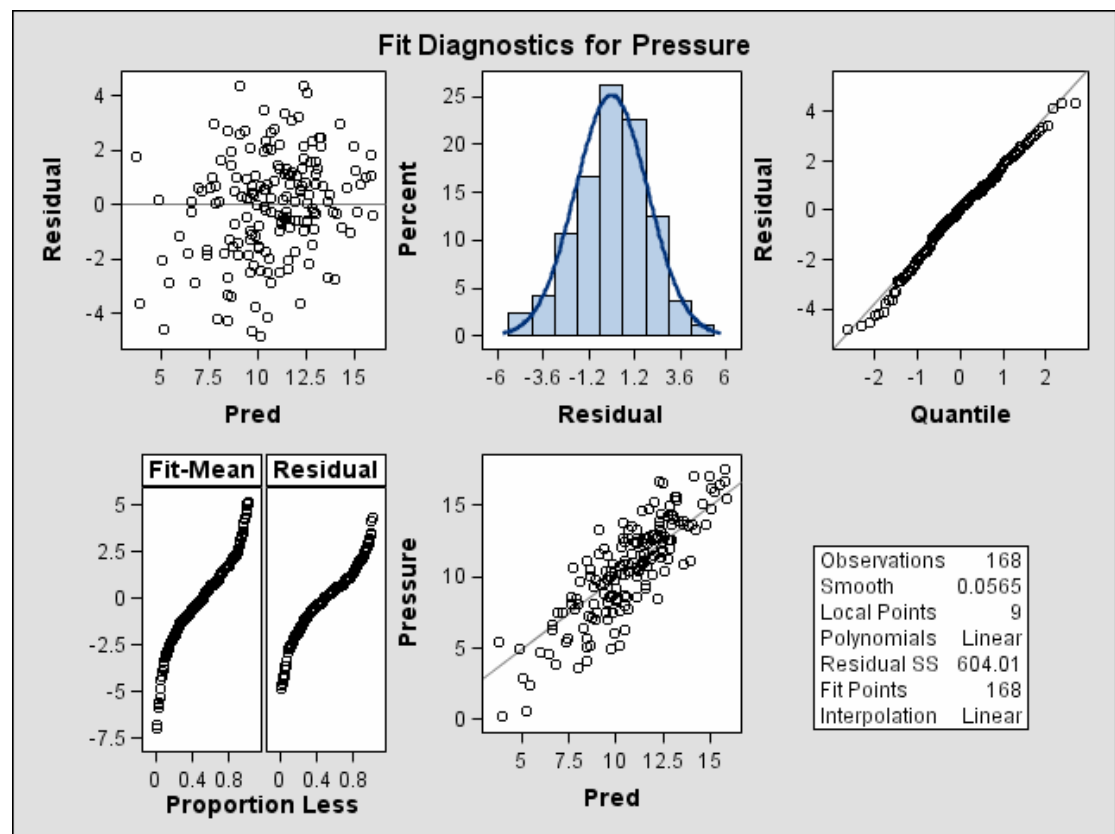

ods graphics off;
ods html close;
```

Output 41.5.3. Residuals by Regressors (Experimental)

The residuals in [Output 41.5.3](#) do not exhibit any obvious patterns, suggesting that the signal in the data has been successfully modeled.

Additional information about the LOESS fit can be seen in the plots in the fit diagnostics panel that is also produced whenever the RESIDUAL option is specified in the MODEL statement. [Output 41.5.4](#) shows this panel for the optimal smoothing parameter.

Output 41.5.4. Fit Diagnostics Panel (Experimental)

These diagnostic plots all suggest that the fit obtained is appropriate for these data:

- The plot of residuals versus predicted value shows no obvious pattern.
- The residual histogram with overlaid normal density supports the assumption of gaussian errors.
- The normal quantile plot is consistent with the assumption of gaussian errors.
- The “Residual-Fit” (or RF) plot consisting of side-by-side quantile plots of the centered fit and the residuals shows that the spread in the residuals is no greater than the spread in the centered fit. For inappropriate models, the spread of the residuals in such a plot is often greater than the spread of the centered fit.
- The plot of the dependent variable versus the predicted values is centered around a 45 degree line and shows no obvious outliers.

If you want to obtain the plots in the Diagnostics Panel as individual plots, you can do so by specifying the PLOTS(UNPACKPANELS) option in the PROC LOESS statement. The following statements provide an example:

```
ods html;  
ods graphics on;  
  
proc loess data=ENSO plots(unpackpanels);  
    model Pressure=Month/smooth = 0.0565 residual;  
run;  
  
ods graphics off;  
ods html close;
```

Output 41.5.5. Residual Histogram (Experimental)

The residual histogram is shown in [Output 41.5.5](#).

Chapter 42

The LOGISTIC Procedure

Overview

Binary responses (for example, success and failure), ordinal responses (for example, normal, mild, and severe), and nominal responses (for example, major TV networks viewed at a certain hour) arise in many fields of study. Logistic regression analysis is often used to investigate the relationship between these discrete responses and a set of explanatory variables. Several texts that discuss logistic regression are Collett (1991), Agresti (1990), Cox and Snell (1989), Hosmer and Lemeshow (2000), and Stokes, Davis, and Koch (2000).

For binary response models, the response, Y , of an individual or an experimental unit can take on one of two possible values, denoted for convenience by 1 and 2 (for example, $Y = 1$ if a disease is present, otherwise $Y = 2$). Suppose \mathbf{x} is a vector of explanatory variables and $\pi = \Pr(Y = 1 \mid \mathbf{x})$ is the response probability to be modeled. The linear logistic model has the form

$$\text{logit}(\pi) \equiv \log\left(\frac{\pi}{1 - \pi}\right) = \alpha + \beta'\mathbf{x}$$

where α is the intercept parameter and β is the vector of parameters. Notice that the LOGISTIC procedure, by default, models the probability of the *lower* response levels.

The logistic model shares a common feature with a more general class of linear models, that a function $g = g(\mu)$ of the mean of the response variable is assumed to be linearly related to the explanatory variables. Since the mean μ implicitly depends on the stochastic behavior of the response, and the explanatory variables are assumed to be fixed, the function g provides the link between the random (stochastic) component and the systematic (deterministic) component of the response variable Y . For this reason, Nelder and Wedderburn (1972) refer to $g(\mu)$ as a link function. One advantage of the logit function over other link functions is that differences on the logistic scale are interpretable regardless of whether the data are sampled prospectively or retrospectively (McCullagh and Nelder 1989, Chapter 4). Other link functions that are widely used in practice are the probit function and the complementary log-log function. The LOGISTIC procedure enables you to choose one of these link functions, resulting in fitting a broader class of binary response models of the form

$$g(\pi) = \alpha + \beta'\mathbf{x}$$

For ordinal response models, the response, Y , of an individual or an experimental unit may be restricted to one of a (usually small) number, $k + 1$ ($k \geq 1$), of ordinal values, denoted for convenience by $1, \dots, k, k + 1$. For example, the severity of

coronary disease can be classified into three response categories as 1=no disease, 2=angina pectoris, and 3=myocardial infarction. The LOGISTIC procedure fits a common slopes cumulative model, which is a parallel lines regression model based on the cumulative probabilities of the response categories rather than on their individual probabilities. The cumulative model has the form

$$g(\Pr(Y \leq i | \mathbf{x})) = \alpha_i + \beta' \mathbf{x}, \quad i = 1, \dots, k$$

where $\alpha_1, \dots, \alpha_k$ are k intercept parameters, and β is the vector of parameters. This model has been considered by many researchers. Aitchison and Silvey (1957) and Ashford (1959) employ a probit scale and provide a maximum likelihood analysis; Walker and Duncan (1967) and Cox and Snell (1989) discuss the use of the log-odds scale. For the log-odds scale, the cumulative logit model is often referred to as the *proportional odds* model.

For nominal response logistic models, where the $k + 1$ possible responses have no natural ordering, the logit model can also be extended to a *generalized logit* model, which has the form

$$\log \left(\frac{\Pr(Y = i | \mathbf{x})}{\Pr(Y = k + 1 | \mathbf{x})} \right) = \alpha_i + \beta_i' \mathbf{x}, \quad i = 1, \dots, k$$

where the $\alpha_1, \dots, \alpha_k$ are k intercept parameters, and the β_1, \dots, β_k are k vectors of parameters. These models were introduced by McFadden (1974) as the *discrete choice* model, and they are also known as *multinomial* models.

The LOGISTIC procedure fits linear logistic regression models for discrete response data by the method of maximum likelihood. It can also perform conditional logistic regression for binary response data and exact conditional logistic regression for binary and nominal response data. The maximum likelihood estimation is carried out with either the Fisher-scoring algorithm or the Newton-Raphson algorithm. You can specify starting values for the parameter estimates. The logit link function in the logistic regression models can be replaced by the probit function, the complementary log-log function, or the generalized logit function.

The LOGISTIC procedure enables you to specify categorical variables (also known as CLASS variables) or continuous variables as explanatory variables. You can also specify more complex model terms such as interactions and nested terms in the same way as in the GLM procedure. Any term specified in the model is referred to as an *effect*, whether it is a continuous variable, a CLASS variable, an interaction, or a nested term.

The LOGISTIC procedure allows either a full-rank parameterization or a less-than-full-rank parameterization. The full-rank parameterization offers eight coding methods: effect, reference, ordinal, polynomial, and orthogonalizations of these. The effect coding is the same method that is used in the CATMOD procedure. The less-than-full-rank parameterization is the same coding as that used in the GLM procedure.

The LOGISTIC procedure provides four effect selection methods: forward selection, backward elimination, stepwise selection, and best subset selection. The best subset

selection is based on the likelihood score statistic. This method identifies a specified number of best models containing one, two, three effects, and so on, up to a single model containing effects for all the explanatory variables.

The LOGISTIC procedure has some additional options to control how to move effects in and out of a model with various model-building strategies such as forward selection, backward elimination, or stepwise selection. When there are no interaction terms, a main effect can enter or leave a model in a single step based on the p -value of the score or Wald statistic. When there are interaction terms, the selection process also depends on whether you want to preserve model hierarchy. These additional options enable you to specify whether model hierarchy is to be preserved, how model hierarchy is applied, and whether a single effect or multiple effects can be moved in a single step.

Odds ratio estimates are displayed along with parameter estimates. You can also specify the change in the explanatory variables for which odds ratio estimates are desired. Confidence intervals for the regression parameters and odds ratios can be computed based either on the profile likelihood function or on the asymptotic normality of the parameter estimators.

Various methods to correct for overdispersion are provided, including Williams' method for grouped binary response data. The adequacy of the fitted model can be evaluated by various goodness-of-fit tests, including the Hosmer-Lemeshow test for binary response data.

Like many procedures in SAS/STAT software that enable the specification of CLASS variables, the LOGISTIC procedure provides a **CONTRAST** statement for specifying customized hypothesis tests concerning the model parameters. The CONTRAST statement also provides estimation of individual rows of contrasts, which is particularly useful for obtaining odds ratio estimates for various levels of the CLASS variables.

You can perform a conditional logistic regression on binary response data by specifying the **STRATA** statement. This enables you to perform matched-set and case-control analyses. The number of events and nonevents can vary across the strata. Many of the features available with the unconditional analysis are also available with a conditional analysis.

The LOGISTIC procedure enables you to perform exact conditional logistic regression using the method of Hirji, Mehta, and Patel (1987) and Mehta, Patel, and Senchaudhuri (1992) by specifying one or more **EXACT** statements. You can test individual parameters or conduct a joint test for several parameters. The procedure computes two exact tests: the exact conditional score test and the exact conditional probability test. You can request exact estimation of specific parameters and corresponding odds ratios where appropriate. Both point estimates and confidence intervals are provided.

Further features of the LOGISTIC procedure enable you to

- control the ordering of the response categories
- compute a generalized R^2 measure for the fitted model

- reclassify binary response observations according to their predicted response probabilities
- test linear hypotheses about the regression parameters
- create a data set for producing a receiver operating characteristic curve for each fitted model
- create a data set containing the estimated response probabilities, residuals, and influence diagnostics
- score a data set using a previously fitted model

Experimental graphics are now available with the LOGISTIC procedure. For more information, see the “[ODS Graphics](#)” section on page 2388.

The remaining sections of this chapter describe how to use PROC LOGISTIC and discuss the underlying statistical methodology. The “[Getting Started](#)” section introduces PROC LOGISTIC with an example for binary response data. The “[Syntax](#)” section (page 2289) describes the syntax of the procedure. The “[Details](#)” section (page 2329) summarizes the statistical technique employed by PROC LOGISTIC. The “[Examples](#)” section (page 2391) illustrates the use of the LOGISTIC procedure with 10 applications.

For more examples and discussion on the use of PROC LOGISTIC, refer to Stokes, Davis, and Koch (2000), Allison (1999), and SAS Institute Inc. (1995).

Getting Started

The LOGISTIC procedure is similar in use to the other regression procedures in the SAS System. To demonstrate the similarity, suppose the response variable y is binary or ordinal, and x_1 and x_2 are two explanatory variables of interest. To fit a logistic regression model, you can use a MODEL statement similar to that used in the REG procedure:

```
proc logistic;
  model y=x1 x2;
run;
```

The response variable y can be either character or numeric. PROC LOGISTIC enumerates the total number of response categories and orders the response levels according to the response variable option [ORDER=](#) in the MODEL statement. The procedure also allows the input of binary response data that are grouped:

```
proc logistic;
  model r/n=x1 x2;
run;
```

Here, n represents the number of trials and r represents the number of events.

The following example illustrates the use of PROC LOGISTIC. The data, taken from Cox and Snell (1989, pp. 10–11), consist of the number, r , of ingots not ready for rolling, out of n tested, for a number of combinations of heating time and soaking time. The following invocation of PROC LOGISTIC fits the binary logit model to the grouped data:

```

data ingots;
  input Heat Soak r n @@;
  datalines;
7 1.0 0 10 14 1.0 0 31 27 1.0 1 56 51 1.0 3 13
7 1.7 0 17 14 1.7 0 43 27 1.7 4 44 51 1.7 0 1
7 2.2 0 7 14 2.2 2 33 27 2.2 0 21 51 2.2 0 1
7 2.8 0 12 14 2.8 0 31 27 2.8 1 22 51 4.0 0 1
7 4.0 0 9 14 4.0 0 19 27 4.0 1 16
;

proc logistic data=ingots;
  model r/n=Heat Soak;
run;

```

The results of this analysis are shown in the following tables.

The LOGISTIC Procedure	
Model Information	
Data Set	WORK.INGOTS
Response Variable (Events)	r
Response Variable (Trials)	n
Model	binary logit
Optimization Technique	Fisher's scoring
Number of Observations Read	19
Number of Observations Used	19
Sum of Frequencies Read	387
Sum of Frequencies Used	387

Figure 42.1. Binary Logit Model

PROC LOGISTIC first lists background information in [Figure 42.1](#) about the fitting of the model. Included are the name of the input data set, the response variable(s) used, the number of observations used, and the link function used.

Response Profile		
Ordered Value	Binary Outcome	Total Frequency
1	Event	12
2	Nonevent	375

Model Convergence Status

Convergence criterion (GCONV=1E-8) satisfied.

Figure 42.2. Response Profile with Events/Trials Syntax

The “Response Profile” table (Figure 42.2) lists the response categories (which are Event and Nonevent when grouped data are input), their ordered values, and their total frequencies for the given data.

Model Fit Statistics			
Criterion	Intercept Only	Intercept and Covariates	
AIC	108.988	101.346	
SC	112.947	113.221	
-2 Log L	106.988	95.346	

Testing Global Null Hypothesis: BETA=0

Test	Chi-Square	DF	Pr > ChiSq
Likelihood Ratio	11.6428	2	0.0030
Score	15.1091	2	0.0005
Wald	13.0315	2	0.0015

Figure 42.3. Fit Statistics and Hypothesis Tests

The “Model Fit Statistics” table (Figure 42.3) contains the Akaike Information Criterion (AIC), the Schwarz Criterion (SC), and the negative of twice the log likelihood (-2 Log L) for the intercept-only model and the fitted model. AIC and SC can be used to compare different models, and the ones with smaller values are preferred. Results of the likelihood ratio test and the efficient score test for testing the joint significance of the explanatory variables (Soak and Heat) are included in the “Testing Global Null Hypothesis: BETA=0” table (Figure 42.3).

Analysis of Maximum Likelihood Estimates					
Parameter	DF	Estimate	Standard Error	Wald Chi-Square	Pr > ChiSq
Intercept	1	-5.5592	1.1197	24.6503	<.0001
Heat	1	0.0820	0.0237	11.9454	0.0005
Soak	1	0.0568	0.3312	0.0294	0.8639

Odds Ratio Estimates			
Effect	Point Estimate	95% Wald Confidence Limits	
Heat	1.085	1.036	1.137
Soak	1.058	0.553	2.026

Figure 42.4. Parameter Estimates and Odds Ratios

The “Analysis of Maximum Likelihood Estimates” table in [Figure 42.4](#) lists the parameter estimates, their standard errors, and the results of the Wald test for individual parameters. The odds ratio for each effect parameter, estimated by exponentiating the corresponding parameter estimate, is shown in the “Odds Ratios Estimates” table ([Figure 42.4](#)), along with 95% Wald confidence intervals.

Using the parameter estimates, you can calculate the estimated logit of π as

$$-5.5592 + 0.082 \times \text{Heat} + 0.0568 \times \text{Soak}$$

If $\text{Heat}=7$ and $\text{Soak}=1$, then $\text{logit}(\hat{\pi}) = -4.9284$. Using this logit estimate, you can calculate $\hat{\pi}$ as follows:

$$\hat{\pi} = 1/(1 + e^{4.9284}) = 0.0072$$

This gives the predicted probability of the event (ingot not ready for rolling) for $\text{Heat}=7$ and $\text{Soak}=1$. Note that PROC LOGISTIC can calculate these statistics for you; use the OUTPUT statement with the `PREDICTED=` option.

Association of Predicted Probabilities and Observed Responses				
Percent Concordant	64.4	Somers' D	0.460	
Percent Discordant	18.4	Gamma	0.555	
Percent Tied	17.2	Tau-a	0.028	
Pairs	4500	c	0.730	

Figure 42.5. Association Table

Finally, the “Association of Predicted Probabilities and Observed Responses” table ([Figure 42.5](#)) contains four measures of association for assessing the predictive abil-

ity of a model. They are based on the number of pairs of observations with different response values, the number of concordant pairs, and the number of discordant pairs, which are also displayed. Formulas for these statistics are given in the “Rank Correlation of Observed Responses and Predicted Probabilities” section on page 2350.

To illustrate the use of an alternative form of input data, the following program creates the INGOTS data set with new variables `NotReady` and `Freq` instead of `n` and `r`. The variable `NotReady` represents the response of individual units; it has a value of 1 for units not ready for rolling (event) and a value of 0 for units ready for rolling (nonevent). The variable `Freq` represents the frequency of occurrence of each combination of `Heat`, `Soak`, and `NotReady`. Note that, compared to the previous data set, `NotReady=1` implies `Freq=r`, and `NotReady=0` implies `Freq=n-r`.

```
data ingots;
  input Heat Soak NotReady Freq @@;
  datalines;
7 1.0 0 10 14 1.0 0 31 14 4.0 0 19 27 2.2 0 21 51 1.0 1 3
7 1.7 0 17 14 1.7 0 43 27 1.0 1 1 27 2.8 1 1 51 1.0 0 10
7 2.2 0 7 14 2.2 1 2 27 1.0 0 55 27 2.8 0 21 51 1.7 0 1
7 2.8 0 12 14 2.2 0 31 27 1.7 1 4 27 4.0 1 1 51 2.2 0 1
7 4.0 0 9 14 2.8 0 31 27 1.7 0 40 27 4.0 0 15 51 4.0 0 1
;
```

The following SAS statements invoke PROC LOGISTIC to fit the same model using the alternative form of the input data set.

```
proc logistic data=ingots;
  model NotReady(event='1') = Soak Heat;
  freq Freq;
run;
```

Results of this analysis are the same as the previous one. The displayed output for the two runs are identical except for the background information of the model fit and the “Response Profile” table shown in Figure 42.6.

The LOGISTIC Procedure		
Response Profile		
Ordered Value	NotReady	Total Frequency
1	0	375
2	1	12

Probability modeled is NotReady=1.

Figure 42.6. Response Profile with Single-Trial Syntax

By default, Ordered Values are assigned to the sorted response values in ascending order, and PROC LOGISTIC models the probability of the response level that corresponds to the Ordered Value 1. There are several methods to change these defaults; the preceding statements specify the response variable option `EVENT=` to model the probability of `NotReady=1` as displayed in Figure 42.6. See the “Response Level Ordering” section on page 2329 for more details.

Syntax

The following statements are available in PROC LOGISTIC:

```

PROC LOGISTIC < options >;
  BY variables ;
  CLASS variable <(v-options)> <variable <(v-options)>... >
    < / v-options >;
  CONTRAST 'label' effect values <,... effect values >< / options >;
  EXACT < 'label' >< Intercept >< effects >< / options >;
  FREQ variable ;
  MODEL events/trials = < effects >< / options >;
  MODEL variable < (variable_options) > = < effects >< / options >;
  OUTPUT < OUT=SAS-data-set >
    < keyword=name...keyword=name >< / option >;
  SCORE < options >;
  STRATA effects < / options >;
  < label: > TEST equation1 < , ... , < equationk >>< / option >;
  UNITS independent1=list1 < ... independentk=listk >< / option >;
  WEIGHT variable < / option >;

```

The PROC LOGISTIC and MODEL statements are required; only one MODEL statement can be specified. The CLASS statement (if used) must precede the MODEL statement, and the CONTRAST, EXACT, and STRATA statements (if used) must follow the MODEL statement. The rest of this section provides detailed syntax information for each of the preceding statements, beginning with the PROC LOGISTIC statement. The remaining statements are covered in alphabetical order.

PROC LOGISTIC Statement

PROC LOGISTIC < options > ;

The PROC LOGISTIC statement starts the LOGISTIC procedure and optionally identifies input and output data sets and suppresses the display of results.

ALPHA= α

specifies the level of significance α for $100(1 - \alpha)\%$ confidence intervals. The value α must be between 0 and 1; the default value is 0.05, which results in 95% intervals. This value is used as the default confidence level for limits computed by the following options.

Statement	Options
CONTRAST	ESTIMATE=
EXACT	ESTIMATE=
MODEL	CLODDS= CLPARG=
OUTPUT	UCL= LCL=
SCORE	CLM

You can override the default in each of these cases by specifying the ALPHA= option for each statement individually.

COVOUT

adds the estimated covariance matrix to the [OUTEST=](#) data set. For the COVOUT option to have an effect, the OUTEST= option must be specified. See the section “[OUTEST= Output Data Set](#)” on page 2374 for more information.

DATA=SAS-data-set

names the SAS data set containing the data to be analyzed. If you omit the DATA= option, the procedure uses the most recently created SAS data set. The [INMODEL=](#) option cannot be specified with this option.

DESCENDING

DESC

reverses the sorting order for the levels of the response variable. If both the DESCENDING and [ORDER=](#) options are specified, PROC LOGISTIC orders the levels according to the ORDER= option and then reverses that order. This option has the same effect as the response variable option [DESCENDING](#) in the MODEL statement. See the “[Response Level Ordering](#)” section on page 2329 for more detail.

EXACTONLY

requests only the exact analyses. The asymptotic analysis that PROC LOGISTIC usually performs is suppressed.

EXACTOPTIONS(*options*)

specifies options that apply to every **EXACT** statement in the program. The following options are available:

ADDTOBS adds the observed sufficient statistic to the sampled exact distribution if the statistic was not sampled. This option has no effect unless the **METHOD=NETWORKMC** option is specified and the **ESTIMATE** option is specified in the **EXACT** statement. If the observed statistic has not been sampled, then the parameter estimate does not exist; by specifying this option, you can produce (biased) estimates.

MAXTIME=seconds specifies the maximum clock time (in seconds) that PROC LOGISTIC can use to calculate the exact distributions. If the limit is exceeded, the procedure halts all computations and prints a note to the LOG. The default maximum clock time is seven days.

METHOD=keyword specifies which exact conditional algorithm to use for every **EXACT** statement specified. You can specify one of the following *keywords*:

DIRECT invokes the multivariate shift algorithm of Hirji, Mehta, and Patel (1987). This method directly builds the exact distribution, but it may require an excessive amount of memory in its intermediate stages. **METHOD=DIRECT** is invoked by default when you are conditioning out at most the intercept, or when the **LINK=GLOGIT** option is specified in the **MODEL** statement.

NETWORK invokes an algorithm similar to that described in Mehta, Patel, and Senchaudhuri (1992). This method builds a network for each parameter that you are conditioning out, combines the networks, then uses the multivariate shift algorithm to create the exact distribution. The **NETWORK** method can be faster and require less memory than the **DIRECT** method. The **NETWORK** method is invoked by default for most analyses.

NETWORKMC invokes the hybrid network and Monte Carlo algorithm of Mehta, Patel, and Senchaudhuri (2000). This method creates a network then samples from that network; this method does not reject any of the samples at the cost of using a large amount of memory to create the network. **METHOD=NETWORKMC** is most useful for producing parameter estimates for problems that are too large for the **DIRECT** and **NETWORK** methods to handle and for which asymptotic methods are invalid; for example, for sparse data on a large grid.

N=n specifies the number of Monte Carlo samples to take when **METHOD=NETWORKMC**. By default $n = 10,000$. If the procedure cannot obtain n samples due to a lack of memory, then a note is printed in the LOG (the number of valid samples is also reported in the listing) and the analysis continues.

Note that the number of samples used to produce any particular statistic may be smaller than n . For example, let X_1 and X_2 be continuous variables, denote their joint distribution by $f(X_1, X_2)$, and let $f(X_1|X_2 = x_2)$ denote the

marginal distribution of $X1$ conditioned on the observed value of $X2$. If you request the JOINT test of $X1$ and $X2$, then n samples are used to generate the estimate $\hat{f}(X1, X2)$ of $f(X1, X2)$, from which the test is computed. However, the parameter estimate for $X1$ is computed from the subset of $\hat{f}(X1, X2)$ having $X2 = x2$, and this subset need not contain n samples. Similarly, the distribution for each level of a classification variable is created by extracting the appropriate subset from the joint distribution for the CLASS variable. The sample sizes used to compute the statistics are written to the ODS OUTPUT data set of the tables.

In some cases, the marginal sample size may be too small to admit accurate estimation of a particular statistic; a note is printed in the LOG when a marginal sample size is less than 100. Increasing n will increase the number of samples used in a marginal distribution; however, if you want to control the sample size exactly, you can:

- Remove the JOINT option from the EXACT statement.
- Create dummy variables in a DATA step to represent the levels of a CLASS variable, and specify them as independent variables in the MODEL statement.

ONDISK uses disk-space instead of random access memory to build the exact conditional distribution. Use this option to handle larger problems at the cost of slower processing.

SEED= n specifies the initial seed for the random number generator used to take the Monte Carlo samples for METHOD=NETWORKMC. The value of the SEED= option must be an integer. If you do not specify a seed, or if you specify a value less than or equal to zero, then PROC LOGISTIC uses the time of day from the computer's clock to generate an initial seed. The seed is displayed in the "Model Information" table.

STATUSEN= n prints a status line in the LOG after every n Monte Carlo samples for METHOD=NETWORKMC. The number of samples taken and the current exact p -value for testing the significance of the model are displayed. You can use this status line to track the progress of the computation of the exact conditional distributions.

STATUSTIME=*seconds* specifies the time interval (in seconds) for printing a status line in the LOG. You can use this status line to track the progress of the computation of the exact conditional distributions. The time interval you specify is approximate; the actual time interval will vary. By default, no status reports are produced.

INEST=SAS-*data-set*

names the SAS data set that contains initial estimates for all the parameters in the model. BY-group processing is allowed in setting up the INEST= data set. See the section "[INEST= Input Data Set](#)" on page 2376 for more information.

INMODEL=SAS-data-set

specifies the name of the SAS data set that contains the model information needed for scoring new data. This INMODEL= data set is the **OUTMODEL=** data set saved in a previous PROC LOGISTIC call. The **DATA=** option cannot be specified with this option; instead, specify the data sets to be scored in the **SCORE** statements.

When the INMODEL= data set is specified, **FORMAT** statements are not allowed; variables in the **DATA=** and **PRIOR=** data sets should be formatted within the data sets. If a **SCORE** statement is specified in the same run as fitting the model, **FORMAT** statements should be specified after the **SCORE** statement in order for the formats to apply to all the **DATA=** and **PRIOR=** data sets in the **SCORE** statement.

You can specify the **BY** statement provided the INMODEL= data set is created under the same **BY**-group processing.

The **CLASS**, **EXACT**, **MODEL**, **OUTPUT**, **TEST**, and **UNIT** statements are not available with the INMODEL= option.

NAMELEN=n

specifies the length of effect names in tables and output data sets to be *n* characters, where *n* is a value between 20 and 200. The default length is 20 characters.

NOCOV

specifies that the covariance matrix is not saved in the **OUTMODEL=** data set. The covariance matrix is needed for computing the confidence intervals for the posterior probabilities in the **OUT=** data set in the **SCORE** statement. Specifying this option will reduce the size of the **OUTMODEL=** data set.

NOPRINT

suppresses all displayed output. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 14, “Using the Output Delivery System,” for more information.

ORDER=DATA | FORMATTED | FREQ | INTERNAL**RORDER=DATA | FORMATTED | INTERNAL**

specifies the sorting order for the levels of the response variable. See the response variable option **ORDER=** in the **MODEL** statement for more information.

OUTDESIGN=SAS-data-set

specifies the name of the data set that contains design matrix for the model. The data set contains the same number of observations as the corresponding **DATA=** data set and includes the response variable (with the same format as in the input data), the **FREQ** variable, the **WEIGHT** variable, the **OFFSET** variable, and the design variables for the covariates, including the Intercept variable of constant value 1 unless the **NOINT** option in the **MODEL** statement is specified.

OUTDESIGNONLY

suppresses the model fitting and only creates the **OUTDESIGN=** data set. This option is ignored if the **OUTDESIGN=** option is not specified.

OUTEST= SAS-data-set

creates an output SAS data set that contains the final parameter estimates and, optionally, their estimated covariances (see the preceding **COVOUT** option). The output data set also includes a variable named `_LNLIKE_`, which contains the log likelihood.

See the section “**OUTEST= Output Data Set**” on page 2374 for more information.

OUTMODEL=SAS-data-set

specifies the name of the SAS data set that contains the information about the fitted model. This data set contains sufficient information to score new data without having to refit the model. It is solely used as the input to the **INMODEL=** option in a subsequent PROC LOGISTIC call. **Note:** information is stored in this data set in a very compact form, hence you should not modify it manually.

SIMPLE

displays simple descriptive statistics (mean, standard deviation, minimum and maximum) for each continuous explanatory variable; and for each CLASS variable involved in the modeling, the frequency counts of the classification levels are displayed. The SIMPLE option generates a breakdown of the simple descriptive statistics or frequency counts for the entire data set and also for individual response categories.

TRUNCATE

specifies that class levels should be determined using no more than the first 16 characters of the formatted values of CLASS, response, and strata variables. When formatted values are longer than 16 characters, you can use this option to revert to the levels as determined in releases previous to Version 9. This option invokes the same option in the **CLASS** statement.

BY Statement

BY variables ;

You can specify a BY statement with PROC LOGISTIC to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. The *variables* are one or more variables in the input data set.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option **NOTSORTED** or **DESCENDING** in the BY statement for the LOGISTIC procedure. The **NOTSORTED** option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure (in base SAS software).

If a **SCORE** statement is specified, then define the *primary data set* to be the **DATA=** or the **INMODEL=** data set in the PROC LOGISTIC statement, and define the *secondary data set* to be the **DATA=** data set and **PRIOR=** data set in the SCORE statement. The primary data set contains all of the BY variables, and the secondary data set must contain either all of them or none of them. If the secondary data set contains all the BY-variables, matching is carried out between the primary and secondary data sets. If the secondary data set does not contain any of the BY-variables, the entire secondary data set is used for every BY-group in the primary data set and the BY-variables are added to the output data sets specified in the SCORE statement.

Caution: The order of your response and classification variables is determined by combining data across all BY groups; however, the observed levels may change between BY groups. This may affect the value of the reference level for these variables, and hence your interpretation of the model and the parameters.

For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

CLASS Statement

```
CLASS variable <(v-options)><variable <(v-options)>... >
      </ v-options > ;
```

The CLASS statement names the classification variables to be used in the analysis. The CLASS statement must precede the MODEL statement. You can specify various *v-options* for each variable by enclosing them in parentheses after the variable name. You can also specify global *v-options* for the CLASS statement by placing them after a slash (/). Global *v-options* are applied to all the variables specified in the CLASS statement. If you specify more than one CLASS statement, the global *v-options* specified on any one CLASS statement apply to all CLASS statements. However, individual CLASS variable *v-options* override the global *v-options*.

CPREFIX= *n*

specifies that, at most, the first *n* characters of a CLASS variable name be used in creating names for the corresponding design variables. The default is 32 – min(32, max(2, *f*)), where *f* is the formatted length of the CLASS variable.

DESCENDING

DESC

reverses the sorting order of the classification variable. If both the DESCENDING and **ORDER=** options are specified, PROC LOGISTIC orders the categories according to the ORDER= option and then reverses that order.

LPREFIX= *n*

specifies that, at most, the first *n* characters of a CLASS variable label be used in creating labels for the corresponding design variables. The default is 256 – min(256, max(2, *f*)), where *f* is the formatted length of the CLASS variable.

MISSING

allows missing value (‘.’ for a numeric variable and blanks for a character variables) as a valid value for the CLASS variable.

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the sorting order for the levels of classification variables. By default, ORDER=FORMATTED. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine dependent. When ORDER=FORMATTED is in effect for numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values. This ordering determines which parameters in the model correspond to each level in the data, so the ORDER= option may be useful when you use the CONTRAST statement.

The following table shows how PROC LOGISTIC interprets values of the ORDER= option.

Value of ORDER=	Levels Sorted By
DATA	order of appearance in the input data set
FORMATTED	external formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ	descending frequency count; levels with the most observations come first in the order
INTERNAL	unformatted value

For more information on sorting order, see the chapter on the SORT procedure in the *SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

PARAM=keyword

specifies the parameterization method for the classification variable or variables. Design matrix columns are created from CLASS variables according to the following coding schemes. The default is PARAM=EFFECT. If PARAM=ORTHPOLY or PARAM=POLY, and the CLASS levels are numeric, then the ORDER= option in the CLASS statement is ignored, and the internal, unformatted values are used. See the “[CLASS Variable Parameterization](#)” section on page 2331 for further details.

EFFECT	specifies effect coding
GLM	specifies less-than-full-rank reference cell coding; this option can only be used as a global option
ORDINAL	specifies the cumulative parameterization for an ordinal CLASS variable.
POLYNOMIAL	
POLY	specifies polynomial coding
REFERENCE	
REF	specifies reference cell coding

ORTHEFFECT	orthogonalizes PARAM=EFFECT
ORTHORDINAL	orthogonalizes PARAM=ORDINAL
ORTHPOLY	orthogonalizes PARAM=POLYNOMIAL
ORTHREF	orthogonalizes PARAM=REFERENCE

The EFFECT, POLYNOMIAL, REFERENCE, ORDINAL, and their orthogonal parameterizations are full rank. The REF= option in the CLASS statement determines the reference level for the EFFECT, REFERENCE, and their orthogonal parameterizations.

Parameter names for a CLASS predictor variable are constructed by concatenating the CLASS variable name with the CLASS levels. However, for the POLYNOMIAL and orthogonal parameterizations, parameter names are formed by concatenating the CLASS variable name and keywords that reflect the parameterization.

REF= *'level' | keyword*

specifies the reference level for PARAM=EFFECT, PARAM=REFERENCE, and their orthogonalizations. For an individual (but not a global) variable REF= *option*, you can specify the *level* of the variable to use as the reference level. For a global or individual variable REF= *option*, you can use one of the following *keywords*. The default is REF=LAST.

FIRST	designates the first ordered level as reference
LAST	designates the last ordered level as reference

TRUNCATE

specifies that class levels should be determined using no more than the first 16 characters of the formatted values of CLASS, response, and strata variables. When formatted values are longer than 16 characters, you can use this option to revert to the levels as determined in releases previous to Version 9. The TRUNCATE option is only available as a global option. This option invokes the same option in the PROC LOGISTIC statement.

CONTRAST Statement

CONTRAST *'label' row-description <,...row-description >< / options >* ;

where a *row-description* is: *effect values <,...effect values >*

The CONTRAST statement provides a mechanism for obtaining customized hypothesis tests. It is similar to the CONTRAST and ESTIMATE statements in PROC GLM and PROC CATMOD, depending on the coding schemes used with any classification variables involved.

The CONTRAST statement enables you to specify a matrix, **L**, for testing the hypothesis $\mathbf{L}\boldsymbol{\theta} = \mathbf{0}$, where $\boldsymbol{\theta}$ is the parameter vector. You must be familiar with the details of the model parameterization that PROC LOGISTIC uses (for more information, see the PARAM= option in the section “[CLASS Statement](#)” on page 2295).

Optionally, the CONTRAST statement enables you to estimate each row, $l'_i\theta$, of $\mathbf{L}\theta$ and test the hypothesis $l'_i\theta = 0$. Computed statistics are based on the asymptotic chi-square distribution of the Wald statistic.

There is no limit to the number of CONTRAST statements that you can specify, but they must appear after the MODEL statement.

The following parameters are specified in the CONTRAST statement:

- label* identifies the contrast on the output. A label is required for every contrast specified, and it must be enclosed in quotes.
- effect* identifies an effect that appears in the MODEL statement. The name INTERCEPT can be used as an effect when one or more intercepts are included in the model. You do not need to include all effects that are included in the MODEL statement.
- values* are constants that are elements of the \mathbf{L} matrix associated with the effect. To correctly specify your contrast, it is crucial to know the ordering of parameters within each effect and the variable levels associated with any parameter. The “Class Level Information” table shows the ordering of levels within variables. The E option, described later in this section, enables you to verify the proper correspondence of *values* to parameters.

The rows of \mathbf{L} are specified in order and are separated by commas. Multiple degree-of-freedom hypotheses can be tested by specifying multiple *row-descriptions*. For any of the full-rank parameterizations, if an effect is not specified in the CONTRAST statement, all of its coefficients in the \mathbf{L} matrix are set to 0. If too many values are specified for an effect, the extra ones are ignored. If too few values are specified, the remaining ones are set to 0.

When you use effect coding (by default or by specifying PARAM=EFFECT in the CLASS statement), all parameters are directly estimable (involve no other parameters). For example, suppose an effect coded CLASS variable A has four levels. Then there are three parameters ($\alpha_1, \alpha_2, \alpha_3$) representing the first three levels, and the fourth parameter is represented by

$$-\alpha_1 - \alpha_2 - \alpha_3$$

To test the first versus the fourth level of A, you would test

$$\alpha_1 = -\alpha_1 - \alpha_2 - \alpha_3$$

or, equivalently,

$$2\alpha_1 + \alpha_2 + \alpha_3 = 0$$

which, in the form $\mathbf{L}\theta = \mathbf{0}$, is

$$\begin{bmatrix} 2 & 1 & 1 \end{bmatrix} \begin{bmatrix} \alpha_1 \\ \alpha_2 \\ \alpha_3 \end{bmatrix} = 0$$

Therefore, you would use the following CONTRAST statement:

```
contrast '1 vs. 4' A 2 1 1;
```

To contrast the third level with the average of the first two levels, you would test

$$\frac{\alpha_1 + \alpha_2}{2} = \alpha_3$$

or, equivalently,

$$\alpha_1 + \alpha_2 - 2\alpha_3 = 0$$

Therefore, you would use the following CONTRAST statement:

```
contrast '1&2 vs. 3' A 1 1 -2;
```

Other CONTRAST statements are constructed similarly. For example,

```
contrast '1 vs. 2' A 1 -1 0;
contrast '1&2 vs. 4' A 3 3 2;
contrast '1&2 vs. 3&4' A 2 2 0;
contrast 'Main Effect' A 1 0 0,
                    A 0 1 0,
                    A 0 0 1;
```

When you use the less-than-full-rank parameterization (by specifying PARAM=GLM in the CLASS statement), each row is checked for estimability. If PROC LOGISTIC finds a contrast to be nonestimable, it displays missing values in corresponding rows in the results. PROC LOGISTIC handles missing level combinations of classification variables in the same manner as PROC GLM. Parameters corresponding to missing level combinations are not included in the model. This convention can affect the way in which you specify the **L** matrix in your CONTRAST statement. If the elements of **L** are not specified for an effect that contains a specified effect, then the elements of the specified effect are distributed over the levels of the higher-order effect just as the GLM procedure does for its CONTRAST and ESTIMATE statements. For example, suppose that the model contains effects A and B and their interaction A*B. If you specify a CONTRAST statement involving A alone, the **L** matrix contains nonzero terms for both A and A*B, since A*B contains A.

The degrees of freedom is the number of linearly independent constraints implied by the CONTRAST statement, that is, the rank of **L**.

You can specify the following options after a slash (/).

ALPHA= α

specifies the level of significance α for the $100(1 - \alpha)\%$ confidence interval for each contrast when the ESTIMATE option is specified. The value α must be between 0 and 1. By default, α is equal to the value of the ALPHA= option in the PROC LOGISTIC statement, or 0.05 if that option is not specified.

E

displays the **L** matrix.

ESTIMATE=keyword

requests that each individual contrast (that is, each row, $l'_i\theta$, of **L** θ) or exponentiated contrast ($e^{l'_i\theta}$) be estimated and tested. PROC LOGISTIC displays the point estimate, its standard error, a Wald confidence interval, and a Wald chi-square test for each contrast. The significance level of the confidence interval is controlled by the ALPHA= option. You can estimate the contrast or the exponentiated contrast ($e^{l'_i\theta}$), or both, by specifying one of the following *keywords*:

PARM	specifies that the contrast itself be estimated
EXP	specifies that the exponentiated contrast be estimated
BOTH	specifies that both the contrast and the exponentiated contrast be estimated

SINGULAR = number

tunes the estimability check. This option is ignored when the full-rank parameterization is used. If v is a vector, define $ABS(v)$ to be the largest absolute value of the elements of v . For a row vector l' of the contrast matrix **L**, define c to be equal to $ABS(l)$ if $ABS(l)$ is greater than 0; otherwise, c equals 1. If $ABS(l' - l'T)$ is greater than $c * number$, then l is declared nonestimable. The **T** matrix is the Hermite form matrix $I_0^- I_0$, where I_0^- represents a generalized inverse of the information matrix I_0 of the null model. The value for *number* must be between 0 and 1; the default value is 1E-4.

EXACT Statement

EXACT <'label'>< Intercept >< effects >< / options > ;

The EXACT statement performs exact tests of the parameters for the specified effects and optionally estimates the parameters and outputs the exact conditional distributions. You can specify the keyword INTERCEPT and any effects in the MODEL statement. Inference on the parameters of the specified effects is performed by conditioning on the sufficient statistics of all the other model parameters (possibly including the intercept).

You can specify several EXACT statements, but they must follow the MODEL statement. Each statement can optionally include an identifying label. If several EXACT statements are specified, any statement without a label will be assigned a label of the form "Exact n ", where " n " indicates the n th EXACT statement. The label is included in the headers of the displayed exact analysis tables.

If a **STRATA** statement is also specified, then a stratified exact conditional logistic regression is performed. The model contains a different intercept for each stratum, and these intercepts are conditioned out of the model along with any other nuisance parameters (essentially, any parameters specified in the **MODEL** statement which are not in the **EXACT** statement).

If the **LINK=GLOGIT** option is specified in the **MODEL** statement, then the **EXACTOPTION** option **METHOD=DIRECT** is invoked by default and a generalized logit model is fit. Since each effect specified in the **MODEL** statement adds k parameters to the model (where $k + 1$ is the number of response levels), exact analysis of the generalized logit model using this method is limited to rather small problems.

The **CONTRAST**, **OUTPUT**, **SCORE**, **TEST**, and **UNITS** statements are not available with an exact analysis. Exact analyses are not performed when you specify a **WEIGHT** statement, a link other than **LINK=LOGIT** or **LINK=GLOGIT**, an offset variable, the **NOFIT** option, or a model-selection method. Exact estimation is not available for ordinal response models.

The following options can be specified in each **EXACT** statement after a slash (/):

ALPHA= α

specifies the level of significance α for $100(1 - \alpha)\%$ confidence limits for the parameters or odds ratios. The value α must be between 0 and 1. By default, α is equal to the value of the **ALPHA=** option in the **PROC LOGISTIC** statement, or 0.05 if that option is not specified.

ESTIMATE < =keyword >

estimates the individual parameters (conditional on all other parameters) for the effects specified in the **EXACT** statement. For each parameter, a point estimate, a confidence interval, and a p -value for a two-sided test that the parameter is zero are displayed. Note that the two-sided p -value is twice the one-sided p -value. You can optionally specify one of the following keywords:

PARM specifies that the parameters be estimated. This is the default.

ODDS specifies that the odds ratios be estimated. For classification variables, use of the reference parameterization is recommended.

BOTH specifies that the parameters and odds ratios be estimated

JOINT

performs the joint test that all of the parameters are simultaneously equal to zero, individual hypothesis tests for the parameter of each continuous variable, and joint tests for the parameters of each classification variable. The joint test is indicated in the “Conditional Exact Tests” table by the label “Joint.”

JOINTONLY

performs only the joint test of the parameters. The test is indicated in the “Conditional Exact Tests” table by the label “Joint.” When this option is specified, individual tests for the parameters of each continuous variable and joint tests for the parameters of the classification variables are not performed.

CLTYPE=EXACT | MIDP

requests either the exact or mid- p confidence intervals for the parameter estimates. By default, the exact intervals are produced. The confidence coefficient can be specified with the `ALPHA=` option. The mid- p interval can be modified with the `MIDPFACTOR=` option. See the “[Inference for a Single Parameter](#)” section on page 2373 for details.

MIDPFACTOR= δ_1 | (δ_1, δ_2)

sets the tie factors used to produce the mid- p hypothesis statistics and the mid- p confidence intervals. δ_1 modifies both the hypothesis tests and confidence intervals, while δ_2 affects only the hypothesis tests. By default, $\delta_1 = 0.5$ and $\delta_2 = 1.0$. See the “[Hypothesis Tests](#)” section on page 2371 and the “[Inference for a Single Parameter](#)” section on page 2373 for details.

ONESIDED

requests one-sided confidence intervals and p -values for the individual parameter estimates and odds ratios. The one-sided p -value is the smaller of the left and right tail probabilities for the observed sufficient statistic of the parameter under the null hypothesis that the parameter is zero. The two-sided p -values (default) are twice the one-sided p -values. See the “[Inference for a Single Parameter](#)” section on page 2373 for more details.

OUTDIST=SAS-data-set

names the SAS data set containing the exact conditional distributions. This data set contains all of the exact conditional distributions required to process the corresponding EXACT statement. The data set contains the possible sufficient statistics for the parameters of the effects specified in the EXACT statement, the counts, and, when hypothesis tests are performed on the parameters, the probability of occurrence and the score value for each sufficient statistic. When you request an OUTDIST= data set, the observed sufficient statistics are displayed in the “Sufficient Statistics” table. See the “[OUTDIST= Output Data Set](#)” section on page 2377 for more information.

EXACT Statement Examples

- In the following example, two exact tests are computed: one for `x1` and the other for `x2`. The test for `x1` is based on the exact conditional distribution of the sufficient statistic for the `x1` parameter given the observed values of the sufficient statistics for the intercept, `x2`, and `x3` parameters; likewise, the test for `x2` is conditional on the observed sufficient statistics for the intercept, `x1`, and `x3`:

```
proc logistic;
  model y= x1 x2 x3;
  exact 'lab1' x1 x2;
run;
```

- You can specify multiple EXACT statements in the same PROC LOGISTIC invocation. PROC LOGISTIC determines, from all the EXACT statements, the distinct conditional distributions that need to be evaluated. For example, there is only one exact conditional distribution for the following two EXACT

statements, and it would be a waste of resources to compute the same exact conditional distribution twice:

```
exact 'One' x1 / estimate=parm;
exact 'Two' x1 / estimate=parm onesided;
```

- For each EXACT statement, individual tests for the parameters of the specified effects are computed unless the JOINTONLY option is specified. Consider the following EXACT statements:

```
exact 'E12' x1 x2 / estimate;
exact 'E1'  x1    / estimate;
exact 'E2'  x2    / estimate;
exact 'J12' x1 x2 / joint;
```

In the E12 statement, the parameters for *x1* and *x2* are estimated and tested separately. Specifying the E12 statement is equivalent to specifying both the E1 and E2 statements. In the J12 statement, the joint test for the parameters of *x1* and *x2* is computed as well as the individual tests for *x1* and *x2*.

All exact conditional distributions for the tests and estimates computed in a single EXACT statement are output to the corresponding OUTDIST= data set. For example, consider the following EXACT statements:

```
exact 'O1'  x1    / outdist=o1;
exact 'OJ12' x1 x2 / jointonly outdist=oj12;
exact 'OA12' x1 x2 / joint outdist=oa12;
exact 'OE12' x1 x2 / estimate outdist=oe12;
```

The O1 statement outputs a single exact conditional distribution. The OJ12 statement outputs only the joint distribution for *x1* and *x2*. The OA12 statement outputs three conditional distributions: one for *x1*, one for *x2*, and one jointly for *x1* and *x2*. The OE12 statement outputs two conditional distributions: one for *x1* and the other for *x2*. Data set *oe12* contains both the *x1* and *x2* variables; the distribution for *x1* has missing values in the *x2* column while the distribution for *x2* has missing values in the *x1* column.

See the “OUTDIST= Output Data Set” section on page 2377 for more information.

FREQ Statement

FREQ *variable* ;

The *variable* in the FREQ statement identifies a variable that contains the frequency of occurrence of each observation. PROC LOGISTIC treats each observation as if it appears *n* times, where *n* is the value of the FREQ variable for the observation. If it is not an integer, the frequency value is truncated to an integer. If the frequency value is less than 1 or missing, the observation is not used in the model fitting. When the FREQ statement is not specified, each observation is assigned a frequency of 1.

If a SCORE statement is specified, then the FREQ variable is used for computing fit statistics and the ROC curve, but they are not required for scoring. If the DATA= data

set in the SCORE statement does not contain the FREQ variable, the frequency values are assumed to be 1 and a warning message is issued in the LOG. If you fit a model and perform the scoring in the same run, the same FREQ variable is used for fitting and scoring. If you fit a model in a previous run and input it with the `INMODEL=` option in the current run, then the FREQ variable can be different from the one used in the previous run; however, if a FREQ variable was not specified in the previous run you can still specify a FREQ variable in the current run.

MODEL Statement

MODEL *events/trials*= < *effects* >< / *options* > ;

MODEL *variable* < (*variable_options*) >= < *effects* >< / *options* > ;

The MODEL statement names the response variable and the explanatory effects, including covariates, main effects, interactions, and nested effects; see the section “Specification of Effects” on page 1784 of Chapter 32, “The GLM Procedure,” for more information. If you omit the explanatory effects, the procedure fits an intercept-only model. [Model options](#) can be specified after a slash (/).

Two forms of the MODEL statement can be specified. The first form, referred to as *single-trial* syntax, is applicable to binary, ordinal, and nominal response data. The second form, referred to as *events/trials* syntax, is restricted to the case of binary response data. The *single-trial* syntax is used when each observation in the DATA= data set contains information on only a single trial, for instance, a single subject in an experiment. When each observation contains information on multiple binary-response trials, such as the counts of the number of subjects observed and the number responding, then *events/trials* syntax can be used.

In the *events/trials* syntax, you specify two variables that contain count data for a binomial experiment. These two variables are separated by a slash. The value of the first variable, *events*, is the number of positive responses (or events). The value of the second variable, *trials*, is the number of trials. The values of both *events* and (*trials*–*events*) must be nonnegative and the value of *trials* must be positive for the response to be valid.

In the *single-trial* syntax, you specify one variable (on the left side of the equal sign) as the response variable. This variable can be character or numeric. [Options](#) specific to the response variable can be specified immediately after the response variable with a pair of parentheses around them.

For both forms of the MODEL statement, explanatory *effects* follow the equal sign. Variables can be either continuous or classification variables. Classification variables can be character or numeric, and they must be declared in the CLASS statement. When an effect is a classification variable, the procedure enters a set of coded columns into the design matrix instead of directly entering a single column containing the values of the variable.

Response Variable Options

You can specify the following options by enclosing them in a pair of parentheses after the response variable.

DESCENDING | DESC

reverses the order of the response categories. If both the DESCENDING and ORDER= options are specified, PROC LOGISTIC orders the response categories according to the ORDER= option and then reverses that order. See the “[Response Level Ordering](#)” section on page 2329 for more detail.

EVENT='category' | keyword

specifies the event category for the binary response model. PROC LOGISTIC models the probability of the event category. The EVENT= option has no effect when there are more than two response categories. You can specify the value (formatted if a format is applied) of the event category in quotes or you can specify one of the following keywords. The default is EVENT=FIRST.

FIRST designates the first ordered category as the event

LAST designates the last ordered category as the event

One of the most common sets of response levels is {0,1}, with 1 representing the event for which the probability is to be modeled. Consider the example where Y takes the values 1 and 0 for event and nonevent, respectively, and Exposure is the explanatory variable. To specify the value 1 as the event category, use the MODEL statement

```
model Y(event='1') = Exposure;
```

ORDER= DATA | FORMATTED | FREQ | INTERNAL

specifies the sorting order for the levels of the response variable. By default, ORDER=FORMATTED. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine dependent. When ORDER=FORMATTED is in effect for numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values.

The following table shows the interpretation of the ORDER= values.

Value of ORDER=	Levels Sorted By
DATA	order of appearance in the input data set
FORMATTED	external formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ	descending frequency count; levels with the most observations come first in the order
INTERNAL	unformatted value

For more information on sorting order, see the chapter on the SORT procedure in the *SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

REFERENCE='category' | keyword

REF='category' | keyword

specifies the reference category for the generalized logit model and the binary response model. For the generalized logit model, each nonreference category is contrasted with the reference category. For the binary response model, specifying one response category as the reference is the same as specifying the other response category as the event category. You can specify the value (formatted if a format is applied) of the reference category in quotes or you can specify one of the following keywords. The default is REF=LAST.

FIRST	designates the first ordered category as the reference
LAST	designates the last ordered category as the reference

Model Options

Table 42.1 summarizes the options available in the MODEL statement, which can be specified after a slash (/).

Table 42.1. Model Statement Options

Option	Description
Model Specification Options	
LINK=	specifies link function
NOINT	suppresses intercept
NOFIT	suppresses model fitting
OFFSET=	specifies offset variable
SELECTION=	specifies effect selection method
Effect Selection Options	
BEST=	controls the number of models displayed for SCORE selection
DETAILS	requests detailed results at each step
FAST	uses fast elimination method
HIERARCHY=	specifies whether and how hierarchy is maintained and whether a single effect or multiple effects are allowed to enter or leave the model per step
INCLUDE=	specifies number of effects included in every model
MAXSTEP=	specifies maximum number of steps for STEPWISE selection
SEQUENTIAL	adds or deletes effects in sequential order
SLENTRY=	specifies significance level for entering effects
SLSTAY=	specifies significance level for removing effects
START=	specifies number of variables in first model
STOP=	specifies number of variables in final model
STOPRES	adds or deletes variables by residual chi-square criterion
Model-Fitting Specification Options	
ABSFCNV=	specifies absolute function convergence criterion
FCONV=	specifies relative function convergence criterion
GCONV=	specifies relative gradient convergence criterion

Table 42.1. (continued)

Option	Description
XCONV=	specifies relative parameter convergence criterion
MAXFUNCTION=	specifies maximum number of function calls for the conditional analysis
MAXITER=	specifies maximum number of iterations
NOCHECK	suppresses checking for infinite parameters
RIDGING=	specifies the technique used to improve the log-likelihood function when its value is worse than that of the previous step
SINGULAR=	specifies tolerance for testing singularity
TECHNIQUE=	specifies iterative algorithm for maximization
Options for Confidence Intervals	
ALPHA=	specifies α for the $100(1 - \alpha)\%$ confidence intervals
CLPARAM=	computes confidence intervals for parameters
CLODDS=	computes confidence intervals for odds ratios
PLCONV=	specifies profile likelihood convergence criterion
Options for Classifying Observations	
CTABLE	displays classification table
PEVENT=	specifies prior event probabilities
PPROB=	specifies probability cutpoints for classification
Options for Overdispersion and Goodness-of-Fit Tests	
AGGREGATE=	determines subpopulations for Pearson chi-square and deviance
SCALE=	specifies method to correct overdispersion
LACKFIT	requests Hosmer and Lemeshow goodness-of-fit test
Options for ROC Curves	
OUTROC=	names the output data set
ROCEPS=	specifies probability grouping criterion
Options for Regression Diagnostics	
INFLUENCE	displays influence statistics
IPLOTS	requests index plots
Options for Display of Details	
CORRB	displays correlation matrix
COVB	displays covariance matrix
EXPB	displays exponentiated values of estimates
ITPRINT	displays iteration history
NODUMMYPRINT	suppresses “Class Level Information” table
PARMLABEL	displays parameter labels
RSQUARE	displays generalized R^2
STB	displays standardized estimates
Computational Options	
NOLOGSCALE	performs calculations using normal scaling

The following list describes these options.

ABSFCONV=value

specifies the absolute function convergence criterion. Convergence requires a small change in the log-likelihood function in subsequent iterations,

$$|l_i - l_{i-1}| < value$$

where l_i is the value of the log-likelihood function at iteration i . See the section “Convergence Criteria” on page 2338.

AGGREGATE**AGGREGATE=** (*variable-list*)

specifies the subpopulations on which the Pearson chi-square test statistic and the likelihood ratio chi-square test statistic (deviance) are calculated. Observations with common values in the given list of variables are regarded as coming from the same subpopulation. Variables in the list can be any variables in the input data set. Specifying the AGGREGATE option is equivalent to specifying the AGGREGATE= option with a variable list that includes all explanatory variables in the MODEL statement. The deviance and Pearson goodness-of-fit statistics are calculated only when the SCALE= option is specified. Thus, the AGGREGATE (or AGGREGATE=) option has no effect if the SCALE= option is not specified. See the section “Rescaling the Covariance Matrix” on page 2354 for more detail.

ALPHA=α

sets the level of significance α for $100(1 - \alpha)\%$ confidence intervals for regression parameters or odds ratios. The value α must be between 0 and 1. By default, α is equal to the value of the ALPHA= option in the PROC LOGISTIC statement, or 0.05 if the option is not specified. This option has no effect unless confidence limits for the parameters or odds ratios are requested.

BEST=n

specifies that n models with the highest score chi-square statistics are to be displayed for each model size. It is used exclusively with the SCORE model selection method. If the BEST= option is omitted and there are no more than ten explanatory variables, then all possible models are listed for each model size. If the option is omitted and there are more than ten explanatory variables, then the number of models selected for each model size is, at most, equal to the number of explanatory variables listed in the MODEL statement.

CLODDS=PL | WALD | BOTH

requests confidence intervals for the odds ratios. Computation of these confidence intervals is based on the profile likelihood (CLODDS=PL) or based on individual Wald tests (CLODDS=WALD). By specifying CLODDS=BOTH, the procedure computes two sets of confidence intervals for the odds ratios, one based on the profile likelihood and the other based on the Wald tests. The confidence coefficient can be specified with the ALPHA= option.

CLPARM=PL | WALD | BOTH

requests confidence intervals for the parameters. Computation of these confidence intervals is based on the profile likelihood (CLPARM=PL) or individual Wald tests (CLPARM=WALD). By specifying CLPARM=BOTH, the procedure computes two sets of confidence intervals for the parameters, one based on the profile likelihood and the other based on individual Wald tests. The confidence coefficient can be specified with the ALPHA= option. See the “[Confidence Intervals for Parameters](#)” section on page 2345 for more information.

CORRB

displays the correlation matrix of the parameter estimates.

COVB

displays the covariance matrix of the parameter estimates.

CTABLE

classifies the input binary response observations according to whether the predicted event probabilities are above or below some cutpoint value z in the range $(0, 1)$. An observation is predicted as an event if the predicted event probability exceeds z . You can supply a list of cutpoints other than the default list by using the [PPROB= option](#) (page 2315). The CTABLE option is ignored if the data have more than two response levels. Also, false positive and negative rates can be computed as posterior probabilities using Bayes’ theorem. You can use the [PEVENT=](#) option to specify prior probabilities for computing these rates. For more information, see the “[Classification Table](#)” section on page 2352.

DETAILS

produces a summary of computational details for each step of the effect selection process. It produces the “Analysis of Effects Not in the Model” table before displaying the effect selected for entry for FORWARD or STEPWISE selection. For each model fitted, it produces the “Type 3 Analysis of Effects” table if the fitted model involves CLASS variables, the “Analysis of Maximum Likelihood Estimates” table, and measures of association between predicted probabilities and observed responses. For the statistics included in these tables, see the “[Displayed Output](#)” section on page 2381. The DETAILS option has no effect when SELECTION=NONE.

EXPB**EXPEST**

displays the exponentiated values ($e^{\hat{\beta}_i}$) of the parameter estimates $\hat{\beta}_i$ in the “Analysis of Maximum Likelihood Estimates” table for the logit model. These exponentiated values are the estimated odds ratios for the parameters corresponding to the continuous explanatory variables.

FAST

uses a computational algorithm of Lawless and Singhal (1978) to compute a first-order approximation to the remaining slope estimates for each subsequent elimination of a variable from the model. Variables are removed from the model based on these approximate estimates. The FAST option is extremely efficient because the model is not refitted for every variable removed. The FAST option is used when SELECTION=BACKWARD and in the backward elimina-

tion steps when SELECTION=STEPWISE. The FAST option is ignored when SELECTION=FORWARD or SELECTION=NONE.

FCNV=value

specifies the relative function convergence criterion. Convergence requires a small relative change in the log-likelihood function in subsequent iterations,

$$\frac{|l_i - l_{i-1}|}{|l_{i-1}| + 1\text{E}-6} < \text{value}$$

where l_i is the value of the log likelihood at iteration i . See the section “[Convergence Criteria](#)” on page 2338.

GCONV=value

specifies the relative gradient convergence criterion. Convergence requires that the normalized prediction function reduction is small,

$$\frac{\mathbf{g}_i' \mathbf{I}_i \mathbf{g}_i}{|l_i| + 1\text{E}-6} < \text{value}$$

where l_i is the value of the log-likelihood function, \mathbf{g}_i is the gradient vector, and \mathbf{I}_i is the (expected) information matrix, all at iteration i . This is the default convergence criterion, and the default value is 1E-8. See the section “[Convergence Criteria](#)” on page 2338.

HIERARCHY=keyword**HIER=keyword**

specifies whether and how the model hierarchy requirement is applied and whether a single effect or multiple effects are allowed to enter or leave the model in one step. You can specify that only CLASS effects, or both CLASS and interval effects, be subject to the hierarchy requirement. The HIERARCHY= option is ignored unless you also specify one of the following options: SELECTION=FORWARD, SELECTION=BACKWARD, or SELECTION=STEPWISE.

Model hierarchy refers to the requirement that, for any term to be in the model, all effects contained in the term must be present in the model. For example, in order for the interaction A*B to enter the model, the main effects A and B must be in the model. Likewise, neither effect A nor B can leave the model while the interaction A*B is in the model.

The keywords you can specify in the HIERARCHY= option are as follows:

NONE	Model hierarchy is not maintained. Any single effect can enter or leave the model at any given step of the selection process.
SINGLE	Only one effect can enter or leave the model at one time, subject to the model hierarchy requirement. For example, suppose that you specify the main effects A and B and the interaction A*B in the model. In the first step of the selection process, either A or B can enter the model. In the second step, the other main effect can enter

the model. The interaction effect can enter the model only when both main effects have already been entered. Also, before A or B can be removed from the model, the A*B interaction must first be removed. All effects (CLASS and interval) are subject to the hierarchy requirement.

SINGLECLASS This is the same as **HIERARCHY=SINGLE** except that only CLASS effects are subject to the hierarchy requirement.

MULTIPLE More than one effect can enter or leave the model at one time, subject to the model hierarchy requirement. In a forward selection step, a single main effect can enter the model, or an interaction can enter the model together with all the effects that are contained in the interaction. In a backward elimination step, an interaction itself, or the interaction together with all the effects that the interaction contains, can be removed. All effects (CLASS and interval) are subject to the hierarchy requirement.

MULTIPLECLASS This is the same as **HIERARCHY=MULTIPLE** except that only CLASS effects are subject to the hierarchy requirement.

The default value is **HIERARCHY=SINGLE**, which means that model hierarchy is to be maintained for all effects (that is, both CLASS and interval effects) and that only a single effect can enter or leave the model at each step.

INCLUDE=*n*

includes the first *n* effects in the MODEL statement in every model. By default, **INCLUDE=0**. The **INCLUDE=** option has no effect when **SELECTION=NONE**.

Note that the **INCLUDE=** and **START=** options perform different tasks: the **INCLUDE=** option includes the first *n* effects variables in every model, whereas the **START=** option only requires that the first *n* effects appear in the first model.

INFLUENCE

displays diagnostic measures for identifying influential observations in the case of a binary response model. It has no effect otherwise. For each observation, the **INFLUENCE** option displays the case number (which is the sequence number of the observation), the values of the explanatory variables included in the final model, and the regression diagnostic measures developed by Pregibon (1981). For a discussion of these diagnostic measures, see the “[Regression Diagnostics](#)” section on page 2359. When a **STRATA** statement is specified, the diagnostics are computed following Storer and Crowley (1985); see the “[Regression Diagnostic Details](#)” section on page 2367 for details.

IPLOTS

produces an index plot for each regression diagnostic statistic. An index plot is a scatterplot with the regression diagnostic statistic represented on the y-axis and the case number on the x-axis. See [Example 42.6](#) on page 2422 for an illustration.

ITPRINT

displays the iteration history of the maximum-likelihood model fitting. The ITPRINT option also displays the last evaluation of the gradient vector and the final change in the -2 Log Likelihood.

LACKFIT**LACKFIT**<(n)>

performs the Hosmer and Lemeshow goodness-of-fit test (Hosmer and Lemeshow 2000) for the case of a binary response model. The subjects are divided into approximately ten groups of roughly the same size based on the percentiles of the estimated probabilities. The discrepancies between the observed and expected number of observations in these groups are summarized by the Pearson chi-square statistic, which is then compared to a chi-square distribution with t degrees of freedom, where t is the number of groups minus n . By default, $n=2$. A small p -value suggests that the fitted model is not an adequate model. See the “[The Hosmer-Lemeshow Goodness-of-Fit Test](#)” section on page 2356 for more information.

LINK=keyword**L=keyword**

specifies the link function linking the response probabilities to the linear predictors. You can specify one of the following keywords. The default is LINK=LOGIT.

CLOGLOG	the complementary log-log function. PROC LOGISTIC fits the binary complementary log-log model when there are two response categories and fits the cumulative complementary log-log model when there are more than two response categories. Aliases: CCLOGLOG, CCLL, CUMCLOGLOG.
GLOGIT	the generalized logit function. PROC LOGISTIC fits the generalized logit model where each nonreference category is contrasted with the reference category. You can use the response variable option REF= to specify the reference category.
LOGIT	the log odds function. PROC LOGISTIC fits the binary logit model when there are two response categories and fits the cumulative logit model when there are more than two response categories. Aliases: CLOGIT, CUMLOGIT.
PROBIT	the inverse standard normal distribution function. PROC LOGISTIC fits the binary probit model when there are two response categories and fits the cumulative probit model when there are more than two response categories. Aliases: NORMIT, CPROBIT, CUMPROBIT.

See the section “[Link Functions and the Corresponding Distributions](#)” on page 2334 for details.

MAXFUNCTION=*n*

specifies the maximum number of function calls to perform when maximizing the conditional likelihood. This option is only valid when a **STRATA** statement is specified. The default values are

- 125 when the number of parameters $p < 40$
- 500 when $40 \leq p < 400$
- 1000 when $p \geq 400$

Since the optimization is terminated only after completing a full iteration, the number of function calls that are actually performed can exceed n . If convergence is not attained, the displayed output and all output data sets created by the procedure contain results based on the last maximum likelihood iteration.

MAXITER=*n*

specifies the maximum number of iterations to perform. By default, **MAXITER=25**. If convergence is not attained in n iterations, the displayed output and all output data sets created by the procedure contain results that are based on the last maximum likelihood iteration.

MAXSTEP=*n*

specifies the maximum number of times any explanatory variable is added to or removed from the model when **SELECTION=STEPWISE**. The default number is twice the number of explanatory variables in the **MODEL** statement. When the **MAXSTEP=** limit is reached, the stepwise selection process is terminated. All statistics displayed by the procedure (and included in output data sets) are based on the last model fitted. The **MAXSTEP=** option has no effect when **SELECTION=NONE**, **FORWARD**, or **BACKWARD**.

NOCHECK

disables the checking process to determine whether maximum likelihood estimates of the regression parameters exist. If you are sure that the estimates are finite, this option can reduce the execution time if the estimation takes more than eight iterations. For more information, see the “[Existence of Maximum Likelihood Estimates](#)” section on page 2338.

NODUMMYPRINT**NODESIGNPRINT****NODP**

suppresses the “Class Level Information” table, which shows how the design matrix columns for the **CLASS** variables are coded.

NOINT

suppresses the intercept for the binary response model, the first intercept for the ordinal response model (which forces all intercepts to be nonnegative), or all intercepts for the generalized logit model. This can be particularly useful in conditional logistic analysis; see [Example 42.10](#) on page 2443.

NOFIT

performs the global score test without fitting the model. The global score test evaluates the joint significance of the effects in the MODEL statement. No further analyses are performed. If the NOFIT option is specified along with other MODEL statement options, NOFIT takes effect and all other options except LINK=, TECHNIQUE=, and OFFSET= are ignored.

NOLOGSCALE

specifies that computations for the conditional and exact conditional logistic model should be computed using normal scaling. Log-scaling can handle numerically larger problems than normal scaling; however, computations in the log-scale are slower than computations in normal-scale.

OFFSET= *name*

names the offset variable. The regression coefficient for this variable will be fixed at 1.

OUTROC=SAS-*data-set***OUTR=SAS-*data-set***

creates, for binary response models, an output SAS data set that contains the data necessary to produce the receiver operating characteristic (ROC) curve. See the section “[OUTROC= Output Data Set](#)” on page 2378 for the list of variables in this data set.

PARMLABEL

displays the labels of the parameters in the “Analysis of Maximum Likelihood Estimates” table.

PEVENT= *value***PEVENT= (*list*)**

specifies one prior probability or a list of prior probabilities for the event of interest. The false positive and false negative rates are then computed as posterior probabilities by Bayes’ theorem. The prior probability is also used in computing the rate of correct prediction. For each prior probability in the given list, a classification table of all observations is computed. By default, the prior probability is the total sample proportion of events. The PEVENT= option is useful for stratified samples. It has no effect if the CTABLE option is not specified. For more information, see the section “[False Positive and Negative Rates Using Bayes’ Theorem](#)” on page 2353. Also see the [PPROB= option](#) for information on how the *list* is specified.

PLCL

is the same as specifying [CLPARM=PL](#).

PLCONV= *value*

controls the convergence criterion for confidence intervals based on the profile likelihood function. The quantity *value* must be a positive number, with a default value of 1E–4. The PLCONV= option has no effect if profile likelihood confidence intervals ([CLPARM=PL](#)) are not requested.

PLRL

is the same as specifying **CLODDS=PL**.

PPROB=value**PPROB= (list)**

specifies one critical probability value (or cutpoint) or a list of critical probability values for classifying observations with the **CTABLE** option. Each *value* must be between 0 and 1. A response that has a cross validated predicted probability greater than or equal to the current **PPROB=** value is classified as an event response. The **PPROB=** option is ignored if the **CTABLE** option is not specified.

A classification table for each of several cutpoints can be requested by specifying a list. For example,

```
pprob= (0.3, 0.5 to 0.8 by 0.1)
```

requests a classification of the observations for each of the cutpoints 0.3, 0.5, 0.6, 0.7, and 0.8. If the **PPROB=** option is not specified, the default is to display the classification for a range of probabilities from the smallest estimated probability (rounded down to the nearest 0.02) to the highest estimated probability (rounded up to the nearest 0.02) with 0.02 increments.

RIDGING=ABSOLUTE | RELATIVE | NONE

specifies the technique used to improve the log-likelihood function when its value in the current iteration is less than that in the previous iteration. If you specify the **RIDGING=ABSOLUTE** option, the diagonal elements of the negative (expected) Hessian are inflated by adding the ridge value. If you specify the **RIDGING=RELATIVE** option, the diagonal elements are inflated by a factor of 1 plus the ridge value. If you specify the **RIDGING=NONE** option, the crude line search method of taking half a step is used instead of ridging. By default, **RIDGING=RELATIVE**.

RISKLIMITS**RL****WALDRL**

is the same as specifying **CLODDS=WALD**.

ROCEPS= number

specifies the criterion for grouping estimated event probabilities that are close to each other for the ROC curve. In each group, the difference between the largest and the smallest estimated event probabilities does not exceed the given value. The value for *number* must be between 0 and 1; the default value is $1E-4$. The smallest estimated probability in each group serves as a cutpoint for predicting an event response. The **ROCEPS=** option has no effect if the **OUTROC=** option is not specified.

RSQUARE**RSQ**

requests a generalized R^2 measure for the fitted model. For more information, see the “[Generalized Coefficient of Determination](#)” section on page 2342.

SCALE= *scale*

enables you to supply the value of the dispersion parameter or to specify the method for estimating the dispersion parameter. It also enables you to display the “Deviance and Pearson Goodness-of-Fit Statistics” table. To correct for overdispersion or underdispersion, the covariance matrix is multiplied by the estimate of the dispersion parameter. Valid values for *scale* are as follows:

D DEVIANCE	specifies that the dispersion parameter be estimated by the deviance divided by its degrees of freedom.
P PEARSON	specifies that the dispersion parameter be estimated by the Pearson chi-square statistic divided by its degrees of freedom.
WILLIAMS <(constant)>	specifies that Williams’ method be used to model overdispersion. This option can be used only with the <i>events/trials</i> syntax. An optional <i>constant</i> can be specified as the scale parameter; otherwise, a scale parameter is estimated under the full model. A set of weights is created based on this scale parameter estimate. These weights can then be used in fitting subsequent models of fewer terms than the full model. When fitting these submodels, specify the computed scale parameter as <i>constant</i> . See Example 42.9 on page 2438 for an illustration.
N NONE	specifies that no correction is needed for the dispersion parameter; that is, the dispersion parameter remains as 1. This specification is used for requesting the deviance and the Pearson chi-square statistic without adjusting for overdispersion.
<i>constant</i>	sets the estimate of the dispersion parameter to be the square of the given <i>constant</i> . For example, SCALE=2 sets the dispersion parameter to 4. The value <i>constant</i> must be a positive number.

You can use the [AGGREGATE](#) (or AGGREGATE=) option to define the subpopulations for calculating the Pearson chi-square statistic and the deviance. In the absence of the AGGREGATE (or AGGREGATE=) option, each observation is regarded as coming from a different subpopulation. For the *events/trials* syntax, each observation consists of *n* Bernoulli trials, where *n* is the value of the *trials* variable. For *single-trial* syntax, each observation consists of a single response, and for this setting it is not appropriate to carry out the Pearson or deviance goodness-of-fit analysis. Thus, PROC LOGISTIC ignores specifications SCALE=P, SCALE=D, and SCALE=N when *single-trial* syntax is specified without the AGGREGATE (or AGGREGATE=) option.

The “Deviance and Pearson Goodness-of-Fit Statistics” table includes the Pearson chi-square statistic, the deviance, their degrees of freedom, the ratio of each statistic

divided by its degrees of freedom, and the corresponding p -value. For more information, see the “[Overdispersion](#)” section on page 2354.

SELECTION=BACKWARD | B
| FORWARD | F
| NONE | N
| STEPWISE | S
| SCORE

specifies the method used to select the variables in the model. BACKWARD requests backward elimination, FORWARD requests forward selection, NONE fits the complete model specified in the MODEL statement, and STEPWISE requests stepwise selection. SCORE requests best subset selection. By default, SELECTION=NONE. For more information, see the “[Effect Selection Methods](#)” section on page 2340.

SEQUENTIAL
SEQ

forces effects to be added to the model in the order specified in the MODEL statement or eliminated from the model in the reverse order specified in the MODEL statement. The model-building process continues until the next effect to be added has an insignificant adjusted chi-square statistic or until the next effect to be deleted has a significant Wald chi-square statistic. The SEQUENTIAL option has no effect when SELECTION=NONE.

SINGULAR=value

specifies the tolerance for testing the singularity of the Hessian matrix (Newton-Raphson algorithm) or the expected value of the Hessian matrix (Fisher-scoring algorithm). The Hessian matrix is the matrix of second partial derivatives of the log-likelihood function. The test requires that a pivot for sweeping this matrix be at least this number times a norm of the matrix. Values of the SINGULAR= option must be numeric. By default, *value* is the machine epsilon times 10^7 , which is approximately 10^{-9} on most machines.

SLENTRY=value

SLE=value

specifies the significance level of the score chi-square for entering an effect into the model in the FORWARD or STEPWISE method. Values of the SLENTRY= option should be between 0 and 1, inclusive. By default, SLENTRY=0.05. The SLENTRY= option has no effect when SELECTION=NONE, SELECTION=BACKWARD, or SELECTION=SCORE.

SLSTAY=value

SLS=value

specifies the significance level of the Wald chi-square for an effect to stay in the model in a backward elimination step. Values of the SLSTAY= option should be between 0 and 1, inclusive. By default, SLSTAY=0.05. The SLSTAY= option has no effect when SELECTION=NONE, SELECTION=FORWARD, or SELECTION=SCORE.

START=*n*

begins the FORWARD, BACKWARD, or STEPWISE effect selection process with the first n effects listed in the MODEL statement. The value of n ranges from 0 to s , where s is the total number of effects in the MODEL statement. The default value of n is s for the BACKWARD method and 0 for the FORWARD and STEPWISE methods. Note that START= n specifies only that the first n effects appear in the first model, while INCLUDE= n requires that the first n effects be included in every model. For the SCORE method, START= n specifies that the smallest models contain n effects, where n ranges from 1 to s ; the default value is 1. The START= option has no effect when SELECTION=NONE.

STB

displays the standardized estimates for the parameters for the continuous explanatory variables in the “Analysis of Maximum Likelihood Estimates” table. The standardized estimate of β_i is given by $\hat{\beta}_i/(s/s_i)$, where s_i is the total sample standard deviation for the i th explanatory variable and

$$s = \begin{cases} \pi/\sqrt{3} & \text{Logistic} \\ 1 & \text{Normal} \\ \pi/\sqrt{6} & \text{Extreme-value} \end{cases}$$

For the intercept parameters and parameters associated with a CLASS variable, the standardized estimates are set to missing.

STOP=*n*

specifies the maximum (FORWARD method) or minimum (BACKWARD method) number of effects to be included in the final model. The effect selection process is stopped when n effects are found. The value of n ranges from 0 to s , where s is the total number of effects in the MODEL statement. The default value of n is s for the FORWARD method and 0 for the BACKWARD method. For the SCORE method, STOP= n specifies that the largest models contain n effects, where n ranges from 1 to s ; the default value of n is s . The STOP= option has no effect when SELECTION=NONE or STEPWISE.

STOPRES**SR**

specifies that the removal or entry of effects be based on the value of the residual chi-square. If SELECTION=FORWARD, then the STOPRES option adds the effects into the model one at a time until the residual chi-square becomes insignificant (until the p -value of the residual chi-square exceeds the SLENTRY= *value*). If SELECTION=BACKWARD, then the STOPRES option removes effects from the model one at a time until the residual chi-square becomes significant (until the p -value of the residual chi-square becomes less than the SLSTAY= *value*). The STOPRES option has no effect when SELECTION=NONE or SELECTION=STEPWISE.

TECHNIQUE=FISHER | NEWTON**TECH=FISHER | NEWTON**

specifies the optimization technique for estimating the regression parameters. NEWTON (or NR) is the Newton-Raphson algorithm and FISHER (or FS) is the

Fisher-scoring algorithm. Both techniques yield the same estimates, but the estimated covariance matrices are slightly different except for the case when the LOGIT link is specified for binary response data. The default is TECHNIQUE=FISHER. See the section “[Iterative Algorithms for Model-Fitting](#)” on page 2336 for details.

WALDCL**CL**

is the same as specifying `CLPARAM=WALD`.

XCONV=value

specifies the relative parameter convergence criterion. Convergence requires a small relative parameter change in subsequent iterations,

$$\max_j |\delta_j^{(i)}| < value$$

where

$$\delta_j^{(i)} = \begin{cases} \frac{\theta_j^{(i)} - \theta_j^{(i-1)}}{\theta_j^{(i-1)}} & |\theta_j^{(i-1)}| < 0.01 \\ \theta_j^{(i)} - \theta_j^{(i-1)} & \text{otherwise} \end{cases}$$

and $\theta_j^{(i)}$ is the estimate of the j th parameter at iteration i . See the section “[Convergence Criteria](#)” on page 2338.

OUTPUT Statement

OUTPUT < **OUT=SAS-data-set** > < *options* > ;

The OUTPUT statement creates a new SAS data set that contains all the variables in the input data set and, optionally, the estimated linear predictors and their standard error estimates, the estimates of the cumulative or individual response probabilities, and the confidence limits for the cumulative probabilities. Regression diagnostic statistics and estimates of cross validated response probabilities are also available for binary response models. Formulas for the statistics are given in the “[Linear Predictor, Predicted Probability, and Confidence Limits](#)” section on page 2350, the “[Regression Diagnostics](#)” section on page 2359, and, for conditional logistic regression, in the “[Conditional Logistic Regression](#)” section on page 2365.

If you use the *single-trial* syntax, the data set also contains a variable named `_LEVEL_`, which indicates the level of the response that the given row of output is referring to. For instance, the value of the cumulative probability variable is the probability that the response variable is as large as the corresponding value of `_LEVEL_`. For details, see the section “[OUT= Output Data Set in the OUTPUT Statement](#)” on page 2376.

The estimated linear predictor, its standard error estimate, all predicted probabilities, and the confidence limits for the cumulative probabilities are computed for all observations in which the explanatory variables have no missing values, even if the

response is missing. By adding observations with missing response values to the input data set, you can compute these statistics for new observations or for settings of the explanatory variables not present in the data without affecting the model fit.

OUT= SAS-data-set

names the output data set. If you omit the OUT= option, the output data set is created and given a default name using the DATA n convention.

The following sections explain options in the OUTPUT statement, divided into [statistic options for any type of categorical responses](#), [statistic options only for binary response](#), and [other options](#). The statistic options specify the statistics to be included in the output data set and name the new variables that contain the statistics. If a STRATA statement is specified, only the PREDICTED=, DFBETAS=, and H= options are available; see the “Regression Diagnostic Details” section on page 2367 for details.

Statistic Options for Any Type of Categorical Response**LOWER=name****L=name**

names the variable containing the lower confidence limits for π , where π is the probability of the event response if *events/trials* syntax or *single-trial* syntax with binary response is specified; for a cumulative model, π is cumulative probability (that is, the probability that the response is less than or equal to the value of _LEVEL_); for the generalized logit model, it is the individual probability (that is, the probability that the response category is represented by the value of _LEVEL_). See the ALPHA= option to set the confidence level.

PREDICTED=name**PRED=name****PROB=name****P=name**

names the variable containing the predicted probabilities. For the *events/trials* syntax or *single-trial* syntax with binary response, it is the predicted event probability. For a cumulative model, it is the predicted cumulative probability (that is, the probability that the response variable is less than or equal to the value of _LEVEL_); and for the generalized logit model, it is the predicted individual probability (that is, the probability of the response category represented by the value of _LEVEL_).

PREDPROBS=(keywords)

requests individual, cumulative, or cross validated predicted probabilities. Descriptions of the *keywords* are as follows.

INDIVIDUAL | I requests the predicted probability of each response level. For a response variable Y with three levels, 1, 2, and 3, the individual probabilities are $\Pr(Y=1)$, $\Pr(Y=2)$, and $\Pr(Y=3)$.

CUMULATIVE | C requests the cumulative predicted probability of each response level. For a response variable Y with three levels, 1, 2, and 3, the cumulative probabilities are $\Pr(Y \leq 1)$, $\Pr(Y \leq 2)$, and $\Pr(Y \leq 3)$. The cumulative probability for the last response level always has the

constant value of 1. For generalized logit models, the cumulative predicted probabilities are not computed and are set to missing.

CROSSVALIDATE | XVALIDATE | X requests the cross validated individual predicted probability of each response level. These probabilities are derived from the leave-one-out principle; that is, dropping the data of one subject and reestimating the parameter estimates. PROC LOGISTIC uses a less expensive one-step approximation to compute the parameter estimates. This option is only valid for binary response models; for nominal and ordinal models, the cross validated probabilities are not computed and are set to missing.

See the “[Details of the PREDPROBS= Option](#)” section on page 2322 at the end of this section for further details.

STDXBETA=*name*

names the variable containing the standard error estimates of **XBETA** (the definition of which follows).

UPPER=*name*

U=*name*

names the variable containing the upper confidence limits for π , where π is the probability of the event response if *events/trials* syntax or *single-trial* syntax with binary response is specified; for a cumulative model, π is cumulative probability (that is, the probability that the response is less than or equal to the value of **_LEVEL_**); for the generalized logit model, it is the individual probability (that is, the probability that the response category is represented by the value of **_LEVEL_**). See the [ALPHA=](#) option to set the confidence level.

XBETA=*name*

names the variable containing the estimates of the linear predictor $\alpha_i + \beta'x$, where i is the corresponding ordered value of **_LEVEL_**.

Statistic Options Only for Binary Response

C=*name*

specifies the confidence interval displacement diagnostic that measures the influence of individual observations on the regression estimates.

CBAR=*name*

specifies the another confidence interval displacement diagnostic, which measures the overall change in the global regression estimates due to deleting an individual observation.

DFBETAS= **_ALL_**

DFBETAS=*var-list*

specifies the standardized differences in the regression estimates for assessing the effects of individual observations on the estimated regression parameters in the fitted model. You can specify a list of up to $s + 1$ variable names, where s is the number of explanatory variables in the MODEL statement, or you can specify just the

keyword `_ALL_`. In the former specification, the first variable contains the standardized differences in the intercept estimate, the second variable contains the standardized differences in the parameter estimate for the first explanatory variable in the MODEL statement, and so on. In the latter specification, the DFBETAS statistics are named `DFBETA_xxx`, where *xxx* is the name of the regression parameter. For example, if the model contains two variables X1 and X2, the specification `DFBETAS=_ALL_` produces three DFBETAS statistics: `DFBETA_Intercept`, `DFBETA_X1`, and `DFBETA_X2`. If an explanatory variable is not included in the final model, the corresponding output variable named in `DFBETAS=var-list` contains missing values.

DIFCHISQ=*name*

specifies the change in the chi-square goodness-of-fit statistic attributable to deleting the individual observation.

DIFDEV=*name*

specifies the change in the deviance attributable to deleting the individual observation.

H=*name*

specifies the diagonal element of the hat matrix for detecting extreme points in the design space.

RESCHI=*name*

specifies the Pearson (Chi) residual for identifying observations that are poorly accounted for by the model.

RESDEV=*name*

specifies the deviance residual for identifying poorly fitted observations.

Other Options

You can specify the following option after a slash.

ALPHA= α

sets the level of significance α for $100(1 - \alpha)\%$ confidence limits for the appropriate response probabilities. The value α must be between 0 and 1. By default, α is equal to the value of the `ALPHA=` option in the PROC LOGISTIC statement, or 0.05 if that option is not specified.

Details of the PREDPROBS= Option

You can request any of the three given types of predicted probabilities. For example, you can request both the individual predicted probabilities and the cross validated probabilities by specifying `PREDPROBS=(I X)`.

When you specify the `PREDPROBS=` option, two automatic variables `_FROM_` and `_INTO_` are included for the *single-trial* syntax and only one variable, `_INTO_`, is included for the *events/trials* syntax. The `_FROM_` variable contains the formatted value of the observed response. The variable `_INTO_` contains the formatted value of the response level with the largest individual predicted probability.

If you specify `PREDPROBS=INDIVIDUAL`, the OUTPUT data set contains *k* additional variables representing the individual probabilities, one for each response level,

where k is the maximum number of response levels across all BY-groups. The names of these variables have the form `IP_xxx`, where xxx represents the particular level. The representation depends on the following situations.

- If you specify *events/trials* syntax, xxx is either ‘Event’ or ‘Nonevent’. Thus, the variable containing the event probabilities is named `IP_Event` and the variable containing the nonevent probabilities is named `IP_Nonevent`.
- If you specify the *single-trial* syntax with more than one BY group, xxx is 1 for the first ordered level of the response, 2 for the second ordered level of the response, . . . , and so forth, as given in the “Response Profile” table. The variable containing the predicted probabilities $\Pr(Y=1)$ is named `IP_1`, where Y is the response variable. Similarly, `IP_2` is the name of the variable containing the predicted probabilities $\Pr(Y=2)$, and so on.
- If you specify the *single-trial* syntax with no BY-group processing, xxx is the left-justified formatted value of the response level (the value may be truncated so that `IP_xxx` does not exceed 32 characters.) For example, if Y is the response variable with response levels ‘None’, ‘Mild’, and ‘Severe’, the variables representing individual probabilities $\Pr(Y='None')$, $\Pr(Y='Mild')$, and $\Pr(Y='Severe')$ are named `IP_None`, `IP_Mild`, and `IP_Severe`, respectively.

If you specify `PREDPROBS=CUMULATIVE`, the OUTPUT data set contains k additional variables representing the cumulative probabilities, one for each response level, where k is the maximum number of response levels across all BY-groups. The names of these variables have the form `CP_xxx`, where xxx represents the particular response level. The naming convention is similar to that given by `PREDPROBS=INDIVIDUAL`. The `PREDPROBS=CUMULATIVE` values are the same as those output by the `PREDICT=keyword`, but are arranged in variables on each output observation rather than in multiple output observations.

If you specify `PREDPROBS=CROSSVALIDATE`, the OUTPUT data set contains k additional variables representing the cross validated predicted probabilities of the k response levels, where k is the maximum number of response levels across all BY-groups. The names of these variables have the form `XP_xxx`, where xxx represents the particular level. The representation is the same as that given by `PREDPROBS=INDIVIDUAL` except that for the *events/trials* syntax there are four variables for the cross validated predicted probabilities instead of two:

`XP_EVENT_R1E` is the cross validated predicted probability of an event when a current event trial is removed.

`XP_NONEVENT_R1E` is the cross validated predicted probability of a nonevent when a current event trial is removed.

`XP_EVENT_R1N` is the cross validated predicted probability of an event when a current nonevent trial is removed.

`XP_NONEVENT_R1N` is the cross validated predicted probability of a nonevent when a current nonevent trial is removed.

The cross validated predicted probabilities are precisely those used in the CTABLE option. See the “[Predicted Probability of an Event for Classification](#)” section on page 2352 for details of the computation.

SCORE Statement

SCORE < options > ;

The SCORE statement creates a data set that contains all the data in the DATA= data set together with posterior probabilities and, optionally, prediction confidence intervals. Fit statistics are displayed on request. If you have binary response data, the SCORE statement can be used to create the OUTROC= data set containing data for the ROC curve. You can specify several SCORE statements. FREQ, WEIGHT, and BY statements can be used with the SCORE statements.

See the “[Scoring Data Sets](#)” section on page 2362 for more information, and see [Example 42.13](#) on page 2462 for an illustration of how to use this statement.

You can specify the following options:

ALPHA= α

specifies the significance level α for $100(1 - \alpha)\%$ confidence intervals. By default, α is equal to the value of the ALPHA= option in the PROC LOGISTIC statement, or 0.05 if that option is not specified. This option has no effect unless the CLM option in the SCORE statement is requested.

CLM

outputs the Wald-test-based confidence limits for the predicted probabilities. This option is not available when the INMODEL= data set is created with the NOCOV option.

DATA=SAS-data-set

names the SAS data set that you want to score. If you omit the DATA= option in the SCORE statement, then scoring is performed on the DATA= input data set in the PROC LOGISTIC statement, if specified; otherwise, the DATA=_LAST_ data set is used.

It is not necessary for the DATA= data set in the SCORE statement to contain the response variable unless you are specifying the FITSTAT or OUTROC= option.

Only those variables involved in the fitted model effects are required in the DATA= data set in the SCORE statement. For example, the following code uses forward selection to select effects.

```
proc logistic data=Neuralgia outmodel=sasuser.Model;
  class Treatment Sex;
  model Pain(event='Yes')= Treatment|Sex Age
    / selection=forward sle=.01;
run;
```

Suppose **Treatment** and **Age** are the effects selected for the final model. You can score a data set which does not contain the variable **Sex** since the effect **Sex** is not in the model that the scoring is based on.

```
proc logistic inmodel=sasuser.Model;
  score data=Neuralgia(drop=Sex);
run;
```

FITSTAT

displays a table of fit statistics. Four statistics are computed: total frequency, total weight, log likelihood, and misclassification rate.

OUT=SAS-data-set

names the SAS data set that contains the predicted information. If you omit the **OUT=** option, the output data set is created and given a default name using the **DATA n** convention.

OUTROC=SAS-data-set

names the SAS data set that contains the ROC curve for the **DATA=** data set. The ROC curve is computed only for binary response data. See the section “[OUTROC= Output Data Set](#)” on page 2378 for the list of variables in this data set.

PRIOR=SAS-data-set

names the SAS data set that contains the priors of the response categories. The priors may be values proportional to the prior probabilities; thus, they do not necessarily sum to one. This data set should include a variable named **_PRIOR_** that contains the prior probabilities. For events/trials **MODEL** syntax, this data set should also include an **_OUTCOME_** variable that contains the values **EVENT** and **NONEVENT**; for single-trial **MODEL** syntax, this data set should include the response variable that contains the unformatted response categories. See [Example 42.13](#) on page 2462 for an example.

PRIOREVENT=value

specifies the prior event probability for a binary response model. If both **PRIOR=** and **PRIOREVENT=** options are specified, the **PRIOR=** option takes precedence.

ROCEPS=value

specifies the criterion for grouping estimated event probabilities that are close to each other for the ROC curve. In each group, the difference between the largest and the smallest estimated event probability does not exceed the given value. The *value* must be between 0 and 1; the default value is $1E-4$. The smallest estimated probability in each group serves as a cutpoint for predicting an event response. The **ROCEPS=** option has no effect if the **OUTROC=** option is not specified.

STRATA Statement

STRATA *variable* <(option)>< *variable* <(option)>...>< /options > ;

The STRATA statement names the *variables* that define *strata* or *matched sets* to use in a *stratified conditional logistic regression* of binary response data. Observations having the same variable levels are in the same matched set. At least one variable must be specified to invoke the stratified analysis, and the usual unconditional asymptotic analysis is not performed. The stratified logistic model has the form

$$\text{logit}(\pi_{hi}) = \alpha_h + \mathbf{x}'_{hi}\boldsymbol{\beta}$$

where π_{hi} is the event probability for the i th observation in stratum h having covariates \mathbf{x}_{hi} , and where the stratum-specific intercepts α_h are the nuisance parameters which are to be conditioned out.

STRATA variables can also be specified in the MODEL statement as classification or continuous covariates; however, the effects are nondegenerate only when crossed with a non-stratification variable. Specifying several STRATA statements is the same as specifying one STRATA statement containing all the strata variables. The STRATA variables can be either character or numeric, and the formatted values of the STRATA variables determine the levels. Thus, you can use also use formats to group values into levels. See the discussion of the FORMAT procedure in the *SAS Procedures Guide*.

If an EXACT statement is also specified, then a stratified *exact* conditional logistic regression is performed.

The SCORE and WEIGHT statements are not available with a STRATA statement. The following MODEL options are also not supported with a STRATA statement: CLPARM=PL, CLODDS=PL, CTABLE, LACKFIT, LINK=, NOFIT, OUTMODEL=, OUTROC=, and SCALE=.

The “Strata Summary” table is displayed by default; it displays the number of strata which have a specific number of events and nonevents. For example, if you are analyzing a 1:5 matched study, this table enables you to verify that every stratum in the analysis has exactly one event and five non-events. Strata containing only events or only non-events are reported in this table, but such strata are uninformative and are not used in the analysis. (Note that you can use the response variable option EVENT= to identify the events; otherwise, the first ordered response category is the event.)

The following option can be specified for a stratification variable by enclosing the option in parentheses after the variable name, or it can be specified globally for all STRATA variables after a slash (/).

MISSING

treats missing values (‘.’, ‘.A’,...,‘.Z’ for numeric variables and blanks for character variables) as valid STRATA variable values.

The following strata options are also available after the slash.

NOSUMMARY

suppresses the display of the “Strata Summary” table.

INFO

displays the “Strata Information” table, which includes the stratum number, levels of the STRATA variables that define the stratum, the number of events, the number of nonevents, and the total frequency for each stratum. Since the number of strata can be very large, this table is only displayed on request.

TEST Statement

< label: > TEST equation1 < , ... , < equationk >>< / option > ;

The TEST statement tests linear hypotheses about the regression coefficients. The Wald test is used to test jointly the null hypotheses ($H_0: \mathbf{L}\boldsymbol{\theta} = \mathbf{c}$) specified in a single TEST statement. When $\mathbf{c} = \mathbf{0}$ you should specify a **CONTRAST** statement instead.

Each *equation* specifies a linear hypothesis (a row of the \mathbf{L} matrix and the corresponding element of the \mathbf{c} vector); multiple *equations* are separated by commas. The label, which must be a valid SAS name, is used to identify the resulting output and should always be included. You can submit multiple TEST statements.

The form of an *equation* is as follows:

term < ±term ... > < = ±term < ±term ... >>

where *term* is a parameter of the model, or a constant, or a constant times a parameter. For a binary response model, the intercept parameter is named INTERCEPT; for an ordinal response model, the intercept parameters are named INTERCEPT, INTERCEPT2, INTERCEPT3, and so on. See the “[Parameter Names in the OUTEST= Data Set](#)” section on page 2375 for details on parameter naming conventions. When no equal sign appears, the expression is set to 0. The following code illustrates possible uses of the TEST statement:

```
proc logistic;
  model y= a1 a2 a3 a4;
  test1: test intercept + .5 * a2 = 0;
  test2: test intercept + .5 * a2;
  test3: test a1=a2=a3;
  test4: test a1=a2, a2=a3;
run;
```

Note that the first and second TEST statements are equivalent, as are the third and fourth TEST statements.

You can specify the following option in the TEST statement after a slash(/).

PRINT

displays intermediate calculations in the testing of the null hypothesis $H_0: \mathbf{L}\boldsymbol{\theta} = \mathbf{c}$. This includes $\mathbf{L}\hat{\mathbf{V}}(\hat{\boldsymbol{\theta}})\mathbf{L}'$ bordered by $(\mathbf{L}\hat{\boldsymbol{\theta}} - \mathbf{c})$ and $[\mathbf{L}\hat{\mathbf{V}}(\hat{\boldsymbol{\theta}})\mathbf{L}']^{-1}$ bordered by $[\mathbf{L}\hat{\mathbf{V}}(\hat{\boldsymbol{\theta}})\mathbf{L}']^{-1}(\mathbf{L}\hat{\boldsymbol{\theta}} - \mathbf{c})$, where $\hat{\boldsymbol{\theta}}$ is the maximum likelihood estimator of $\boldsymbol{\theta}$ and $\hat{\mathbf{V}}(\hat{\boldsymbol{\theta}})$ is the estimated covariance matrix of $\hat{\boldsymbol{\theta}}$.

For more information, see the “[Testing Linear Hypotheses about the Regression Coefficients](#)” section on page 2358.

UNITS Statement

UNITS *independent1 = list1 < . . . independentk = listk >< / option > ;*

The UNITS statement enables you to specify units of change for the continuous explanatory variables so that customized odds ratios can be estimated. An estimate of the corresponding odds ratio is produced for each unit of change specified for an explanatory variable. The UNITS statement is ignored for CLASS variables. If the [CLODDS=](#) option is specified in the MODEL statement, the corresponding confidence limits for the odds ratios are also displayed.

The term *independent* is the name of an explanatory variable and *list* represents a list of units of change, separated by spaces, that are of interest for that variable. Each unit of change in a list has one of the following forms:

- *number*
- SD or –SD
- *number* * SD

where *number* is any nonzero number, and SD is the sample standard deviation of the corresponding independent variable. For example, $X = -2$ requests an odds ratio that represents the change in the odds when the variable X is decreased by two units. $X = 2*SD$ requests an estimate of the change in the odds when X is increased by two sample standard deviations.

You can specify the following option in the UNITS statement after a slash(/).

DEFAULT= *list*

gives a list of units of change for all explanatory variables that are not specified in the UNITS statement. Each unit of change can be in any of the forms described previously. If the DEFAULT= option is not specified, PROC LOGISTIC does not produce customized odds ratio estimates for any explanatory variable that is not listed in the UNITS statement.

For more information, see the “[Odds Ratio Estimation](#)” section on page 2347.

WEIGHT Statement

WEIGHT *variable < / option > ;*

When a WEIGHT statement appears, each observation in the input data set is weighted by the value of the WEIGHT variable. The values of the WEIGHT variable can be nonintegral and are not truncated. Observations with negative, zero, or missing values for the WEIGHT variable are not used in the model fitting. When the WEIGHT statement is not specified, each observation is assigned a weight of 1.

If a [SCORE](#) statement is specified, then the WEIGHT variable is used for computing fit statistics and the ROC curve, but it is not required for scoring. If the [DATA=](#) data

set in the SCORE statement does not contain the WEIGHT variable, the weights are assumed to be 1 and a warning message is issued in the LOG. If you fit a model and perform the scoring in the same run, the same WEIGHT variable is used for fitting and scoring. If you fit a model in a previous run and input it with the `INMODEL=` option in the current run, then the WEIGHT variable can be different from the one used in the previous run; however, if a WEIGHT variable was not specified in the previous run you can still specify a WEIGHT variable in the current run.

The following option can be added to the WEIGHT statement after a slash (/).

NORMALIZE

NORM

causes the weights specified by the WEIGHT variable to be normalized so that they add up to the actual sample size. With this option, the estimated covariance matrix of the parameter estimators is invariant to the scale of the WEIGHT variable.

Details

Missing Values

Any observation with missing values for the response, offset, strata, or explanatory variables is excluded from the analysis; however, missing values are valid for variables specified with the MISSING option in the `CLASS` or `STRATA` statements. The estimated linear predictor and its standard error estimate, the fitted probabilities and confidence limits, and the regression diagnostic statistics are not computed for any observation with missing offset or explanatory variable values. However, if only the response value is missing, the linear predictor, its standard error, the fitted individual and cumulative probabilities, and confidence limits for the cumulative probabilities can be computed and output to a data set using the OUTPUT statement.

Response Level Ordering

Response level ordering is important because, by default, PROC LOGISTIC models the probability of response levels with *lower Ordered Value*. Ordered Values are assigned to response levels in ascending sorted order (that is, the lowest response level is assigned Ordered Value 1, the next lowest is assigned Ordered Value 2, and so on) and are displayed in the “Response Profiles” table. If your response variable Y takes values in $\{1, \dots, k + 1\}$, then, by default, the functions modeled with the cumulative model are

$$\text{logit}(\Pr(Y \leq i | \mathbf{x})), \quad i = 1, \dots, k$$

and for the generalized logit model the functions modeled are

$$\log \left(\frac{\Pr(Y = i | \mathbf{x})}{\Pr(Y = k + 1 | \mathbf{x})} \right), \quad i = 1, \dots, k$$

where the highest Ordered Value $Y = k + 1$ is the reference level. You can change which probabilities are modeled by specifying the `EVENT=`, `REF=`, `DESCENDING`, or `ORDER=` response variable options in the MODEL statement.

For binary response data with event and nonevent categories, if your event category has a higher Ordered Value, then the nonevent is modeled and, since the default response function modeled is

$$\text{logit}(\pi) = \log\left(\frac{\pi}{1 - \pi}\right)$$

where π is the probability of the response level assigned Ordered Value 1, and since

$$\text{logit}(\pi) = -\text{logit}(1 - \pi)$$

the effect of reversing the order of the two response values is to change the signs of α and β in the model $\text{logit}(\pi) = \alpha + \beta'x$.

For example, suppose the binary response variable Y takes the values 1 and 0 for event and nonevent, respectively, and `Exposure` is the explanatory variable. By default, PROC LOGISTIC assigns Ordered Value 1 to response level $Y=0$, and Ordered Value 2 to response level $Y=1$. As a result, PROC LOGISTIC models the probability of the nonevent (Ordered Value=1) category. To model the event without changing the values of the variable Y , you can do the following:

- Explicitly state which response level is to be modeled using the response variable option `EVENT=` in the MODEL statement,

```
model Y(event='1') = Exposure;
```

- Specify the response variable option `REF=` in the MODEL statement as the nonevent category for the response variable. This option is most useful for generalized logit models.

```
model Y(ref='0') = Exposure;
```

- Specify the response variable option `DESCENDING` in the MODEL statement,

```
model Y(descending)=Exposure;
```

- Assign a format to Y such that the first formatted value (when the formatted values are put in sorted order) corresponds to the event. For this example, $Y=1$ is assigned formatted value 'event' and $Y=0$ is assigned formatted value 'nonevent'. Since `ORDER=FORMATTED` by default, Ordered Value 1 is assigned to response level $Y=1$ so the procedure models the event.

```
proc format;
  value Disease 1='event' 0='nonevent';
run;
proc logistic;
  format Y Disease.;
  model Y=Exposure;
run;
```

CLASS Variable Parameterization

Consider a model with one CLASS variable *A* with four levels, 1, 2, 5, and 7. Details of the possible choices for the PARAM= option follow.

EFFECT Three columns are created to indicate group membership of the nonreference levels. For the reference level, all three design variables have a value of -1 . For instance, if the reference level is 7 (REF='7'), the design matrix columns for *A* are as follows.

Effect Coding			
	Design Matrix		
A	A1	A2	A5
1	1	0	0
2	0	1	0
5	0	0	1
7	-1	-1	-1

Parameter estimates of CLASS main effects using the effect coding scheme estimate the difference in the effect of each nonreference level compared to the average effect over all 4 levels.

Caution: PROC LOGISTIC initially parameterizes the CLASS variables by looking at the levels of the variables across the complete data set. If you have an *unbalanced* replication of levels across variables, then the design matrix and the parameter interpretation may be different from what you expect. For instance, suppose that in addition to the four-level variable *A* discussed above, you have another variable *B* with two levels, where the fourth level of *A* only occurs with the first level of *B*. If your model contains the effect *A*(*B*), then the design for *A* within the second level of *B* will not be a differential effect. In particular, the design will look like the following.

Effect Coding							
		Design Matrix					
		A(B=1)			A(B=2)		
B	A	A1	A2	A5	A1	A2	A5
1	1	1	0	0	0	0	0
1	2	0	1	0	0	0	0
1	5	0	0	1	0	0	0
1	7	-1	-1	-1	0	0	0
2	1	0	0	0	1	0	0
2	2	0	0	0	0	1	0
2	5	0	0	0	0	0	1

PROC LOGISTIC will then detect linear dependency among the last three design variables and set the parameter for A5(B=2) to zero, resulting in an interpretation of these parameters as if they were reference- or dummy-coded. The GLM or REFERENCE parameterization may be more appropriate for such problems.

GLM

As in PROC GLM, four columns are created to indicate group membership. The design matrix columns for A are as follows.

GLM Coding				
A	Design Matrix			
	A1	A2	A5	A7
1	1	0	0	0
2	0	1	0	0
5	0	0	1	0
7	0	0	0	1

Parameter estimates of CLASS main effects using the GLM coding scheme estimate the difference in the effects of each level compared to the last level.

ORDINAL

Three columns are created to indicate group membership of the higher levels of the effect. For the first level of the effect (which for A is 1), all three design variables have a value of 0. The design matrix columns for A are as follows.

Ordinal Coding			
A	Design Matrix		
	A2	A5	A7
1	0	0	0
2	1	0	0
5	1	1	0
7	1	1	1

The first level of the effect is a control or baseline level. Parameter estimates of CLASS main effects using the ORDINAL coding scheme estimate the effect on the response as the ordinal factor is set to each succeeding level. When the parameters for an ordinal main effect have the same sign, the response effect is monotonic across the levels.

POLYNOMIAL

POLY

Three columns are created. The first represents the linear term (x), the second represents the quadratic term (x^2), and the third represents the cubic term (x^3), where x is the level value. If the CLASS levels are not numeric, they are translated into 1, 2, 3, ... according to their sorting order. The design matrix columns for A are as follows.

Polynomial Coding			
Design Matrix			
A	APOLY1	APOLY2	APOLY3
1	1	1	1
2	2	4	8
5	5	25	125
7	7	49	343

REFERENCE

REF

Three columns are created to indicate group membership of the nonreference levels. For the reference level, all three design variables have a value of 0. For instance, if the reference level is 7 (REF='7'), the design matrix columns for A are as follows.

Reference Coding			
Design Matrix			
A	A1	A2	A5
1	1	0	0
2	0	1	0
5	0	0	1
7	0	0	0

Parameter estimates of CLASS main effects using the reference coding scheme estimate the difference in the effect of each nonreference level compared to the effect of the reference level.

ORTHEFFECT

The columns are obtained by applying the Gram-Schmidt orthogonalization to the columns for PARAM=EFFECT. The design matrix columns for A are as follows.

Orthogonal Effect Coding			
Design Matrix			
A	AOEFF1	AOEFF2	AOEFF3
1	1.41421	-0.81650	-0.57735
2	0.00000	1.63299	-0.57735
5	0.00000	0.00000	1.73205
7	-1.41421	-0.81649	-0.57735

ORTHORDINAL The columns are obtained by applying the Gram-Schmidt orthogonalization to the columns for `PARAM=ORDINAL`. The design matrix columns for `A` are as follows.

Orthogonal Ordinal Coding			
A	Design Matrix		
	AOORD1	AOORD2	AOORD3
1	-1.73205	0.00000	0.00000
2	0.57735	-1.63299	0.00000
5	0.57735	0.81650	-1.41421
7	0.57735	0.81650	1.41421

ORTHPOLY The columns are obtained by applying the Gram-Schmidt orthogonalization to the columns for `PARAM=POLY`. The design matrix columns for `A` are as follows.

Orthogonal Polynomial Coding			
A	Design Matrix		
	AOPOLY1	AOPOLY2	AOPOLY5
1	-1.153	0.907	-0.921
2	-0.734	-0.540	1.473
5	0.524	-1.370	-0.921
7	1.363	1.004	0.368

ORTHREF The columns are obtained by applying the Gram-Schmidt orthogonalization to the columns for `PARAM=REFERENCE`. The design matrix columns for `A` are as follows.

Orthogonal Reference Coding			
A	Design Matrix		
	AOREF1	AOREF2	AOREF3
1	1.73205	0.00000	0.00000
2	-0.57735	1.63299	0.00000
5	-0.57735	-0.81650	1.41421
7	-0.57735	-0.81650	-1.41421

Link Functions and the Corresponding Distributions

Four link functions are available in the LOGISTIC procedure. The logit function is the default. To specify a different link function, use the `LINK=` option in the MODEL statement. The link functions and the corresponding distributions are as follows:

- The logit function

$$g(p) = \log(p/(1 - p))$$

is the inverse of the cumulative logistic distribution function, which is

$$F(x) = 1/(1 + \exp(-x)) = \exp(x)/(1 + \exp(x))$$

- The probit (or normit) function

$$g(p) = \Phi^{-1}(p)$$

is the inverse of the cumulative standard normal distribution function, which is

$$F(x) = \Phi(x) = (2\pi)^{-1/2} \int_{-\infty}^x \exp(-z^2/2) dz$$

Traditionally, the probit function contains the additive constant 5, but throughout PROC LOGISTIC, the terms probit and normit are used interchangeably.

- The complementary log-log function

$$g(p) = \log(-\log(1 - p))$$

is the inverse of the cumulative extreme-value function (also called the Gompertz distribution), which is

$$F(x) = 1 - \exp(-\exp(x))$$

- The generalized logit function extends the binary logit link to a vector of levels (p_1, \dots, p_{k+1}) by contrasting each level with a fixed level

$$g(p_i) = \log(p_i/p_{k+1}) \quad i = 1, \dots, k$$

The variances of the normal, logistic, and extreme-value distributions are not the same. Their respective means and variances are

Distribution	Mean	Variance
Normal	0	1
Logistic	0	$\pi^2/3$
Extreme-value	$-\gamma$	$\pi^2/6$

where γ is the Euler constant. In comparing parameter estimates using different link functions, you need to take into account the different scalings of the corresponding distributions and, for the complementary log-log function, a possible shift in location. For example, if the fitted probabilities are in the neighborhood of 0.1 to 0.9, then the parameter estimates using the logit link function should be about $\pi/\sqrt{3}$ larger than the estimates from the probit link function.

Determining Observations for Likelihood Contributions

If you use *events/trials* MODEL syntax, each observation is split into two observations. One has response value 1 with a frequency equal to the frequency of the original observation (which is 1 if the *FREQ* statement is not used) times the value of the *events* variable. The other observation has response value 2 and a frequency equal to the frequency of the original observation times the value of (*trials* – *events*). These two observations will have the same explanatory variable values and the same *FREQ* and *WEIGHT* values as the original observation.

For either *single-trial* or *events/trials* syntax, let j index all observations. In other words, for *single-trial* syntax, j indexes the actual observations. And, for *events/trials* syntax, j indexes the observations after splitting (as described previously). If your data set has 30 observations and you use *single-trial* syntax, j has values from 1 to 30; if you use *events/trials* syntax, j has values from 1 to 60.

Suppose the response variable in a cumulative response model can take on the ordered values $1, \dots, k, k+1$ where k is an integer ≥ 1 . The likelihood for the j th observation with ordered response value y_j and explanatory variables vector \mathbf{x}_j is given by

$$L_j = \begin{cases} F(\alpha_1 + \beta' \mathbf{x}_j) & y_j = 1 \\ F(\alpha_i + \beta' \mathbf{x}_j) - F(\alpha_{i-1} + \beta' \mathbf{x}_j) & 1 < y_j = i \leq k \\ 1 - F(\alpha_k + \beta' \mathbf{x}_j) & y_j = k + 1 \end{cases}$$

where $F(\cdot)$ is the logistic, normal, or extreme-value distribution function, $\alpha_1, \dots, \alpha_k$ are ordered intercept parameters, and β is the slope parameter vector.

For the generalized logit model, letting the $k + 1$ st level be the reference level, the intercepts $\alpha_1, \dots, \alpha_k$ are unordered and the slope vector β_i varies with each logit. The likelihood for the j th observation with ordered response value y_j and explanatory variables vector \mathbf{x}_j is given by

$$L_j = \Pr(Y = y_j | \mathbf{x}_j) = \begin{cases} \frac{e^{\alpha_i + \mathbf{x}'_j \beta_i}}{1 + \sum_{m=1}^k e^{\alpha_m + \mathbf{x}'_j \beta_m}} & 1 \leq y_j = i \leq k \\ \frac{1}{1 + \sum_{m=1}^k e^{\alpha_m + \mathbf{x}'_j \beta_m}} & y_j = k + 1 \end{cases}$$

Iterative Algorithms for Model-Fitting

Two iterative maximum likelihood algorithms are available in PROC LOGISTIC. The default is the Fisher-scoring method, which is equivalent to fitting by iteratively reweighted least squares. The alternative algorithm is the Newton-Raphson method. Both algorithms give the same parameter estimates; however, the estimated covariance matrix of the parameter estimators may differ slightly. This is due to the fact that the Fisher-scoring method is based on the expected information matrix while the Newton-Raphson method is based on the observed information matrix. In the case of a binary logit model, the observed and expected information matrices are identical, resulting in identical estimated covariance matrices for both algorithms. For a generalized logit model, only the Newton-Raphson technique is available. You can use the `TECHNIQUE=` option to select a fitting algorithm.

Iteratively Reweighted Least-Squares Algorithm (Fisher Scoring)

Consider the multinomial variable $\mathbf{Z}_j = (Z_{1j}, \dots, Z_{kj})'$ such that

$$Z_{ij} = \begin{cases} 1 & \text{if } Y_j = i \\ 0 & \text{otherwise} \end{cases}$$

With π_{ij} denoting the probability that the j th observation has response value i , the expected value of \mathbf{Z}_j is $\boldsymbol{\pi}_j = (\pi_{1j}, \dots, \pi_{kj})'$, and $\pi_{(k+1)j} = 1 - \sum_{i=1}^k \pi_{ij}$. The covariance matrix of \mathbf{Z}_j is \mathbf{V}_j , which is the covariance matrix of a multinomial random variable for one trial with parameter vector $\boldsymbol{\pi}_j$. Let $\boldsymbol{\theta}$ be the vector of regression parameters; in other words, $\boldsymbol{\theta} = (\alpha_1, \dots, \alpha_k, \boldsymbol{\beta}')$. Let \mathbf{D}_j be the matrix of partial derivatives of $\boldsymbol{\pi}_j$ with respect to $\boldsymbol{\theta}$. The estimating equation for the regression parameters is

$$\sum_j \mathbf{D}_j' \mathbf{W}_j (\mathbf{Z}_j - \boldsymbol{\pi}_j) = \mathbf{0}$$

where $\mathbf{W}_j = w_j f_j \mathbf{V}_j^{-}$, w_j and f_j are the WEIGHT and FREQ values of the j th observation, and \mathbf{V}_j^{-} is a generalized inverse of \mathbf{V}_j . PROC LOGISTIC chooses \mathbf{V}_j^{-} as the inverse of the diagonal matrix with $\boldsymbol{\pi}_j$ as the diagonal.

With a starting value of $\boldsymbol{\theta}_0$, the maximum likelihood estimate of $\boldsymbol{\theta}$ is obtained iteratively as

$$\boldsymbol{\theta}_{m+1} = \boldsymbol{\theta}_m + \left(\sum_j \mathbf{D}_j' \mathbf{W}_j \mathbf{D}_j \right)^{-1} \sum_j \mathbf{D}_j' \mathbf{W}_j (\mathbf{Z}_j - \boldsymbol{\pi}_j)$$

where \mathbf{D}_j , \mathbf{W}_j , and $\boldsymbol{\pi}_j$ are evaluated at $\boldsymbol{\theta}_m$. The expression after the plus sign is the step size. If the likelihood evaluated at $\boldsymbol{\theta}_{m+1}$ is less than that evaluated at $\boldsymbol{\theta}_m$, then $\boldsymbol{\theta}_{m+1}$ is recomputed by step-halving or ridging. The iterative scheme continues until convergence is obtained, that is, until $\boldsymbol{\theta}_{m+1}$ is sufficiently close to $\boldsymbol{\theta}_m$. Then the maximum likelihood estimate of $\boldsymbol{\theta}$ is $\hat{\boldsymbol{\theta}} = \boldsymbol{\theta}_{m+1}$.

The covariance matrix of $\hat{\boldsymbol{\theta}}$ is estimated by

$$\widehat{\text{cov}}(\hat{\boldsymbol{\theta}}) = \left(\sum_j \hat{\mathbf{D}}_j' \hat{\mathbf{W}}_j \hat{\mathbf{D}}_j \right)^{-1}$$

where $\hat{\mathbf{D}}_j$ and $\hat{\mathbf{W}}_j$ are, respectively, \mathbf{D}_j and \mathbf{W}_j evaluated at $\hat{\boldsymbol{\theta}}$.

By default, starting values are zero for the slope parameters, and for the intercept parameters, starting values are the observed cumulative logits (that is, logits of the observed cumulative proportions of response). Alternatively, the starting values may be specified with the `INEST=` option.

Newton-Raphson Algorithm

For cumulative models, let the parameter vector be $\boldsymbol{\theta} = (\alpha_1, \dots, \alpha_k, \boldsymbol{\beta}')'$, and for the generalized logit model denote $\boldsymbol{\theta} = (\alpha_1, \dots, \alpha_k, \boldsymbol{\beta}'_1, \dots, \boldsymbol{\beta}'_k)'$. The gradient vector and the Hessian matrix are given, respectively, by

$$\mathbf{g} = \sum_j w_j f_j \frac{\partial l_j}{\partial \boldsymbol{\theta}}$$

$$\mathbf{H} = \sum_j -w_j f_j \frac{\partial^2 l_j}{\partial \boldsymbol{\theta}^2}$$

where $l_j = \log L_j$ is the log likelihood for the j th observation. With a starting value of $\boldsymbol{\theta}_0$, the maximum likelihood estimate $\hat{\boldsymbol{\theta}}$ of $\boldsymbol{\theta}$ is obtained iteratively until convergence is obtained:

$$\boldsymbol{\theta}_{m+1} = \boldsymbol{\theta}_m + \mathbf{H}^{-1} \mathbf{g}$$

where \mathbf{H} and \mathbf{g} are evaluated at $\boldsymbol{\theta}_m$. If the likelihood evaluated at $\boldsymbol{\theta}_{m+1}$ is less than that evaluated at $\boldsymbol{\theta}_m$, then $\boldsymbol{\theta}_{m+1}$ is recomputed by step-halving or ridging.

The covariance matrix of $\hat{\boldsymbol{\theta}}$ is estimated by

$$\widehat{\text{cov}}(\hat{\boldsymbol{\theta}}) = \hat{\mathbf{H}}^{-1}$$

where $\hat{\mathbf{H}}$ is \mathbf{H} evaluated at $\hat{\boldsymbol{\theta}}$.

Convergence Criteria

Four convergence criteria are allowed, namely, **ABSFCONV=**, **FCONV=**, **GCONV=**, and **XCONV=**. If you specify more than one convergence criterion, the optimization is terminated as soon as one of the criteria is satisfied. If none of the criteria is specified, the default is **GCONV=1E-8**.

If you specify a **STRATA** statement, then all unspecified (or non-default) criteria are also compared to zero. For example, only specifying the criterion **XCONV=1e-8** but attaining **FCONV=0** terminates the optimization even if the **XCONV=** criterion is not satisfied, because the log likelihood has reached its maximum.

Existence of Maximum Likelihood Estimates

The likelihood equation for a logistic regression model does not always have a finite solution. Sometimes there is a nonunique maximum on the boundary of the parameter space, at infinity. The existence, finiteness, and uniqueness of maximum likelihood estimates for the logistic regression model depend on the patterns of data points in the observation space (Albert and Anderson 1984; Santner and Duffy 1986). The existence checks are not performed for conditional logistic regression.

Consider a binary response model. Let Y_j be the response of the i th subject and let \mathbf{x}_j be the vector of explanatory variables (including the constant 1 associated with the intercept). There are three mutually exclusive and exhaustive types of data configurations: complete separation, quasi-complete separation, and overlap.

Complete Separation There is a complete separation of data points if there exists a vector \mathbf{b} that correctly allocates all observations to their response groups; that is,

$$\begin{cases} \mathbf{b}'\mathbf{x}_j > 0 & Y_j = 1 \\ \mathbf{b}'\mathbf{x}_j < 0 & Y_j = 2 \end{cases}$$

This configuration gives nonunique infinite estimates. If the iterative process of maximizing the likelihood function is allowed to continue, the log likelihood diminishes to zero, and the dispersion matrix becomes unbounded.

Quasi-Complete Separation The data are not completely separable but there is a vector \mathbf{b} such that

$$\begin{cases} \mathbf{b}'\mathbf{x}_j \geq 0 & Y_j = 1 \\ \mathbf{b}'\mathbf{x}_j \leq 0 & Y_j = 2 \end{cases}$$

and equality holds for at least one subject in each response group. This configuration also yields nonunique infinite estimates. If the iterative process of maximizing the likelihood function is allowed to continue, the dispersion matrix becomes unbounded and the log likelihood diminishes to a nonzero constant.

Overlap If neither complete nor quasi-complete separation exists in the sample points, there is an overlap of sample points. In this configuration, the maximum likelihood estimates exist and are unique.

Complete separation and quasi-complete separation are problems typically encountered with small data sets. Although complete separation can occur with any type of data, quasi-complete separation is not likely with truly continuous explanatory variables.

The LOGISTIC procedure uses a simple empirical approach to recognize the data configurations that lead to infinite parameter estimates. The basis of this approach is that any convergence method of maximizing the log likelihood must yield a solution giving complete separation, if such a solution exists. In maximizing the log likelihood, there is no checking for complete or quasi-complete separation if convergence is attained in eight or fewer iterations. Subsequent to the eighth iteration, the probability of the observed response is computed for each observation. If the probability of the observed response is one for all observations, there is a complete separation

of data points and the iteration process is stopped. If the complete separation of data has not been determined and an observation is identified to have an extremely large probability (≥ 0.95) of the observed response, there are two possible situations. First, there is overlap in the data set, and the observation is an atypical observation of its own group. The iterative process, if allowed to continue, will stop when a maximum is reached. Second, there is quasi-complete separation in the data set, and the asymptotic dispersion matrix is unbounded. If any of the diagonal elements of the dispersion matrix for the standardized observations vectors (all explanatory variables standardized to zero mean and unit variance) exceeds 5000, quasi-complete separation is declared and the iterative process is stopped. If either complete separation or quasi-complete separation is detected, a warning message is displayed in the procedure output.

Checking for quasi-complete separation is less foolproof than checking for complete separation. The `NOCHECK` option in the `MODEL` statement turns off the process of checking for infinite parameter estimates. In cases of complete or quasi-complete separation, turning off the checking process typically results in the procedure failing to converge. The presence of a `WEIGHT` statement also turns off the checking process.

Effect Selection Methods

Five `effect-selection` methods are available. The simplest method (and the default) is `SELECTION=NONE`, for which `PROC LOGISTIC` fits the complete model as specified in the `MODEL` statement. The other four methods are `FORWARD` for forward selection, `BACKWARD` for backward elimination, `STEPWISE` for stepwise selection, and `SCORE` for best subsets selection. These methods are specified with the `SELECTION=` option in the `MODEL` statement. Intercept parameters are forced to stay in the model unless the `NOINT` option is specified.

When `SELECTION=FORWARD`, `PROC LOGISTIC` first estimates parameters for effects forced into the model. These effects are the intercepts and the first n explanatory effects in the `MODEL` statement, where n is the number specified by the `START=` or `INCLUDE=` option in the `MODEL` statement (n is zero by default). Next, the procedure computes the score chi-square statistic for each effect not in the model and examines the largest of these statistics. If it is significant at the `SLENTRY=` level, the corresponding effect is added to the model. Once an effect is entered in the model, it is never removed from the model. The process is repeated until none of the remaining effects meet the specified level for entry or until the `STOP=` value is reached.

When `SELECTION=BACKWARD`, parameters for the complete model as specified in the `MODEL` statement are estimated unless the `START=` option is specified. In that case, only the parameters for the intercepts and the first n explanatory effects in the `MODEL` statement are estimated, where n is the number specified by the `START=` option. Results of the Wald test for individual parameters are examined. The least significant effect that does not meet the `SLSTAY=` level for staying in the model is removed. Once an effect is removed from the model, it remains excluded. The process is repeated until no other effect in the model meets the specified level for removal or

until the **STOP=** value is reached. Backward selection is often less successful than forward or stepwise selection because the full model fit in the first step is the model most likely to result in a complete or quasi-complete separation of response values as described in the previous section.

The **SELECTION=STEPWISE** option is similar to the **SELECTION=FORWARD** option except that effects already in the model do not necessarily remain. Effects are entered into and removed from the model in such a way that each forward selection step may be followed by one or more backward elimination steps. The stepwise selection process terminates if no further effect can be added to the model or if the effect just entered into the model is the only effect removed in the subsequent backward elimination.

For **SELECTION=SCORE**, PROC LOGISTIC uses the branch and bound algorithm of Furnival and Wilson (1974) to find a specified number of models with the highest likelihood score (chi-square) statistic for all possible model sizes, from 1, 2, 3 effect models, and so on, up to the single model containing all of the explanatory effects. The number of models displayed for each model size is controlled by the **BEST=** option. You can use the **START=** option to impose a minimum model size, and you can use the **STOP=** option to impose a maximum model size. For instance, with **BEST=3**, **START=2**, and **STOP=5**, the **SCORE** selection method displays the best three models (that is, the three models with the highest score chi-squares) containing 2, 3, 4, and 5 effects. The **SELECTION=SCORE** option is not available for models with **CLASS** variables.

The options **FAST**, **SEQUENTIAL**, and **STOPRES** can alter the default criteria for entering or removing effects from the model when they are used with the **FORWARD**, **BACKWARD**, or **STEPWISE** selection methods.

Model Fitting Information

Suppose the model contains s explanatory effects. For the j th observation, let $\hat{\pi}_j$ be the estimated probability of the observed response. The three criteria displayed by the LOGISTIC procedure are calculated as follows:

- -2 Log Likelihood:

$$-2 \text{ Log L} = -2 \sum_j w_j f_j \log(\hat{\pi}_j)$$

where w_j and f_j are the weight and frequency values of the j th observation. For binary response models using *events/trials* MODEL syntax, this is equivalent to

$$-2 \text{ Log L} = -2 \sum_j w_j f_j \{r_j \log(\hat{\pi}_j) + (n_j - r_j) \log(1 - \hat{\pi}_j)\}$$

where r_j is the number of events, n_j is the number of trials, and $\hat{\pi}_j$ is the estimated event probability.

- Akaike Information Criterion:

$$\text{AIC} = -2 \text{Log } L + 2p$$

where p is the number of parameters in the model. For cumulative response models, $p = k + s$ where k is the total number of response levels minus one, and s is the number of explanatory effects. For the generalized logit model, $p = k(s + 1)$.

- Schwarz Criterion:

$$\text{SC} = -2 \text{Log } L + p \log\left(\sum_j f_j\right)$$

where p is as defined previously.

The -2Log Likelihood statistic has a chi-square distribution under the null hypothesis (that all the explanatory effects in the model are zero) and the procedure produces a p -value for this statistic. The AIC and SC statistics give two different ways of adjusting the -2Log Likelihood statistic for the number of terms in the model and the number of observations used. These statistics should be used when comparing different models for the same data (for example, when you use the `METHOD=STEPWISE` option in the `MODEL` statement); lower values of the statistic indicate a more desirable model.

Generalized Coefficient of Determination

Cox and Snell (1989, pp. 208–209) propose the following generalization of the coefficient of determination to a more general linear model:

$$R^2 = 1 - \left\{ \frac{L(\mathbf{0})}{L(\hat{\boldsymbol{\theta}})} \right\}^{\frac{2}{n}}$$

where $L(\mathbf{0})$ is the likelihood of the intercept-only model, $L(\hat{\boldsymbol{\theta}})$ is the likelihood of the specified model, and n is the sample size. The quantity R^2 achieves a maximum of less than one for discrete models, where the maximum is given by

$$R_{\max}^2 = 1 - \{L(\mathbf{0})\}^{\frac{2}{n}}$$

Nagelkerke (1991) proposes the following adjusted coefficient, which can achieve a maximum value of one:

$$\tilde{R}^2 = \frac{R^2}{R_{\max}^2}$$

Properties and interpretation of R^2 and \tilde{R}^2 are provided in Nagelkerke (1991). In the “Testing Global Null Hypothesis: BETA=0” table, R^2 is labeled as “RSquare” and \tilde{R}^2 is labeled as “Max-rescaled RSquare.” Use the `RSQUARE` option to request R^2 and \tilde{R}^2 .

Score Statistics and Tests

To understand the general form of the score statistics, let $\mathbf{U}(\boldsymbol{\theta})$ be the vector of first partial derivatives of the log likelihood with respect to the parameter vector $\boldsymbol{\theta}$, and let $\mathbf{H}(\boldsymbol{\theta})$ be the matrix of second partial derivatives of the log likelihood with respect to $\boldsymbol{\theta}$. That is, $\mathbf{U}(\boldsymbol{\theta})$ is the gradient vector, and $\mathbf{H}(\boldsymbol{\theta})$ is the Hessian matrix. Let $\mathbf{I}(\boldsymbol{\theta})$ be either $-\mathbf{H}(\boldsymbol{\theta})$ or the expected value of $-\mathbf{H}(\boldsymbol{\theta})$. Consider a null hypothesis H_0 . Let $\hat{\boldsymbol{\theta}}_0$ be the MLE of $\boldsymbol{\theta}$ under H_0 . The chi-square score statistic for testing H_0 is defined by

$$\mathbf{U}'(\hat{\boldsymbol{\theta}}_0)\mathbf{I}^{-1}(\hat{\boldsymbol{\theta}}_0)\mathbf{U}(\hat{\boldsymbol{\theta}}_0)$$

and it has an asymptotic χ^2 distribution with r degrees of freedom under H_0 , where r is the number of restrictions imposed on $\boldsymbol{\theta}$ by H_0 .

Residual Chi-Square

When you use SELECTION=FORWARD, BACKWARD, or STEPWISE, the procedure calculates a residual score chi-square score statistic and reports the statistic, its degrees of freedom, and the p -value. This section describes how the statistic is calculated.

Suppose there are s explanatory effects of interest. The full cumulative response model has a parameter vector

$$\boldsymbol{\theta} = (\alpha_1, \dots, \alpha_k, \beta_1, \dots, \beta_s)'$$

where $\alpha_1, \dots, \alpha_k$ are intercept parameters, and β_1, \dots, β_s are the common slope parameters for the explanatory effects, and the full generalized logit model has a parameter vector

$$\begin{aligned} \boldsymbol{\theta} &= (\alpha_1, \dots, \alpha_k, \boldsymbol{\beta}'_1, \dots, \boldsymbol{\beta}'_k)' \quad \text{with} \\ \boldsymbol{\beta}'_i &= (\beta_{i1}, \dots, \beta_{is}), \quad i = 1, \dots, k \end{aligned}$$

where β_{ij} is the slope parameter for the j th effect in the i th logit.

Consider the null hypothesis $H_0: \beta_{t+1} = \dots = \beta_s = 0$ where $t < s$ for the cumulative response model, and $H_0: \beta_{i,t+1} = \dots = \beta_{is} = 0, t < s, i = 1, \dots, k$ for the generalized logit model. For the reduced model with t explanatory effects, let $\hat{\alpha}_1, \dots, \hat{\alpha}_k$ be the MLEs of the unknown intercept parameters, let $\hat{\beta}_1, \dots, \hat{\beta}_t$ be the MLEs of the unknown slope parameters, and let $\hat{\boldsymbol{\beta}}'_{i(t)} = (\hat{\beta}_{i1}, \dots, \hat{\beta}_{it}), i = 1, \dots, k$ be those for the generalized logit model. The residual chi-square is the chi-square score statistic testing the null hypothesis H_0 ; that is, the residual chi-square is

$$\mathbf{U}'(\hat{\boldsymbol{\theta}}_0)\mathbf{I}^{-1}(\hat{\boldsymbol{\theta}}_0)\mathbf{U}(\hat{\boldsymbol{\theta}}_0)$$

where for the cumulative response model $\hat{\boldsymbol{\theta}}_0 = (\hat{\alpha}_1, \dots, \hat{\alpha}_k, \hat{\beta}_1, \dots, \hat{\beta}_t, 0, \dots, 0)'$, and for the generalized logit model $\hat{\boldsymbol{\theta}}_0 = (\hat{\alpha}_1, \dots, \hat{\alpha}_k, \hat{\boldsymbol{\beta}}'_{1(t)}, \mathbf{0}'_{(s-t)}, \dots, \hat{\boldsymbol{\beta}}'_{k(t)}, \mathbf{0}'_{(s-t)})'$, where $\mathbf{0}_{(s-t)}$ denote a vector of $s - t$ zeros.

The residual chi-square has an asymptotic chi-square distribution with $s - t$ degrees of freedom ($k(s - t)$ for the generalized logit model). A special case is the global score chi-square, where the reduced model consists of the k intercepts and no explanatory effects. The global score statistic is displayed in the “Testing Global Null Hypothesis: BETA=0” table. The table is not produced when the **NOFIT** option is used, but the global score statistic is displayed.

Testing Individual Effects Not in the Model

These tests are performed in the FORWARD or STEPWISE method, and are displayed when the **DETAILS** option is specified. In the displayed output, the tests are labeled “Score Chi-Square” in the “Analysis of Effects Not in the Model” table and in the “Summary of Stepwise (Forward) Selection” table. This section describes how the tests are calculated.

Suppose that k intercepts and t explanatory variables (say v_1, \dots, v_t) have been fitted to a model and that v_{t+1} is another explanatory variable of interest. Consider a full model with the k intercepts and $t + 1$ explanatory variables (v_1, \dots, v_t, v_{t+1}) and a reduced model with v_{t+1} excluded. The significance of v_{t+1} adjusted for v_1, \dots, v_t can be determined by comparing the corresponding residual chi-square with a chi-square distribution with one degree of freedom (k degrees of freedom for the generalized logit model).

Testing the Parallel Lines Assumption

For an ordinal response, PROC LOGISTIC performs a test of the parallel lines assumption. In the displayed output, this test is labeled “Score Test for the Equal Slopes Assumption” when the **LINK=** option is **NORMIT** or **CLOGLOG**. When **LINK=LOGIT**, the test is labeled as “Score Test for the Proportional Odds Assumption” in the output. For small sample sizes, this test may be too liberal (Stokes, Davis, and Koch 2000). This section describes the methods used to calculate the test.

For this test the number of response levels, $k + 1$, is assumed to be strictly greater than 2. Let Y be the response variable taking values $1, \dots, k, k + 1$. Suppose there are s explanatory variables. Consider the general cumulative model without making the parallel lines assumption

$$g(\Pr(Y \leq i | \mathbf{x})) = (1, \mathbf{x}')\boldsymbol{\theta}_i, \quad 1 \leq i \leq k$$

where $g(\cdot)$ is the link function, and $\boldsymbol{\theta}_i = (\alpha_i, \beta_{i1}, \dots, \beta_{is})'$ is a vector of unknown parameters consisting of an intercept α_i and s slope parameters $\beta_{i1}, \dots, \beta_{is}$. The parameter vector for this general cumulative model is

$$\boldsymbol{\theta} = (\boldsymbol{\theta}'_1, \dots, \boldsymbol{\theta}'_k)'$$

Under the null hypothesis of parallelism $H_0: \beta_{1m} = \beta_{2m} = \dots = \beta_{km}, 1 \leq m \leq s$, there is a single common slope parameter for each of the s explanatory variables. Let β_1, \dots, β_s be the common slope parameters. Let $\hat{\alpha}_1, \dots, \hat{\alpha}_k$ and $\hat{\beta}_1, \dots, \hat{\beta}_s$ be the MLEs of the intercept parameters and the common slope parameters. Then, under H_0 , the MLE of θ is

$$\hat{\theta}_0 = (\hat{\theta}'_1, \dots, \hat{\theta}'_k)' \quad \text{with} \quad \hat{\theta}_i = (\hat{\alpha}_i, \hat{\beta}_1, \dots, \hat{\beta}_s)' \quad 1 \leq i \leq k$$

and the chi-squared score statistic $\mathbf{U}'(\hat{\theta}_0)\mathbf{I}^{-1}(\hat{\theta}_0)\mathbf{U}(\hat{\theta}_0)$ has an asymptotic chi-square distribution with $s(k-1)$ degrees of freedom. This tests the parallel lines assumption by testing the equality of separate slope parameters simultaneously for all explanatory variables.

Confidence Intervals for Parameters

There are two methods of computing confidence intervals for the regression parameters. One is based on the profile likelihood function, and the other is based on the asymptotic normality of the parameter estimators. The latter is not as time-consuming as the former, since it does not involve an iterative scheme; however, it is not thought to be as accurate as the former, especially with small sample size. You use the `CLPARM=` option to request confidence intervals for the parameters.

Likelihood Ratio-Based Confidence Intervals

The likelihood ratio-based confidence interval is also known as the profile likelihood confidence interval. The construction of this interval is derived from the asymptotic χ^2 distribution of the generalized likelihood ratio test (Venzon and Moolgavkar 1988). Suppose that the parameter vector is $\beta = (\beta_0, \beta_1, \dots, \beta_s)'$ and you want to compute a confidence interval for β_j . The profile likelihood function for $\beta_j = \gamma$ is defined as

$$l_j^*(\gamma) = \max_{\beta \in \mathcal{B}_j(\gamma)} l(\beta)$$

where $\mathcal{B}_j(\gamma)$ is the set of all β with the j th element fixed at γ , and $l(\beta)$ is the log-likelihood function for β . If $l_{\max} = l(\hat{\beta})$ is the log likelihood evaluated at the maximum likelihood estimate $\hat{\beta}$, then $2(l_{\max} - l_j^*(\beta_j))$ has a limiting chi-square distribution with one degree of freedom if β_j is the true parameter value. Let $l_0 = l_{\max} - .5\chi_1^2(1 - \alpha)$, where $\chi_1^2(1 - \alpha)$ is the $100(1 - \alpha)$ percentile of the chi-square distribution with one degree of freedom. A $100(1 - \alpha)\%$ confidence interval for β_j is

$$\{\gamma : l_j^*(\gamma) \geq l_0\}$$

The endpoints of the confidence interval are found by solving numerically for values of β_j that satisfy equality in the preceding relation. To obtain an iterative algorithm

for computing the confidence limits, the log-likelihood function in a neighborhood of β is approximated by the quadratic function

$$\tilde{l}(\beta + \delta) = l(\beta) + \delta' \mathbf{g} + \frac{1}{2} \delta' \mathbf{V} \delta$$

where $\mathbf{g} = \mathbf{g}(\beta)$ is the gradient vector and $\mathbf{V} = \mathbf{V}(\beta)$ is the Hessian matrix. The increment δ for the next iteration is obtained by solving the likelihood equations

$$\frac{d}{d\delta} \{ \tilde{l}(\beta + \delta) + \lambda(\mathbf{e}_j' \delta - \gamma) \} = \mathbf{0}$$

where λ is the Lagrange multiplier, \mathbf{e}_j is the j th unit vector, and γ is an unknown constant. The solution is

$$\delta = -\mathbf{V}^{-1}(\mathbf{g} + \lambda \mathbf{e}_j)$$

By substituting this δ into the equation $\tilde{l}(\beta + \delta) = l_0$, you can estimate λ as

$$\lambda = \pm \left(\frac{2(l_0 - l(\beta) + \frac{1}{2} \mathbf{g}' \mathbf{V}^{-1} \mathbf{g})}{\mathbf{e}_j' \mathbf{V}^{-1} \mathbf{e}_j} \right)^{\frac{1}{2}}$$

The upper confidence limit for β_j is computed by starting at the maximum likelihood estimate of β and iterating with positive values of λ until convergence is attained. The process is repeated for the lower confidence limit using negative values of λ .

Convergence is controlled by value ϵ specified with the PLCONV= option in the MODEL statement (the default value of ϵ is 1E-4). Convergence is declared on the current iteration if the following two conditions are satisfied:

$$|l(\beta) - l_0| \leq \epsilon$$

and

$$(\mathbf{g} + \lambda \mathbf{e}_j)' \mathbf{V}^{-1} (\mathbf{g} + \lambda \mathbf{e}_j) \leq \epsilon$$

Wald Confidence Intervals

Wald confidence intervals are sometimes called the normal confidence intervals. They are based on the asymptotic normality of the parameter estimators. The $100(1 - \alpha)\%$ Wald confidence interval for β_j is given by

$$\hat{\beta}_j \pm z_{1-\alpha/2} \hat{\sigma}_j$$

where z_p is the 100 p th percentile of the standard normal distribution, $\hat{\beta}_j$ is the maximum likelihood estimate of β_j , and $\hat{\sigma}_j$ is the standard error estimate of $\hat{\beta}_j$.

Odds Ratio Estimation

Consider a dichotomous response variable with outcomes *event* and *nonevent*. Consider a dichotomous risk factor variable X that takes the value 1 if the risk factor is present and 0 if the risk factor is absent. According to the logistic model, the log odds function, $g(X)$, is given by

$$g(X) \equiv \log\left(\frac{\Pr(\text{event} | X)}{\Pr(\text{nonevent} | X)}\right) = \beta_0 + \beta_1 X$$

The odds ratio ψ is defined as the ratio of the odds for those with the risk factor ($X = 1$) to the odds for those without the risk factor ($X = 0$). The log of the odds ratio is given by

$$\log(\psi) \equiv \log(\psi(X = 1, X = 0)) = g(X = 1) - g(X = 0) = \beta_1$$

The parameter, β_1 , associated with X represents the change in the log odds from $X = 0$ to $X = 1$. So, the odds ratio is obtained by simply exponentiating the value of the parameter associated with the risk factor. The odds ratio indicates how the odds of *event* change as you change X from 0 to 1. For instance, $\psi = 2$ means that the odds of an event when $X = 1$ are twice the odds of an event when $X = 0$.

Suppose the values of the dichotomous risk factor are coded as constants a and b instead of 0 and 1. The odds when $X = a$ become $\exp(\beta_0 + a\beta_1)$, and the odds when $X = b$ become $\exp(\beta_0 + b\beta_1)$. The odds ratio corresponding to an increase in X from a to b is

$$\psi = \exp[(b - a)\beta_1] = [\exp(\beta_1)]^{b-a} \equiv [\exp(\beta_1)]^c$$

Note that for any a and b such that $c = b - a = 1$, $\psi = \exp(\beta_1)$. So the odds ratio can be interpreted as the change in the odds for any increase of one unit in the corresponding risk factor. However, the change in odds for some amount other than one unit is often of greater interest. For example, a change of one pound in body weight may be too small to be considered important, while a change of 10 pounds may be more meaningful. The odds ratio for a change in X from a to b is estimated by raising the odds ratio estimate for a unit change in X to the power of $c = b - a$ as shown previously.

For a polytomous risk factor, the computation of odds ratios depends on how the risk factor is parameterized. For illustration, suppose that **Race** is a risk factor with four categories: White, Black, Hispanic, and Other.

For the effect parameterization scheme (PARAM=EFFECT) with White as the reference group, the design variables for **Race** are as follows.

Race	Design Variables		
	X_1	X_2	X_3
Black	1	0	0
Hispanic	0	1	0
Other	0	0	1
White	-1	-1	-1

The log odds for Black is

$$\begin{aligned} g(\text{Black}) &= \beta_0 + \beta_1(X_1 = 1) + \beta_2(X_2 = 0) + \beta_3(X_3 = 0) \\ &= \beta_0 + \beta_1 \end{aligned}$$

The log odds for White is

$$\begin{aligned} g(\text{White}) &= \beta_0 + \beta_1(X_1 = -1) + \beta_2(X_2 = -1) + \beta_3(X_3 = -1) \\ &= \beta_0 - \beta_1 - \beta_2 - \beta_3 \end{aligned}$$

Therefore, the log odds ratio of Black versus White becomes

$$\begin{aligned} \log(\psi(\text{Black}, \text{White})) &= g(\text{Black}) - g(\text{White}) \\ &= 2\beta_1 + \beta_2 + \beta_3 \end{aligned}$$

For the reference cell parameterization scheme (PARAM=REF) with White as the reference cell, the design variables for race are as follows.

Race	Design Variables		
	X_1	X_2	X_3
Black	1	0	0
Hispanic	0	1	0
Other	0	0	1
White	0	0	0

The log odds ratio of Black versus White is given by

$$\begin{aligned} \log(\psi(\text{Black}, \text{White})) &= g(\text{Black}) - g(\text{White}) \\ &= (\beta_0 + \beta_1(X_1 = 1) + \beta_2(X_2 = 0) + \beta_3(X_3 = 0)) - \\ &\quad (\beta_0 + \beta_1(X_1 = 0) + \beta_2(X_2 = 0) + \beta_3(X_3 = 0)) \\ &= \beta_1 \end{aligned}$$

For the GLM parameterization scheme (PARAM=GLM), the design variables are as follows.

Race	Design Variables			
	X_1	X_2	X_3	X_4
Black	1	0	0	0
Hispanic	0	1	0	0
Other	0	0	1	0
White	0	0	0	1

The log odds ratio of Black versus White is

$$\begin{aligned}
 & \log(\psi(\text{Black}, \text{White})) \\
 &= g(\text{Black}) - g(\text{White}) \\
 &= (\beta_0 + \beta_1(X_1 = 1) + \beta_2(X_2 = 0) + \beta_3(X_3 = 0) + \beta_4(X_4 = 0)) - \\
 &\quad (\beta_0 + \beta_1(X_1 = 0) + \beta_2(X_2 = 0) + \beta_3(X_3 = 0) + \beta_4(X_4 = 1)) \\
 &= \beta_1 - \beta_4
 \end{aligned}$$

Consider the hypothetical example of heart disease among race in Hosmer and Lemeshow (2000, p 56). The entries in the following contingency table represent counts.

Disease Status	Race			
	White	Black	Hispanic	Other
Present	5	20	15	10
Absent	20	10	10	10

The computation of odds ratio of Black versus White for various parameterization schemes is tabulated in the following table.

Odds Ratio of Heart Disease Comparing Black to White					
PARAM	Parameter Estimates				Odds Ratio Estimation
	$\hat{\beta}_1$	$\hat{\beta}_2$	$\hat{\beta}_3$	$\hat{\beta}_4$	
EFFECT	0.7651	0.4774	0.0719		$\exp(2 \times 0.7651 + 0.4774 + 0.0719) = 8$
REF	2.0794	1.7917	1.3863		$\exp(2.0794) = 8$
GLM	2.0794	1.7917	1.3863	0.0000	$\exp(2.0794) = 8$

Since the log odds ratio ($\log(\psi)$) is a linear function of the parameters, the Wald confidence interval for $\log(\psi)$ can be derived from the parameter estimates and the estimated covariance matrix. Confidence intervals for the odds ratios are obtained by exponentiating the corresponding confidence intervals for the log odds ratios. In the displayed output of PROC LOGISTIC, the “Odds Ratio Estimates” table contains the odds ratio estimates and the corresponding 95% Wald confidence intervals. For continuous explanatory variables, these odds ratios correspond to a unit increase in the risk factors.

To customize odds ratios for specific units of change for a continuous risk factor, you can use the **UNITS** statement to specify a list of relevant units for each explanatory variable in the model. Estimates of these customized odds ratios are given in a separate table. Let (L_j, U_j) be a confidence interval for $\log(\psi)$. The corresponding lower and upper confidence limits for the customized odds ratio $\exp(c\beta_j)$ are $\exp(cL_j)$ and $\exp(cU_j)$, respectively (for $c > 0$), or $\exp(cU_j)$ and $\exp(cL_j)$, respectively (for

$c < 0$). You use the `CLODDS=` option to request the confidence intervals for the odds ratios.

For a generalized logit model, odds ratios are computed similarly, except k odds ratios are computed for each effect, corresponding to the k logits in the model.

Rank Correlation of Observed Responses and Predicted Probabilities

The predicted mean score of an observation is the sum of the Ordered Values (shown in the Response Profile table) minus one, weighted by the corresponding predicted probabilities for that observation; that is, the predicted mean score = $\sum_{i=1}^{k+1} (i-1)\hat{\pi}_i$, where $k+1$ is the number of response levels and $\hat{\pi}_i$ is the predicted probability of the i th (ordered) response.

A pair of observations with different observed responses is said to be *concordant* if the observation with the lower ordered response value has a lower predicted mean score than the observation with the higher ordered response value. If the observation with the lower ordered response value has a higher predicted mean score than the observation with the higher ordered response value, then the pair is *discordant*. If the pair is neither concordant nor discordant, it is a *tie*. Enumeration of the total numbers of concordant and discordant pairs is carried out by categorizing the predicted mean score into intervals of length $k/500$ and accumulating the corresponding frequencies of observations.

Let N be the sum of observation frequencies in the data. Suppose there is a total of t pairs with different responses, n_c of them are concordant, n_d of them are discordant, and $t - n_c - n_d$ of them are tied. PROC LOGISTIC computes the following four indices of rank correlation for assessing the predictive ability of a model:

$$c = (n_c + 0.5(t - n_c - n_d))/t$$

$$\text{Somers' } D = (n_c - n_d)/t$$

$$\text{Goodman-Kruskal Gamma} = (n_c - n_d)/(n_c + n_d)$$

$$\text{Kendall's Tau-}a = (n_c - n_d)/(0.5N(N - 1))$$

Note that c also gives an estimate of the area under the receiver operating characteristic (ROC) curve when the response is binary (Hanley and McNeil 1982).

For binary responses, the predicted mean score is equal to the predicted probability for Ordered Value 2. As such, the preceding definition of concordance is consistent with the definition used in previous releases for the binary response model.

Linear Predictor, Predicted Probability, and Confidence Limits

This section describes how predicted probabilities and confidence limits are calculated using the maximum likelihood estimates (MLEs) obtained from PROC LOGISTIC. For a specific example, see the “Getting Started” section on page 2284. Predicted probabilities and confidence limits can be output to a data set with the OUTPUT statement.

Cumulative Response Models

For a vector of explanatory variables \mathbf{x} , the linear predictor

$$\eta_i = g(\Pr(Y \leq i | \mathbf{x})) = \alpha_i + \beta' \mathbf{x} \quad 1 \leq i \leq k$$

is estimated by

$$\hat{\eta}_i = \hat{\alpha}_i + \hat{\beta}' \mathbf{x}$$

where $\hat{\alpha}_i$ and $\hat{\beta}$ are the MLEs of α_i and β . The estimated standard error of η_i is $\hat{\sigma}(\hat{\eta}_i)$, which can be computed as the square root of the quadratic form $(1, \mathbf{x}') \hat{\mathbf{V}}_{\mathbf{b}} (1, \mathbf{x}')'$ where $\hat{\mathbf{V}}_{\mathbf{b}}$ is the estimated covariance matrix of the parameter estimates. The asymptotic $100(1 - \alpha)\%$ confidence interval for η_i is given by

$$\hat{\eta}_i \pm z_{\alpha/2} \hat{\sigma}(\hat{\eta}_i)$$

where $z_{\alpha/2}$ is the $100(1 - \alpha/2)$ percentile point of a standard normal distribution.

The predicted value and the $100(1 - \alpha)\%$ confidence limits for $\Pr(Y \leq i | \mathbf{x})$ are obtained by back-transforming the corresponding measures for the linear predictor.

Link	Predicted Probability	100(1- α) Confidence Limits
LOGIT	$1/(1 + e^{-\hat{\eta}_i})$	$1/(1 + e^{-\hat{\eta}_i \pm z_{\alpha/2} \hat{\sigma}(\hat{\eta}_i)})$
PROBIT	$\Phi(\hat{\eta}_i)$	$\Phi(\hat{\eta}_i \pm z_{\alpha/2} \hat{\sigma}(\hat{\eta}_i))$
CLOGLOG	$1 - e^{-e^{\hat{\eta}_i}}$	$1 - e^{-e^{\hat{\eta}_i \pm z_{\alpha/2} \hat{\sigma}(\hat{\eta}_i)}}$

Generalized Logit Model

For a vector of explanatory variables \mathbf{x} , let π_i denote the probability of obtaining the response value i :

$$\pi_i = \begin{cases} \frac{\pi_{k+1} e^{\alpha_i + \mathbf{x}' \beta_i}}{1 + \sum_{i=1}^k e^{\alpha_i + \mathbf{x}' \beta_i}} & 1 \leq i \leq k \\ \pi_{k+1} & i = k + 1 \end{cases}$$

By the *delta method*,

$$\sigma^2(\pi_i) = \left(\frac{\partial \pi_i}{\partial \boldsymbol{\theta}} \right)' \mathbf{V}(\boldsymbol{\theta}) \frac{\partial \pi_i}{\partial \boldsymbol{\theta}}$$

A $100(1 - \alpha)\%$ confidence level for π_i is given by

$$\hat{\pi}_i \pm z_{\alpha/2} \hat{\sigma}(\hat{\pi}_i)$$

where $\hat{\pi}_i$ is the estimated expected probability of response i , and $\hat{\sigma}(\hat{\pi}_i)$ is obtained by evaluating $\sigma(\pi_i)$ at $\boldsymbol{\theta} = \hat{\boldsymbol{\theta}}$.

Classification Table

For binary response data, the response is either an *event* or a *nonevent*. In PROC LOGISTIC, the response with Ordered Value 1 is regarded as the *event*, and the response with Ordered Value 2 is the *nonevent*. PROC LOGISTIC models the probability of the *event*. From the fitted model, a predicted *event* probability can be computed for each observation. The method to compute a reduced-bias estimate of the predicted probability is given in the “[Predicted Probability of an Event for Classification](#)” section on page 2352, which follows. If the predicted *event* probability exceeds some cutpoint value $z \in [0, 1]$, the observation is predicted to be an *event* observation; otherwise, it is predicted as a *nonevent*. A 2×2 frequency table can be obtained by cross-classifying the observed and predicted responses. The `CTABLE` option produces this table, and the `PPROB=` option selects one or more cutpoints. Each cutpoint generates a classification table. If the `PEVENT=` option is also specified, a classification table is produced for each combination of `PEVENT=` and `PPROB=` values.

The accuracy of the classification is measured by its *sensitivity* (the ability to predict an *event* correctly) and *specificity* (the ability to predict a *nonevent* correctly). *Sensitivity* is the proportion of *event* responses that were predicted to be *events*. *Specificity* is the proportion of *nonevent* responses that were predicted to be *nonevents*. PROC LOGISTIC also computes three other conditional probabilities: *false positive rate*, *false negative rate*, and *rate of correct classification*. The *false positive rate* is the proportion of predicted *event* responses that were observed as *nonevents*. The *false negative rate* is the proportion of predicted *nonevent* responses that were observed as *events*. Given prior probabilities specified with the `PEVENT=` option, these conditional probabilities can be computed as posterior probabilities using Bayes’ theorem.

Predicted Probability of an Event for Classification

When you classify a set of binary data, if the same observations used to fit the model are also used to estimate the classification error, the resulting error-count estimate is biased. One way of reducing the bias is to remove the binary observation to be classified from the data, reestimate the parameters of the model, and then classify the observation based on the new parameter estimates. However, it would be costly to fit the model leaving out each observation one at a time. The LOGISTIC procedure provides a less expensive one-step approximation to the preceding parameter estimates. Let \mathbf{b} be the MLE of the parameter vector $(\alpha, \beta^t)'$ based on all observations. Let \mathbf{b}_j denote the MLE computed without the j th observation. The one-step estimate of \mathbf{b}_j is given by

$$\mathbf{b}_j^1 = \mathbf{b} - \frac{w_j(y_j - \hat{\pi}_j)}{1 - h_{jj}} \hat{\mathbf{V}}_{\mathbf{b}} \begin{pmatrix} 1 \\ \mathbf{x}_j \end{pmatrix}$$

where

y_j is 1 for an event response and 0 otherwise

w_j is the WEIGHT value

$\hat{\pi}_j$ is the predicted event probability based on \mathbf{b}

h_{jj} is the **hat diagonal element** (defined on page 2359) with $n_j = 1$ and $r_j = y_j$

$\hat{\mathbf{V}}_{\mathbf{b}}$ is the estimated covariance matrix of \mathbf{b}

False Positive and Negative Rates Using Bayes' Theorem

Suppose n_1 of n individuals experience an event, for example, a disease. Let this group be denoted by \mathcal{C}_1 , and let the group of the remaining $n_2 = n - n_1$ individuals who do not have the disease be denoted by \mathcal{C}_2 . The j th individual is classified as giving a positive response if the predicted probability of disease ($\hat{\pi}_j^*$) is large. The probability $\hat{\pi}_j^*$ is the reduced-bias estimate based on a one-step approximation given in the preceding section. For a given cutpoint z , the j th individual is predicted to give a positive response if $\hat{\pi}_j^* \geq z$.

Let B denote the event that a subject has the disease and \bar{B} denote the event of not having the disease. Let A denote the event that the subject responds positively, and let \bar{A} denote the event of responding negatively. Results of the classification are represented by two conditional probabilities, $\Pr(A|B)$ and $\Pr(A|\bar{B})$, where $\Pr(A|B)$ is the sensitivity, and $\Pr(A|\bar{B})$ is one minus the specificity.

These probabilities are given by

$$\Pr(A|B) = \frac{\sum_{j \in \mathcal{C}_1} I(\hat{\pi}_j^* \geq z)}{n_1}$$

$$\Pr(A|\bar{B}) = \frac{\sum_{j \in \mathcal{C}_2} I(\hat{\pi}_j^* \geq z)}{n_2}$$

where $I(\cdot)$ is the indicator function.

Bayes' theorem is used to compute the error rates of the classification. For a given prior probability $\Pr(B)$ of the disease, the false positive rate P_{F+} and the false negative rate P_{F-} are given by Fleiss (1981, pp. 4–5) as follows:

$$P_{F+} = \Pr(\bar{B}|A) = \frac{\Pr(A|\bar{B})[1 - \Pr(B)]}{\Pr(A|\bar{B}) + \Pr(B)[\Pr(A|B) - \Pr(A|\bar{B})]}$$

$$P_{F-} = \Pr(B|\bar{A}) = \frac{[1 - \Pr(A|B)]\Pr(B)}{1 - \Pr(A|\bar{B}) - \Pr(B)[\Pr(A|B) - \Pr(A|\bar{B})]}$$

The prior probability $\Pr(B)$ can be specified by the **PEVENT=** option. If the **PEVENT=** option is not specified, the sample proportion of diseased individuals is used; that is, $\Pr(B) = n_1/n$. In such a case, the false positive rate and the false negative rate reduce to

$$P_{F+} = \frac{\sum_{j \in \mathcal{C}_2} I(\hat{\pi}_j^* \geq z)}{\sum_{j \in \mathcal{C}_1} I(\hat{\pi}_j^* \geq z) + \sum_{j \in \mathcal{C}_2} I(\hat{\pi}_j^* \geq z)}$$

$$P_{F-} = \frac{\sum_{j \in \mathcal{C}_1} I(\hat{\pi}_j^* < z)}{\sum_{j \in \mathcal{C}_1} I(\hat{\pi}_j^* < z) + \sum_{j \in \mathcal{C}_2} I(\hat{\pi}_j^* < z)}$$

Note that for a stratified sampling situation in which n_1 and n_2 are chosen a priori, n_1/n is not a desirable estimate of $\Pr(B)$. For such situations, the `PEVENT=` option should be specified.

Overdispersion

For a correctly specified model, the Pearson chi-square statistic and the deviance, divided by their degrees of freedom, should be approximately equal to one. When their values are much larger than one, the assumption of binomial variability may not be valid and the data are said to exhibit overdispersion. Underdispersion, which results in the ratios being less than one, occurs less often in practice.

When fitting a model, there are several problems that can cause the goodness-of-fit statistics to exceed their degrees of freedom. Among these are such problems as outliers in the data, using the wrong link function, omitting important terms from the model, and needing to transform some predictors. These problems should be eliminated before proceeding to use the following methods to correct for overdispersion.

Rescaling the Covariance Matrix

One way of correcting overdispersion is to multiply the covariance matrix by a dispersion parameter. This method assumes that the sample sizes in each subpopulation are approximately equal. You can supply the value of the dispersion parameter directly, or you can estimate the dispersion parameter based on either the Pearson chi-square statistic or the deviance for the fitted model.

The Pearson chi-square statistic χ_P^2 and the deviance χ_D^2 are given by

$$\chi_P^2 = \sum_{i=1}^m \sum_{j=1}^{k+1} \frac{(r_{ij} - n_i \hat{\pi}_{ij})^2}{n_i \hat{\pi}_{ij}}$$

$$\chi_D^2 = 2 \sum_{i=1}^m \sum_{j=1}^{k+1} r_{ij} \log \left(\frac{r_{ij}}{n_i \hat{\pi}_{ij}} \right)$$

where m is the number of subpopulation profiles, $k + 1$ is the number of response levels, r_{ij} is the total weight (sum of the product of the frequencies and the weights) associated with j th level responses in the i th profile, $n_i = \sum_{j=1}^{k+1} r_{ij}$, and $\hat{\pi}_{ij}$ is the fitted probability for the j th level at the i th profile. Each of these chi-square statistics has $mk - p$ degrees of freedom, where p is the number of parameters estimated. The dispersion parameter is estimated by

$$\hat{\sigma}^2 = \begin{cases} \chi_P^2 / (mk - p) & \text{SCALE=PEARSON} \\ \chi_D^2 / (mk - p) & \text{SCALE=DEVIANC} \\ (\text{constant})^2 & \text{SCALE=constant} \end{cases}$$

In order for the Pearson statistic and the deviance to be distributed as chi-square, there must be sufficient replication within the subpopulations. When this is not true, the data are sparse, and the p -values for these statistics are not valid and should be

ignored. Similarly, these statistics, divided by their degrees of freedom, cannot serve as indicators of overdispersion. A large difference between the Pearson statistic and the deviance provides some evidence that the data are too sparse to use either statistic.

You can use the **AGGREGATE** (or **AGGREGATE=**) option to define the subpopulation profiles. If you do not specify this option, each observation is regarded as coming from a separate subpopulation. For *events/trials* syntax, each observation represents n Bernoulli trials, where n is the value of the *trials* variable; for *single-trial* syntax, each observation represents a single trial. Without the **AGGREGATE** (or **AGGREGATE=**) option, the Pearson chi-square statistic and the deviance are calculated only for *events/trials* syntax.

Note that the parameter estimates are not changed by this method. However, their standard errors are adjusted for overdispersion, affecting their significance tests.

Williams' Method

Suppose that the data consist of n binomial observations. For the i th observation, let r_i/n_i be the observed proportion and let \mathbf{x}_i be the associated vector of explanatory variables. Suppose that the response probability for the i th observation is a random variable P_i with mean and variance

$$E(P_i) = \pi_i \quad \text{and} \quad V(P_i) = \phi\pi_i(1 - \pi_i)$$

where p_i is the probability of the event, and ϕ is a nonnegative but otherwise unknown scale parameter. Then the mean and variance of r_i are

$$E(r_i) = n_i\pi_i \quad \text{and} \quad V(r_i) = n_i\pi_i(1 - \pi_i)[1 + (n_i - 1)\phi]$$

Williams (1982) estimates the unknown parameter ϕ by equating the value of Pearson's chi-square statistic for the full model to its approximate expected value. Suppose w_i^* is the weight associated with the i th observation. The Pearson chi-square statistic is given by

$$\chi^2 = \sum_{i=1}^n \frac{w_i^*(r_i - n_i\hat{\pi}_i)^2}{n_i\hat{\pi}_i(1 - \hat{\pi}_i)}$$

Let $g'(\cdot)$ be the first derivative of the link function $g(\cdot)$. The approximate expected value of χ^2 is

$$E_{\chi^2} = \sum_{i=1}^n w_i^*(1 - w_i^*v_i d_i)[1 + \phi(n_i - 1)]$$

where $v_i = n_i/(\pi_i(1 - \pi_i)[g'(\pi_i)]^2)$ and d_i is the variance of the linear predictor $\hat{\alpha}_i + \mathbf{x}_i'\hat{\beta}$. The scale parameter ϕ is estimated by the following iterative procedure.

At the start, let $w_i^* = 1$ and let π_i be approximated by r_i/n_i , $i = 1, 2, \dots, n$. If you apply these weights and approximated probabilities to χ^2 and E_{χ^2} and then equate them, an initial estimate of ϕ is therefore

$$\hat{\phi}_0 = \frac{\chi^2 - (n - p)}{\sum_i (n_i - 1)(1 - v_i d_i)}$$

where p is the total number of parameters. The initial estimates of the weights become $\hat{w}_{i0}^* = [1 + (n_i - 1)\hat{\phi}_0]^{-1}$. After a weighted fit of the model, $\hat{\beta}$ is recalculated, and so is χ^2 . Then a revised estimate of ϕ is given by

$$\hat{\phi}_1 = \frac{\chi^2 - \sum_i w_i^* (1 - w_i^* v_i d_i)}{w_i^* (n_i - 1)(1 - w_i^* v_i d_i)}$$

The iterative procedure is repeated until χ^2 is very close to its degrees of freedom.

Once ϕ has been estimated by $\hat{\phi}$ under the full model, weights of $(1 + (n_i - 1)\hat{\phi})^{-1}$ can be used in fitting models that have fewer terms than the full model. See [Example 42.9](#) on page 2438 for an illustration.

The Hosmer-Lemeshow Goodness-of-Fit Test

Sufficient replication within subpopulations is required to make the Pearson and deviance goodness-of-fit tests valid. When there are one or more continuous predictors in the model, the data are often too sparse to use these statistics. Hosmer and Lemeshow (2000) proposed a statistic that they show, through simulation, is distributed as chi-square when there is no replication in any of the subpopulations. This test is only available for binary response models.

First, the observations are sorted in increasing order of their estimated event probability. The event is the response level specified in the response variable option `EVENT=`, or the response level which is not specified in the `REF=` option, or, if neither of these options were specified, then the event is the response level identified in the “Response Profiles” table as “Ordered Value 1”. The observations are then divided into approximately ten groups according to the following scheme. Let N be the total number of subjects. Let M be the target number of subjects for each group given by

$$M = [0.1 \times N + 0.5]$$

where $[x]$ represents the integral value of x . If the *single-trial* syntax is used, blocks of subjects are formed of observations with identical values of the explanatory variables. Blocks of subjects are not divided when being placed into groups.

Suppose there are n_1 subjects in the first block and n_2 subjects in the second block. The first block of subjects is placed in the first group. Subjects in the second block are added to the first group if

$$n_1 < M \quad \text{and} \quad n_1 + [0.5 \times n_2] \leq M$$

Otherwise, they are placed in the second group. In general, suppose subjects of the $(j-1)$ th block have been placed in the k th group. Let c be the total number of subjects currently in the k th group. Subjects for the j th block (containing n_j subjects) are also placed in the k th group if

$$c < M \quad \text{and} \quad c + [0.5 \times n_j] \leq M$$

Otherwise, the n_j subjects are put into the next group. In addition, if the number of subjects in the last group does not exceed $[0.05 \times N]$ (half the target group size), the last two groups are collapsed to form only one group.

Note that the number of groups, g , may be smaller than 10 if there are fewer than 10 patterns of explanatory variables. There must be at least three groups in order for the Hosmer-Lemeshow statistic to be computed.

The Hosmer-Lemeshow goodness-of-fit statistic is obtained by calculating the Pearson chi-square statistic from the $2 \times g$ table of observed and expected frequencies, where g is the number of groups. The statistic is written

$$\chi_{HL}^2 = \sum_{i=1}^g \frac{(O_i - N_i \bar{\pi}_i)^2}{N_i \bar{\pi}_i (1 - \bar{\pi}_i)}$$

where N_i is the total frequency of subjects in the i th group, O_i is the total frequency of event outcomes in the i th group, and $\bar{\pi}_i$ is the average estimated predicted probability of an event outcome for the i th group. The Hosmer-Lemeshow statistic is then compared to a chi-square distribution with $(g - n)$ degrees of freedom, where the value of n can be specified in the **LACKFIT** option in the MODEL statement. The default is $n = 2$. Large values of χ_{HL}^2 (and small p -values) indicate a lack of fit of the model.

Receiver Operating Characteristic Curves

In a sample of n individuals, suppose n_1 individuals are observed to have a certain condition or event. Let this group be denoted by \mathcal{C}_1 , and let the group of the remaining $n_2 = n - n_1$ individuals who do not have the condition be denoted by \mathcal{C}_2 . Risk factors are identified for the sample, and a logistic regression model is fitted to the data. For the j th individual, an estimated probability $\hat{\pi}_j$ of the event of interest is calculated. Note that the $\hat{\pi}_j$ are computed as shown in the “**Linear Predictor, Predicted Probability, and Confidence Limits**” section on page 2350 and are not the cross validated estimates discussed in the “**Classification Table**” section on page 2352.

Suppose the n individuals undergo a test for predicting the event and the test is based on the estimated probability of the event. Higher values of this estimated probability are assumed to be associated with the event. A receiver operating characteristic (ROC) curve can be constructed by varying the cutpoint that determines which estimated event probabilities are considered to predict the event. For each cutpoint z , the following measures can be output to a data set using the **OUTROC=** option in the

MODEL statement or the `OUTROC=` option in the SCORE statement:

$$\begin{aligned} _POS_ (z) &= \sum_{i \in \mathcal{C}_1} I(\hat{\pi}_i \geq z) \\ _NEG_ (z) &= \sum_{i \in \mathcal{C}_2} I(\hat{\pi}_i < z) \\ _FALPOS_ (z) &= \sum_{i \in \mathcal{C}_2} I(\hat{\pi}_i \geq z) \\ _FALNEG_ (z) &= \sum_{i \in \mathcal{C}_1} I(\hat{\pi}_i < z) \\ _SENSIT_ (z) &= \frac{_POS_ (z)}{n_1} \\ _1MSPEC_ (z) &= \frac{_FALPOS_ (z)}{n_2} \end{aligned}$$

where $I(\cdot)$ is the indicator function.

Note that $_POS_ (z)$ is the number of correctly predicted event responses, $_NEG_ (z)$ is the number of correctly predicted nonevent responses, $_FALPOS_ (z)$ is the number of falsely predicted event responses, $_FALNEG_ (z)$ is the number of falsely predicted nonevent responses, $_SENSIT_ (z)$ is the sensitivity of the test, and $_1MSPEC_ (z)$ is one minus the specificity of the test.

A plot of the ROC curve can be constructed by using the PLOT or GPLOT procedure with the `OUTROC=` data set and plotting sensitivity ($_SENSIT_$) against 1-specificity ($_1MSPEC_$); see [Example 42.7](#) on page 2429 for an illustration. The area under the ROC curve, as determined by the trapezoidal rule, is estimated by the statistic c in the “Association of Predicted Probabilities and Observed Responses” table.

Testing Linear Hypotheses about the Regression Coefficients

Linear hypotheses for $\boldsymbol{\theta}$ are expressed in matrix form as

$$H_0: \mathbf{L}\boldsymbol{\theta} = \mathbf{c}$$

where \mathbf{L} is a matrix of coefficients for the linear hypotheses, and \mathbf{c} is a vector of constants. The vector of regression coefficients $\boldsymbol{\theta}$ includes slope parameters as well as intercept parameters. The Wald chi-square statistic for testing H_0 is computed as

$$\chi_W^2 = (\mathbf{L}\hat{\boldsymbol{\theta}} - \mathbf{c})' [\mathbf{L}\hat{\mathbf{V}}(\hat{\boldsymbol{\theta}})\mathbf{L}']^{-1} (\mathbf{L}\hat{\boldsymbol{\theta}} - \mathbf{c})$$

where $\hat{\mathbf{V}}(\hat{\boldsymbol{\theta}})$ is the estimated covariance matrix. Under H_0 , χ_W^2 has an asymptotic chi-square distribution with r degrees of freedom, where r is the rank of \mathbf{L} .

Regression Diagnostics

For binary response data, regression diagnostics developed by Pregibon (1981) can be requested by specifying the **INFLUENCE** option. For diagnostics available with conditional logistic regression, see the “**Regression Diagnostic Details**” section on page 2367.

This section uses the following notation:

r_j, n_j	r_j is the number of event responses out of n_j trials for the j th observation. If <i>events/trials</i> syntax is used, r_j is the value of <i>events</i> and n_j is the value of <i>trials</i> . For <i>single-trial</i> syntax, $n_j = 1$, and $r_j = 1$ if the ordered response is 1, and $r_j = 0$ if the ordered response is 2.
w_j	is the weight of the j th observation.
π_j	is the probability of an event response for the j th observation given by $\pi_j = F(\alpha + \beta' \mathbf{x}_j)$, where $F(\cdot)$ is the inverse link function defined on page 2335.
\mathbf{b}	is the maximum likelihood estimate (MLE) of $(\alpha, \beta)'$.
$\hat{\mathbf{V}}_{\mathbf{b}}$	is the estimated covariance matrix of \mathbf{b} .
\hat{p}_j, \hat{q}_j	\hat{p}_j is the estimate of π_j evaluated at \mathbf{b} , and $\hat{q}_j = 1 - \hat{p}_j$.

Pregibon suggests using the index plots of several diagnostic statistics to identify influential observations and to quantify the effects on various aspects of the maximum likelihood fit. In an index plot, the diagnostic statistic is plotted against the observation number. In general, the distributions of these diagnostic statistics are not known, so cutoff values cannot be given for determining when the values are large. However, the **IPLOTS** and **INFLUENCE** options provide displays of the diagnostic values allowing visual inspection and comparison of the values across observations. In these plots, if the model is correctly specified and fits all observations well, then no extreme points should appear.

The next five sections give formulas for these diagnostic statistics.

Hat Matrix Diagonal

The diagonal elements of the hat matrix are useful in detecting extreme points in the design space where they tend to have larger values. The j th diagonal element is

$$h_{jj} = \begin{cases} \tilde{w}_j(1, \mathbf{x}'_j) \hat{\mathbf{V}}_{\mathbf{b}}(1, \mathbf{x}'_j)' & \text{Fisher-Scoring} \\ \hat{w}_j(1, \mathbf{x}'_j) \hat{\mathbf{V}}_{\mathbf{b}}(1, \mathbf{x}'_j)' & \text{Newton-Raphson} \end{cases}$$

where

$$\begin{aligned} \tilde{w}_j &= \frac{w_j n_j}{\hat{p}_j \hat{q}_j [g'(\hat{p}_j)]^2} \\ \hat{w}_j &= \tilde{w}_j + \frac{w_j (r_j - n_j \hat{p}_j) [\hat{p}_j \hat{q}_j g''(\hat{p}_j) + (\hat{q}_j - \hat{p}_j) g'(\hat{p}_j)]}{(\hat{p}_j \hat{q}_j)^2 [g'(\hat{p}_j)]^3} \end{aligned}$$

and $g'(\cdot)$ and $g''(\cdot)$ are the first and second derivatives of the link function $g(\cdot)$, respectively.

For a binary response logit model, the hat matrix diagonal elements are

$$h_{jj} = w_j n_j \hat{p}_j \hat{q}_j (1, \mathbf{x}'_j) \hat{\mathbf{V}}_{\mathbf{b}} \begin{pmatrix} 1 \\ \mathbf{x}_j \end{pmatrix}$$

If the estimated probability is extreme (less than 0.1 and greater than 0.9, approximately), then the hat diagonal may be greatly reduced in value. Consequently, when an observation has a very large or very small estimated probability, its hat diagonal value is not a good indicator of the observation's distance from the design space (Hosmer and Lemeshow 2000, p 171).

Pearson Residuals and Deviance Residuals

Pearson and Deviance residuals are useful in identifying observations that are not explained well by the model. Pearson residuals are components of the Pearson chi-square statistic and deviance residuals are components of the deviance. The Pearson residual for the j th observation is

$$\chi_j = \frac{\sqrt{w_j}(r_j - n_j \hat{p}_j)}{\sqrt{n_j \hat{p}_j \hat{q}_j}}$$

The Pearson chi-square statistic is the sum of squares of the Pearson residuals. The deviance residual for the j th observation is

$$d_j = \begin{cases} -\sqrt{-2w_j n_j \log(\hat{q}_j)} & \text{if } r_j = 0 \\ \pm \sqrt{2w_j [r_j \log(\frac{r_j}{n_j \hat{p}_j}) + (n_j - r_j) \log(\frac{n_j - r_j}{n_j \hat{q}_j})]} & \text{if } 0 < r_j < n_j \\ \sqrt{-2w_j n_j \log(\hat{p}_j)} & \text{if } r_j = n_j \end{cases}$$

where the plus (minus) in \pm is used if r_j/n_j is greater (less) than \hat{p}_j . The deviance is the sum of squares of the deviance residuals.

DFBETAS

For each parameter estimate, the procedure calculates a DFBETAS diagnostic for each observation. The DFBETAS diagnostic for an observation is the standardized difference in the parameter estimate due to deleting the observation, and it can be used to assess the effect of an individual observation on each estimated parameter of the fitted model. Instead of re-estimating the parameter every time an observation is deleted, PROC LOGISTIC uses the one-step estimate. See the section “[Predicted Probability of an Event for Classification](#)” on page 2352. For the j th observation, the DFBETAS are given by

$$\text{DFBETAS}_{ij} = \Delta_i \mathbf{b}_j^1 / \hat{\sigma}(b_i)$$

where $i = 0, 1, \dots, s$, $\hat{\sigma}(b_i)$ is the standard error of the i th component of \mathbf{b} , and $\Delta_i \mathbf{b}_j^1$ is the i th component of the one-step difference

$$\Delta \mathbf{b}_j^1 = \frac{w_j(r_j - n_j \hat{p}_j)}{1 - h_{jj}} \hat{\mathbf{V}}_{\mathbf{b}} \begin{pmatrix} 1 \\ \mathbf{x}_j \end{pmatrix}$$

$\Delta \mathbf{b}_j^1$ is the approximate change $(\mathbf{b} - \mathbf{b}_j^1)$ in the vector of parameter estimates due to the omission of the j th observation. The DFBETAS are useful in detecting observations that are causing instability in the selected coefficients.

C and CBAR

C and CBAR are confidence interval displacement diagnostics that provide scalar measures of the influence of individual observations on \mathbf{b} . These diagnostics are based on the same idea as the Cook distance in linear regression theory, and by using the one-step estimate, C and CBAR for the j th observation are computed as

$$C_j = \chi_j^2 h_{jj} / (1 - h_{jj})^2$$

and

$$\bar{C}_j = \chi_j^2 h_{jj} / (1 - h_{jj})$$

respectively.

Typically, to use these statistics, you plot them against an index (as the IPLOT option does) and look for outliers.

DIFDEV and DIFCHISQ

DIFDEV and DIFCHISQ are diagnostics for detecting ill-fitted observations; in other words, observations that contribute heavily to the disagreement between the data and the predicted values of the fitted model. DIFDEV is the change in the deviance due to deleting an individual observation while DIFCHISQ is the change in the Pearson chi-square statistic for the same deletion. By using the one-step estimate, DIFDEV and DIFCHISQ for the j th observation are computed as

$$\text{DIFDEV} = d_j^2 + \bar{C}_j$$

and

$$\text{DIFCHISQ} = \bar{C}_j / h_{jj}$$

Scoring Data Sets

Scoring a data set, which is especially important for predictive modeling, means applying a previously fitted model to a new data set in order to compute the conditional, or *posterior*, probabilities of each response category given the values of the explanatory variables in each observation.

The **SCORE** statement enables you to score new data sets and output the scored values and, optionally, the corresponding confidence limits into a SAS data set. If the response variable is included in the new data set, then you can request fit statistics for the data, which is especially useful for test or validation data. If the response is binary, you can also create a SAS data set containing the *receiver operating characteristic* (ROC) curve. You can specify multiple SCORE statements in the same invocation of PROC LOGISTIC.

By default, the posterior probabilities are based on implicit prior probabilities that are proportional to the frequencies of the response categories in the *training data* (the data used to fit the model). Explicit prior probabilities should be specified when the sample proportions of the response categories in the training data differ substantially from the operational data to be scored. For example, to detect a rare category, it is common practice to use a training set in which the rare categories are over-represented; without prior probabilities that reflect the true incidence rate, the predicted posterior probabilities for the rare category will be too high. By specifying the correct priors, the posterior probabilities are adjusted appropriately.

The model fit to the **DATA=** data set in the PROC LOGISTIC statement is the default model used for the scoring. Alternatively, you can save a fit model on one run of PROC LOGISTIC and use it to score new data on a subsequent run. The **OUTMODEL=** option in the PROC LOGISTIC statement saves the model information in a SAS data set. Specifying this data set in the **INMODEL=** option of a new PROC LOGISTIC run will score the **DATA=** data set in the SCORE statement without refitting the model.

The rest of this section provides some computational details about the scoring.

Posterior Probabilities and Confidence Limits

Let F be the inverse link function. That is,

$$F(t) = \begin{cases} \frac{1}{1+\exp(-t)} & \text{logistic} \\ \Phi(t) & \text{normal} \\ 1 - \exp(-\exp(t)) & \text{complementary log-log} \end{cases}$$

The first derivative of F is given by

$$F'(t) = \begin{cases} \frac{\exp(-t)}{(1+\exp(-t))^2} & \text{logistic} \\ \phi(t) & \text{normal} \\ \exp(t) \exp(-\exp(t)) & \text{complementary log-log} \end{cases}$$

Suppose there are $k + 1$ response categories. Let Y be the response variable with levels $1, \dots, k + 1$. Let $\mathbf{x} = (x_0, x_1, \dots, x_p)'$ be a $(p + 1)$ -vector of covariates, with $x_0 \equiv 1$. Let $\boldsymbol{\theta}$ be the vector of regression parameters.

Posterior probabilities are given by

$$P_n(i) = \frac{P_o(i) \frac{\widetilde{p}_n(i)}{P_o(i)}}{\sum_j P_o(j) \frac{\widetilde{p}_n(j)}{P_o(j)}} \quad i = 1, \dots, k + 1$$

where the old posterior probabilities (P_o) are the conditional probabilities of the response categories given \mathbf{x} , and the old priors (p_o) are the sample proportions of response categories of the training data. To simplify notation, absorb the old priors into the new priors; that is

$$p_n(i) = \frac{\widetilde{p}_n(i)}{p_o(i)} \quad i = 1, \dots, k + 1$$

The posterior probabilities are functions of $\boldsymbol{\theta}$ and their estimates are obtained by substituting $\boldsymbol{\theta}$ by its MLE $\widehat{\boldsymbol{\theta}}$. The variances of the estimated posterior probabilities are given by the *delta method* as follows:

$$Var(\widehat{P}_n(i)) = \left[\frac{\partial P_n(i)}{\partial \boldsymbol{\theta}} \right]' Var(\widehat{\boldsymbol{\theta}}) \left[\frac{\partial P_n(i)}{\partial \boldsymbol{\theta}} \right]$$

where

$$\frac{\partial P_n(i)}{\partial \boldsymbol{\theta}} = \frac{\frac{\partial P_o(i)}{\partial \boldsymbol{\theta}} p_n(i)}{\sum_j P_o(j) p_n(j)} - \frac{P_o(i) p_n(i) \sum_j \frac{\partial P_o(j)}{\partial \boldsymbol{\theta}} p_n(j)}{[\sum_j P_o(j) p_n(j)]^2}$$

A $100(1-\alpha)$ percent confidence interval for $P_n(i)$ is

$$\widehat{P}_n(i) \pm z_{1-\alpha/2} \sqrt{Var(\widehat{P}_n(i))}$$

where z_τ is the upper 100τ percentile of the standard normal distribution.

Cumulative Response Model

Let $\alpha_1, \dots, \alpha_k$ be the intercept parameters and let $\boldsymbol{\beta}$ be the vector of slope parameters. Denote $\boldsymbol{\theta} = (\alpha_1, \dots, \alpha_k, \boldsymbol{\beta}')'$. Let

$$\eta_i = \eta_i(\boldsymbol{\theta}) = \alpha_i + \mathbf{x}'\boldsymbol{\beta}, \quad i = 1, \dots, k$$

Estimates of η_1, \dots, η_k are obtained by substituting the maximum likelihood estimate $\widehat{\boldsymbol{\theta}}$ for $\boldsymbol{\theta}$.

The predicted probabilities of the responses are

$$\widehat{P}_o(i) = \widehat{\Pr}(Y = i) = \begin{cases} F(\hat{\eta}_1) & i = 1 \\ F(\hat{\eta}_i) - F(\hat{\eta}_{i-1}) & i = 2, \dots, k \\ 1 - F(\hat{\eta}_k) & i = k + 1 \end{cases}$$

For $i = 1, \dots, k$, let $\delta_i(x)$ be a $(k+1)$ column vector with i th entry equal to 1, $k+1$ th entry equal to x , and all other entries 0. The derivative of $P_o(i)$ with respect to θ are

$$\frac{\partial P_o(i)}{\partial \theta} = \begin{cases} F'(\alpha_1 + x'\beta)\delta_1(x) & i = 1 \\ F'(\alpha_i + x'\beta)\delta_i(x) - F'(\alpha_{i-1} + x'\beta)\delta_{i-1}(x) & i = 2, \dots, k \\ -F'(\alpha_k + x'\beta)\delta_k(x) & i = k + 1 \end{cases}$$

Generalized Logit Model

Consider the last response level ($Y=k+1$) as the reference. Let β_1, \dots, β_k be the parameter vectors for the first k logits, respectively. Denote $\theta = (\beta_1', \dots, \beta_k')$. Let $\eta = (\eta_1, \dots, \eta_k)'$ with

$$\eta_i = \eta_i(\theta) = \mathbf{x}'\beta_i \quad i = 1, \dots, k$$

Estimates of η_1, \dots, η_k are obtained by substituting the maximum likelihood estimate $\hat{\theta}$ for θ .

The predicted probabilities are

$$\begin{aligned} \widehat{P}_o(k+1) &\equiv \Pr(Y = k+1 | \mathbf{x}) = \frac{1}{1 + \sum_{l=1}^k \exp(\hat{\eta}_l)} \\ \widehat{P}_o(i) &\equiv \Pr(Y = i | \mathbf{x}) = \widehat{P}_o(k+1) \exp(\eta_i), \quad i = 1, \dots, k \end{aligned}$$

The derivative of $P_o(i)$ with respect to θ are

$$\begin{aligned} \frac{\partial P_o(i)}{\partial \theta} &= \frac{\partial \eta}{\partial \theta} \frac{\partial P_o(i)}{\partial \eta} \\ &= (I_k \otimes \mathbf{x}) \left(\frac{\partial P_o(i)}{\partial \eta_1}, \dots, \frac{\partial P_o(i)}{\partial \eta_k} \right)' \end{aligned}$$

where

$$\frac{\partial P_o(i)}{\partial \eta_j} = \begin{cases} P_o(i)(1 - P_o(i)) & j = i \\ -P_o(i)P_o(j) & \text{otherwise} \end{cases}$$

Special Case of Binary Response Model with No Priors

Let β be the vector of regression parameters. Let

$$\eta = \eta(\beta) = \mathbf{x}'\beta$$

The variance of $\hat{\eta}$ is given by

$$\text{Var}(\hat{\eta}) = \mathbf{x}'\text{Var}(\hat{\beta})\mathbf{x}$$

A $100(1-\alpha)$ percent confidence interval for η is

$$\hat{\eta} \pm z_{1-\alpha/2} \sqrt{\widehat{\text{Var}}(\hat{\eta})}$$

Estimates of $P_o(1)$ and confidence intervals for the $P_o(1)$ are obtained by back-transforming $\hat{\eta}$ and the confidence intervals for η , respectively. That is,

$$\widehat{P}_o(1) = F(\hat{\eta})$$

and the confidence intervals are

$$F\left(\hat{\eta} \pm z_{1-\alpha/2} \sqrt{\widehat{\text{Var}}(\hat{\eta})}\right)$$

Conditional Logistic Regression

The method of maximum likelihood described in the preceding sections relies on large-sample asymptotic normality for the validity of estimates and especially of their standard errors. When you do not have a large sample size compared to the number of parameters, this approach may be inappropriate resulting in biased inferences. This situation typically arises when your data are stratified and you fit intercepts to each stratum so that the number of parameters is of the same order as the sample size. For example, in a 1:1 matched pairs study with n pairs and p covariates, you would estimate $n - 1$ intercept parameters and p slope parameters. Taking the stratification into account by “conditioning out” (and not estimating) the stratum-specific intercepts gives consistent and asymptotically normal MLEs for the slope coefficients. See Breslow and Day (1980) and Stokes, Davis, and Koch (2000) for more information. If your nuisance parameters are not just stratum-specific intercepts, you can perform an [exact conditional logistic regression](#).

Computational Details

For each stratum h , $h = 1, \dots, H$, number the observations as $i = 1, \dots, n_h$ so that hi indexes the i th observation in the h th stratum. Denote the p covariates for observation hi as \mathbf{x}_{hi} and its binary response as y_{hi} , let $\mathbf{y} = (y_{11}, \dots, y_{1n_1}, \dots, y_{H1}, \dots, y_{Hn_H})'$, $\mathbf{X}_h = (\mathbf{x}_{h1} \dots \mathbf{x}_{hn_h})'$, and $\mathbf{X} = (\mathbf{X}'_1 \dots \mathbf{X}'_H)'$. Let the dummy variables z_h , $h = 1, \dots, H$, be indicator

functions for the strata ($z_h = 1$ if the observation is in stratum h), denote $\mathbf{z}_{hi} = (z_1, \dots, z_H)$ for observation hi , $\mathbf{Z}_h = (\mathbf{z}_{h1} \dots \mathbf{z}_{hn_h})'$, and $\mathbf{Z} = (\mathbf{Z}'_1 \dots \mathbf{Z}'_H)'$. Denote $\mathbf{X}^* = (\mathbf{Z}|\mathbf{X})$ and $\mathbf{x}^*_{hi} = (\mathbf{z}'_{hi}|\mathbf{x}'_{hi})'$. Arrange the observations in each stratum h so that $y_{hi} = 1$ for $i = 1, \dots, m_h$, and $y_{hi} = 0$ for $i = m_h+1, \dots, n_h$. Suppose all observations have unit frequency.

Consider the [binary logistic regression model](#) on page 2405 written as

$$\text{logit}(\pi) = \mathbf{X}^* \boldsymbol{\theta}$$

where the parameter vector $\boldsymbol{\theta} = (\boldsymbol{\alpha}', \boldsymbol{\beta}')$ consists of $\boldsymbol{\alpha} = (\alpha_1, \dots, \alpha_H)'$, α_h is the intercept for stratum h , $h = 1, \dots, H$, and $\boldsymbol{\beta}$ is the parameter vector for the p covariates.

From the “[Determining Observations for Likelihood Contributions](#)” section on page 2336, you can write the likelihood contribution of observation hi , $i = 1, \dots, n_h$, $h = 1, \dots, H$, as

$$L_{hi}(\boldsymbol{\theta}) = \frac{e^{y_{hi}\mathbf{x}^*_{hi}'\boldsymbol{\theta}}}{1 + e^{\mathbf{x}^*_{hi}'\boldsymbol{\theta}}}$$

where $y_{hi} = 1$ when the response takes Ordered Value 1, and $y_{hi} = 0$ otherwise.

The full likelihood is

$$L(\boldsymbol{\theta}) = \prod_{h=1}^H \prod_{i=1}^{n_h} L_{hi}(\boldsymbol{\theta}) = \frac{e^{\mathbf{y}'\mathbf{X}^*\boldsymbol{\theta}}}{\prod_{h=1}^H \prod_{i=1}^{n_h} (1 + e^{\mathbf{x}^*_{hi}'\boldsymbol{\theta}})}$$

Unconditional likelihood inference is based on maximizing this likelihood function.

When your nuisance parameters are the stratum-specific intercepts $(\alpha_1, \dots, \alpha_H)'$, and $\boldsymbol{\beta}$ are your parameters of interest, “conditioning out” the nuisance parameters produces the following conditional likelihood (Lachin 2000)

$$L(\boldsymbol{\beta}) = \prod_{h=1}^H L_h(\boldsymbol{\beta}) = \prod_{h=1}^H \frac{\prod_{i=1}^{m_h} \exp(\mathbf{x}'_{hi}\boldsymbol{\beta})}{\sum \prod_{j=j_1}^{j_{m_h}} \exp(\mathbf{x}'_{hj}\boldsymbol{\beta})}$$

where the summation is over all $\binom{n_h}{m_h}$ subsets $\{j_1, \dots, j_{m_h}\}$ of m_h observations chosen from the n_h observations in stratum h . Note that the nuisance parameters have been factored out of this equation.

For conditional asymptotic inference, maximum likelihood estimates $\widehat{\boldsymbol{\beta}}$ of the regression parameters are obtained by maximizing the conditional likelihood, and asymptotic results are applied to the conditional likelihood function and the maximum likelihood estimators. A relatively fast method for computing this conditional likelihood and its derivatives is given by Gail, Lubin, and Rubinstein (1981) and Howard (1972). The default optimization techniques, which are the same as those implemented by the NLP procedure in SAS/OR software, are

- Newton-Raphson with ridging when the number of parameters $p < 40$
- quasi-Newton when $40 \leq p < 400$
- conjugate gradient when $p \geq 400$

Sometimes the log likelihood converges but the estimates diverge. This condition is flagged by having inordinately large standard errors for some of your parameter estimates, and can be monitored by specifying the `ITPRINT` option. Unfortunately, broad existence criteria such as those discussed in the “[Existence of Maximum Likelihood Estimates](#)” section on page 2338 do not exist for this model. It may be possible to circumvent such a problem by standardizing your independent variables before fitting the model.

Regression Diagnostic Details

Diagnostics are used to indicate observations that may have undue influence on the model fit, or which may be outliers. Further investigation should be performed before removing such an observation from the data set.

The derivations in this section follow Storer and Crowley’s (1985) method of augmenting the logistic regression model, which provides an estimate of the “one-step” DFBETAS estimates advocated by Pregibon (1984). The method also provides estimates of conditional stratum-specific predicted values, residuals, and leverage for each observation.

Following Storer and Crowley (1985), the log-likelihood contribution can be written as

$$l_h = \log(L_h) = \mathbf{y}'_h \boldsymbol{\gamma}_h - a(\boldsymbol{\gamma}_h) \quad \text{where}$$

$$a(\boldsymbol{\gamma}_h) = \log \left[\sum_{j=1}^{j_{m_h}} \prod_{j=1}^{j_{m_h}} \exp(\gamma_{hj}) \right]$$

and the h subscript on matrices indicates the submatrix for the stratum, $\boldsymbol{\gamma}'_h = (\gamma_{h1}, \dots, \gamma_{hn_h})$, and $\gamma_{hi} = \mathbf{x}'_{hi} \boldsymbol{\beta}$. Then the gradient and information matrix are

$$\mathbf{g}(\boldsymbol{\beta}) = \left\{ \frac{\partial l_h}{\partial \boldsymbol{\beta}} \right\}_{h=1}^H = \mathbf{X}'(\mathbf{y} - \boldsymbol{\pi})$$

$$\boldsymbol{\Lambda}(\boldsymbol{\beta}) = \left\{ \frac{\partial^2 l_h}{\partial \boldsymbol{\beta}^2} \right\}_{h=1}^H = \mathbf{X}' \text{diag}(\mathbf{U}_1, \dots, \mathbf{U}_H) \mathbf{X}$$

where

$$\pi_{hi} = \frac{\partial a(\boldsymbol{\gamma}_h)}{\partial \gamma_{hi}} = \frac{\sum_{j(i)} \prod_{j=1}^{j_{m_h}} \exp(\gamma_{hj})}{\sum_{j=1}^{j_{m_h}} \prod_{j=1}^{j_{m_h}} \exp(\gamma_{hj})}$$

$$\boldsymbol{\pi}_h = (\pi_{h1}, \dots, \pi_{hn_h})$$

$$\mathbf{U}_h = \frac{\partial^2 a(\gamma_h)}{\partial \gamma_h^2} = \left\{ \frac{\partial^2 \mathbf{a}(\gamma_h)}{\partial \gamma_{hi} \partial \gamma_{hj}} \right\} = \{a_{ij}\}$$

$$a_{ij} = \frac{\sum_{k(i,j)} \prod_{k=k_1}^{k_{m_h}} \exp(\gamma_{hk})}{\sum \prod_{k=k_1}^{k_{m_h}} \exp(\gamma_{hk})} - \frac{\partial a(\gamma_h)}{\partial \gamma_{hi}} \frac{\partial a(\gamma_h)}{\partial \gamma_{hj}} = \pi_{hi} \pi_{hj} - \pi_{hi} \pi_{hj}$$

where π_{hi} is the conditional stratum-specific probability that subject i in stratum h is a case, the summation on $j(i)$ is over all subsets from $\{1, \dots, n_h\}$ of size m_h that contain the index i , and the summation on $k(i, j)$ is over all subsets from $\{1, \dots, n_h\}$ of size m_h that contain the indices i and j .

To produce the true one-step estimate β_{hi}^1 , start at the MLE $\hat{\beta}$, delete the hi th observation, and take one-step of the Newton-Raphson algorithm using the reduced data set. Note that if there is only one event or one nonevent in a stratum, deletion of that single observation is equivalent to deletion of the entire stratum. The augmentation method does not take this into account.

The augmented model is

$$\text{logit}(\Pr(y_{hi} = 1 | \mathbf{x}_{hi})) = \mathbf{x}'_{hi} \boldsymbol{\beta} + \mathbf{z}'_{hi} \gamma$$

where $\mathbf{z}_{hi} = (0, \dots, 0, 1, 0, \dots, 0)'$ has a 1 in the hi th coordinate, and use $\boldsymbol{\beta}^0 = (\hat{\boldsymbol{\beta}}, 0)'$ as the initial estimate for $(\boldsymbol{\beta}, \gamma)'$. The gradient and information matrix before the step are

$$\mathbf{g}(\boldsymbol{\beta}^0) = \begin{bmatrix} \mathbf{X}' \\ \mathbf{z}'_{hi} \end{bmatrix} (\mathbf{y} - \boldsymbol{\pi}) = \begin{bmatrix} \mathbf{0} \\ y_{hi} - \pi_{hi} \end{bmatrix}$$

$$\boldsymbol{\Lambda}(\boldsymbol{\beta}^0) = \begin{bmatrix} \mathbf{X}' \\ \mathbf{z}'_{hi} \end{bmatrix} \mathbf{U} [\mathbf{X} \quad \mathbf{z}_{hi}] = \begin{bmatrix} \boldsymbol{\Lambda}(\boldsymbol{\beta}) & \mathbf{X}' \mathbf{U} \mathbf{z}_{hi} \\ \mathbf{z}'_{hi} \mathbf{U} \mathbf{X} & \mathbf{z}'_{hi} \mathbf{U} \mathbf{z}_{hi} \end{bmatrix}$$

Inserting the $\boldsymbol{\beta}^0$ and $(\mathbf{X}', \mathbf{z}'_{hi})'$ into the Gail, Lubin, and Rubinstein (1981) algorithm provides the appropriate estimates of $\mathbf{g}(\boldsymbol{\beta}^0)$ and $\boldsymbol{\Lambda}(\boldsymbol{\beta}^0)$. Indicate these estimates with $\hat{\boldsymbol{\pi}} = \boldsymbol{\pi}(\hat{\boldsymbol{\beta}})$, $\hat{\mathbf{U}} = \mathbf{U}(\hat{\boldsymbol{\beta}})$, $\hat{\mathbf{g}}$, and $\hat{\boldsymbol{\Lambda}}$.

DFBETA is computed from the information matrix as

$$\begin{aligned} \Delta_{hi} \boldsymbol{\beta} &= \boldsymbol{\beta}^0 - \boldsymbol{\beta}_{hi}^1 \\ &= -\hat{\boldsymbol{\Lambda}}^{-1}(\boldsymbol{\beta}^0) \hat{\mathbf{g}}(\boldsymbol{\beta}^0) \\ &= -\hat{\boldsymbol{\Lambda}}^{-1}(\hat{\boldsymbol{\beta}}) (\mathbf{X}' \hat{\mathbf{U}} \mathbf{z}_{hi}) \mathbf{M}^{-1} \mathbf{z}'_{hi} (\mathbf{y} - \hat{\boldsymbol{\pi}}) \quad \text{where} \\ \mathbf{M} &= (\mathbf{z}'_{hi} \hat{\mathbf{U}} \mathbf{z}_{hi}) - (\mathbf{z}'_{hi} \hat{\mathbf{U}} \mathbf{X}) \hat{\boldsymbol{\Lambda}}^{-1}(\hat{\boldsymbol{\beta}}) (\mathbf{X}' \hat{\mathbf{U}} \mathbf{z}_{hi}) \end{aligned}$$

For each observation in the dataset, a DFBETA statistic is computed for each parameter β_j , $1 \leq j \leq p$, and standardized by the standard error of β_j from the full data set to produce the estimate of DFBETAS.

The estimated residuals $e_{hi} = y_{hi} - \hat{\pi}_{hi}$ are obtained from $\hat{\mathbf{g}}(\boldsymbol{\beta}^0)$, and the weights, or predicted probabilities, are then $\hat{\pi}_{hi} = y_{hi} - e_{hi}$. The residuals are standardized and reported as (estimated) Pearson residuals:

$$\frac{r_{hi} - n_{hi}\hat{\pi}_{hi}}{\sqrt{n_{hi}\hat{\pi}_{hi}(1 - \hat{\pi}_{hi})}}$$

where r_{hi} is the number of events in the observation and n_{hi} is the number of trials.

The estimated leverage is defined as

$$h_{hi} = \frac{\text{trace}\{(\mathbf{z}'_{hi}\hat{\mathbf{U}}\mathbf{X})\hat{\boldsymbol{\Lambda}}^{-1}(\hat{\boldsymbol{\beta}})(\mathbf{X}'\hat{\mathbf{U}}\mathbf{z}_{hi})\}}{\text{trace}\{\mathbf{z}'_{hi}\hat{\mathbf{U}}\mathbf{z}_{hi}\}}$$

This definition of leverage produces different values from those defined by Pregibon (1984), Moolgavkar, Lustbader, and Venzon (1985), and Hosmer and Lemeshow (2000); however, it has the advantage that no extra computations beyond those for the DFBETAS are required.

For events/trials MODEL syntax, treat each observation as two observations (the first for the nonevents and the second for the events) with frequencies $f_{h,2i-1} = n_{hi} - r_{hi}$ and $f_{h,2i} = r_{hi}$, and augment the model with a matrix $\mathbf{Z}_{hi} = [\mathbf{z}_{h,2i-1}\mathbf{z}_{h,2i}]$ instead of a single \mathbf{z}_{hi} vector. Writing $\gamma_{hi} = \mathbf{x}'_{hi}\boldsymbol{\beta}f_{hi}$ in the preceding section results in the following gradient and information matrix.

$$\mathbf{g}(\boldsymbol{\beta}^0) = \begin{bmatrix} \mathbf{0} \\ f_{h,2i-1}(y_{h,2i-1} - \pi_{h,2i-1}) \\ f_{h,2i}(y_{h,2i} - \pi_{h,2i}) \end{bmatrix}$$

$$\boldsymbol{\Lambda}(\boldsymbol{\beta}^0) = \begin{bmatrix} \boldsymbol{\Lambda}(\boldsymbol{\beta}) & \mathbf{X}'\text{diag}(\mathbf{f})\mathbf{U}\text{diag}(\mathbf{f})\mathbf{Z}_{hi} \\ \mathbf{Z}'_{hi}\text{diag}(\mathbf{f})\mathbf{U}\text{diag}(\mathbf{f})\mathbf{X} & \mathbf{Z}'_{hi}\text{diag}(\mathbf{f})\mathbf{U}\text{diag}(\mathbf{f})\mathbf{Z}_{hi} \end{bmatrix}$$

The predicted probabilities are then $\hat{\pi}_{hi} = y_{h,2i} - e_{h,2i}/r_{h,2i}$, while the leverage and the DFBETAs are produced from $\boldsymbol{\Lambda}(\boldsymbol{\beta}^0)$ in a similar fashion as for the preceding single-trial equations.

Exact Conditional Logistic Regression

The theory of exact conditional logistic regression analysis was originally laid out by Cox (1970), and the computational methods employed in PROC LOGISTIC are described in Hirji, Mehta, and Patel (1987), Hirji (1992), and Mehta, Patel, and Senchaudhuri (1992). Other useful references for the derivations include Cox and Snell (1989), Agresti (1990), and Mehta and Patel (1995).

Exact conditional inference is based on generating the conditional distribution for the sufficient statistics of the parameters of interest. This distribution is called the *permutation* or *exact conditional* distribution. Using the notation in the “Computational

Details” section on page 2365, follow Mehta and Patel (1995) and first note that the sufficient statistics $\mathbf{T} = (T_1, \dots, T_p)$ for $\boldsymbol{\theta}$ are

$$T_j = \sum_{i=1}^n y_i x_{ij}, \quad j = 1, \dots, p$$

Denote a vector of observable sufficient statistics as $\mathbf{t} = (t_1, \dots, t_p)'$.

The probability density function (pdf) for \mathbf{T} can be created by summing over all binary sequences \mathbf{y} that generate an observable \mathbf{t} and letting $C(\mathbf{t}) = \|\{\mathbf{y} : \mathbf{y}'\mathbf{X} = \mathbf{t}'\}\|$ denote the number of sequences \mathbf{y} that generate \mathbf{t}

$$\Pr(\mathbf{T} = \mathbf{t}) = \frac{C(\mathbf{t}) \exp(\mathbf{t}'\boldsymbol{\theta})}{\prod_{i=1}^n [1 + \exp(\mathbf{x}_i'\boldsymbol{\theta})]}$$

In order to condition out the stratum parameters, partition the parameter vector $\boldsymbol{\theta} = (\boldsymbol{\theta}'_0, \boldsymbol{\theta}'_1)'$, where $\boldsymbol{\theta}_0$ is a $p_0 \times 1$ vector of the nuisance parameters, and $\boldsymbol{\theta}_1$ is the parameter vector for the remaining $p_1 = p - p_0$ parameters of interest. Likewise, partition \mathbf{X} into \mathbf{X}_0 and \mathbf{X}_1 , \mathbf{T} into \mathbf{T}_0 and \mathbf{T}_1 , and \mathbf{t} into \mathbf{t}_0 and \mathbf{t}_1 . The nuisance parameters can be removed from the analysis by conditioning on their sufficient statistics to create the conditional likelihood of \mathbf{T}_1 given $\mathbf{T}_0 = \mathbf{t}_0$

$$\begin{aligned} \Pr(\mathbf{T}_1 = \mathbf{t}_1 | \mathbf{T}_0 = \mathbf{t}_0) &= \frac{\Pr(\mathbf{T} = \mathbf{t})}{\Pr(\mathbf{T}_0 = \mathbf{t}_0)} \\ &= f_{\boldsymbol{\theta}_1}(\mathbf{t}_1 | \mathbf{t}_0) = \frac{C(\mathbf{t}_0, \mathbf{t}_1) \exp(\mathbf{t}'_1 \boldsymbol{\theta}_1)}{\sum_{\mathbf{u}} C(\mathbf{t}_0, \mathbf{u}) \exp(\mathbf{u}' \boldsymbol{\theta}_1)} \end{aligned}$$

where $C(\mathbf{t}_0, \mathbf{u})$ is the number of vectors \mathbf{y} such that $\mathbf{y}'\mathbf{X}_0 = \mathbf{t}_0$ and $\mathbf{y}'\mathbf{X}_1 = \mathbf{u}$. Note that the nuisance parameters have factored out of this equation, and that $C(\mathbf{t}_0, \mathbf{t}_1)$ is a constant.

The goal of the exact conditional analysis is to determine how likely the observed response y_0 is with respect to all 2^n possible responses $\mathbf{y} = (y_1, \dots, y_n)'$. One way to proceed is to generate every \mathbf{y} vector for which $\mathbf{y}'\mathbf{X}_0 = \mathbf{t}_0$, and count the number of vectors \mathbf{y} for which $\mathbf{y}'\mathbf{X}_1$ is equal to each unique \mathbf{t}_1 . Generating the conditional distribution from complete enumeration of the joint distribution is conceptually simple; however, this method becomes computationally infeasible very quickly. For example, if you had only 30 observations, you'd have to scan through 2^{30} different \mathbf{y} vectors.

Several algorithms are available in PROC LOGISTIC to generate the exact distribution. All of the algorithms are based on the following observation. Given any $\mathbf{y} = (y_1, \dots, y_n)'$ and a design $\mathbf{X} = (\mathbf{x}_1, \dots, \mathbf{x}_n)'$, let $\mathbf{y}_{(i)} = (y_1, \dots, y_i)'$ and $\mathbf{X}_{(i)} = (\mathbf{x}_1, \dots, \mathbf{x}_i)'$ be the first i rows of each matrix. Write the sufficient statistic based on these i rows as $\mathbf{t}'_{(i)} = \mathbf{y}'_{(i)}\mathbf{X}_{(i)}$. A recursion relation results: $\mathbf{t}_{(i+1)} = \mathbf{t}_{(i)} + y_{i+1}\mathbf{x}_{i+1}$.

The following methods are available.

- The *multivariate shift algorithm* developed by Hirji, Mehta, and Patel (1987) steps through the recursion relation by adding one observation at a time and building an intermediate distribution at each step. If it determines that $\mathbf{t}_{(i)}$ for the nuisance parameters could eventually equal \mathbf{t} , then $\mathbf{t}_{(i)}$ is added to the intermediate distribution.
- Hirji (1992) extends the multivariate shift algorithm to generalized logit models. Since the generalized logit model fits a new set of parameters to each logit, the number of parameters in the model can easily get too large for this algorithm to handle. Note for these models that the hypothesis tests for each effect are computed across the logit functions, while individual parameters are estimated for each logit function.
- A network algorithm described in Mehta, Patel, and Senchaudhuri (1992) builds a network for each parameter that you are conditioning out in order to identify feasible y_i for the \mathbf{y} vector. These networks are combined and the set of feasible y_i is further reduced, then the multivariate shift algorithm uses this knowledge to build the exact distribution without adding as many intermediate $\mathbf{t}_{(i+1)}$ as the multivariate shift algorithm does.
- Mehta, Patel, and Senchaudhuri (2000) devised a hybrid Monte-Carlo and network algorithm that extends their 1992 algorithm by sampling from the combined network to build the exact distribution.

The bulk of the computation time and memory for these algorithms is consumed by the creation of the networks and the exact joint distribution. After the joint distribution for a set of effects is created, the computational effort required to produce hypothesis tests and parameter estimates for any subset of the effects is (relatively) trivial.

Hypothesis Tests

Consider testing the null hypothesis $H_0: \beta_1 = \mathbf{0}$ against the alternative $H_A: \beta_1 \neq \mathbf{0}$, conditional on $\mathbf{T}_0 = \mathbf{t}_0$. Under the null hypothesis, the test statistic for the *exact probability test* is just $f_{\beta_1=0}(\mathbf{t}_1|\mathbf{t}_0)$, while the corresponding p -value is the probability of getting a less likely (more extreme) statistic,

$$p(\mathbf{t}_1|\mathbf{t}_0) = \sum_{\mathbf{u} \in \Omega_p} f_0(\mathbf{u}|\mathbf{t}_0)$$

where $\Omega_p = \{\mathbf{u}: \text{there exist } \mathbf{y} \text{ with } \mathbf{y}'\mathbf{X}_1 = \mathbf{u}, \mathbf{y}'\mathbf{X}_0 = \mathbf{t}_0, \text{ and } f_0(\mathbf{u}|\mathbf{t}_0) \leq f_0(\mathbf{t}_1|\mathbf{t}_0)\}$.

For the *exact conditional scores test*, the conditional mean $\boldsymbol{\mu}_1$ and variance matrix $\boldsymbol{\Sigma}_1$ of the \mathbf{T}_1 (conditional on $\mathbf{T}_0 = \mathbf{t}_0$) are calculated, and the score statistic for the observed value,

$$s = (\mathbf{t}_1 - \boldsymbol{\mu}_1)' \boldsymbol{\Sigma}_1^{-1} (\mathbf{t}_1 - \boldsymbol{\mu}_1)$$

is compared to the score for each member of the distribution

$$S(\mathbf{T}_1) = (\mathbf{T}_1 - \boldsymbol{\mu}_1)' \boldsymbol{\Sigma}_1^{-1} (\mathbf{T}_1 - \boldsymbol{\mu}_1)$$

The resulting p -value is

$$p(\mathbf{t}_1 | \mathbf{t}_0) = Pr(S \geq s) = \sum_{\mathbf{u} \in \Omega_s} f_0(\mathbf{u} | \mathbf{t}_0)$$

where $\Omega_s = \{\mathbf{u}: \text{there exist } \mathbf{y} \text{ with } \mathbf{y}'\mathbf{X}_1 = \mathbf{u}, \mathbf{y}'\mathbf{X}_0 = \mathbf{t}_0, \text{ and } S(\mathbf{u}) \geq s\}$.

The mid- p statistic, defined as

$$p(\mathbf{t}_1 | \mathbf{t}_0) - \frac{1}{2} f_0(\mathbf{t}_1 | \mathbf{t}_0)$$

was proposed by Lancaster (1961) to compensate for the discreteness of a distribution. Refer to Agresti (1992) for more information. However, to allow for more flexibility in handling ties, you can write the mid- p statistic as (based on a suggestion by LaMotte 2002 and generalizing Vollset, Hirji, and Afifi 1991)

$$\sum_{\mathbf{u} \in \Omega_{<}} f_0(\mathbf{u} | \mathbf{t}_0) + \delta_1 f_0(\mathbf{t}_1 | \mathbf{t}_0) + \delta_2 \sum_{\mathbf{u} \in \Omega_{=}} f_0(\mathbf{u} | \mathbf{t}_0)$$

where, for $i \in \{p, s\}$, $\Omega_{<}$ is Ω_i using strict inequalities, and $\Omega_{=}$ is Ω_i using equalities with the added restriction that $\mathbf{u} \neq \mathbf{t}_1$. Letting $(\delta_1, \delta_2) = (0.5, 1.0)$ yields Lancaster's mid- p .

Caution: When the exact distribution has ties and METHOD=NETWORKMCMC is specified, the Monte Carlo algorithm estimates $p(\mathbf{t} | \mathbf{t}_0)$ with error, and hence it cannot determine precisely which values contribute to the reported p -values. For example, if the exact distribution has densities $\{0.2, 0.2, 0.2, 0.4\}$ and if the observed statistic has probability 0.2, then the exact probability p -value is exactly 0.6. Under Monte Carlo sampling, if the densities after N samples are $\{0.18, 0.21, 0.23, 0.38\}$ and the observed probability is 0.21, then the resulting p -value is 0.39. Therefore, the exact probability test p -value for this example fluctuates between 0.2, 0.4, and 0.6, and the reported p -values are actually lower bounds for the true p -values. If you need more precise values, you can specify the OUTDIST= option, determine appropriate cutoff values for the observed probability and score, then construct the true p -value estimates from the OUTDIST= data set using the following statements.

```
data _null_;
  set outdist end=end;
  retain pvalueProb 0 pvalueScore 0;
  if prob < ProbCutOff then pvalueProb+prob;
  if score > ScoreCutOff then pvalueScore+prob;
  if end then put pvalueProb pvalueScore;
run;
```

Inference for a Single Parameter

Exact parameter estimates are derived for a single parameter β_i by regarding all the other parameters $\boldsymbol{\beta}_0 = (\beta_1, \dots, \beta_{i-1}, \beta_{i+1}, \dots, \beta_{p+q})'$ as nuisance parameters. The appropriate sufficient statistics are $\mathbf{T}_1 = T_i$ and $\mathbf{T}_0 = (T_1, \dots, T_{i-1}, T_{i+1}, \dots, T_{p+q})'$, with their observed values denoted by the lowercase t . Hence, the conditional pdf used to create the parameter estimate for β_i is

$$f_{\beta_i}(t_i|\mathbf{t}_0) = \frac{C(\mathbf{t}_0, t_i) \exp(t_i \beta_i)}{\sum_{u \in \Omega} C(\mathbf{t}_0, u) \exp(u \beta_i)}$$

for $\Omega = \{u: \text{there exist } \mathbf{y} \text{ with } T_i = u \text{ and } \mathbf{T}_0 = \mathbf{t}_0\}$.

The maximum exact conditional likelihood estimate is the quantity $\hat{\beta}_i$, which maximizes the conditional pdf. A Newton-Raphson algorithm is used to perform this search. However, if the observed t_i attains either its maximum or minimum value in the exact distribution (that is, either $t_i = \min\{u : u \in \Omega\}$ or $t_i = \max\{u : u \in \Omega\}$), then the conditional pdf is monotonically increasing in β_i and cannot be maximized. In this case, a median unbiased estimate (Hirji, Tsiatis, and Mehta 1989) $\hat{\beta}_i$ is produced that satisfies $f_{\hat{\beta}_i}(t_i|\mathbf{t}_0) = 0.5$, and a Newton-Raphson-type algorithm is used to perform the search.

Likelihood ratio tests based on the conditional pdf are used to test the null $H_0: \beta_i = 0$ against the alternative $H_A: \beta_i > 0$. The critical region for this UMP test consists of the upper tail of values for T_i in the exact distribution. Thus, the one-sided significance level $p_+(t_i; 0)$ is

$$p_+(t_i; 0) = \sum_{u \geq t_i} f_0(u|\mathbf{t}_0)$$

Similarly, the one-sided significance level $p_-(t_i; 0)$ against $H_A: \beta_i < 0$ is

$$p_-(t_i; 0) = \sum_{u \leq t_i} f_0(u|\mathbf{t}_0)$$

The two-sided significance level $p(t_i; 0)$ against $H_A: \beta_i \neq 0$ is calculated as

$$p(t_i; 0) = 2 \min[p_-(t_i; 0), p_+(t_i; 0)]$$

An upper $100(1 - 2\epsilon)\%$ exact confidence limit for $\hat{\beta}_i$ corresponding to the observed t_i is the solution $\beta_U(t_i)$ of $\epsilon = p_-(t_i, \beta_U(t_i))$, while the lower exact confidence limit is the solution $\beta_L(t_i)$ of $\epsilon = p_+(t_i, \beta_L(t_i))$. Again, a Newton-Raphson procedure is used to search for the solutions.

Specifying the ONESIDED option displays only one p -value and one confidence interval, because small values of $p_+(t_i; 0)$ and $p_-(t_i; 0)$ support different alternative hypotheses and only one of these p -values can be less than 0.50.

The mid- p confidence limits are the solutions to $\min\{p_-(t_i, \beta(t_i)), p_+(t_i, \beta(t_i))\} - (1 - \delta_1)f_{\beta(t_i)}(u|t_0) = \epsilon$ for $\epsilon = \alpha/2, 1 - \alpha/2$ (Vollset, Hirji, and Afifi 1991). $\delta_1 = 1$ produces the usual exact (or *max- p*) confidence interval, $\delta_1 = 0.5$ yields the mid- p interval, and $\delta_1 = 0$ gives the *min- p* interval. The mean of the endpoints of the *max- p* and *min- p* intervals provides the *mean- p* interval as defined by Hirji, Mehta, and Patel (1988).

Estimates and confidence intervals for the odds-ratios are produced by exponentiating the estimates and interval endpoints for the parameters.

OUTEST= Output Data Set

The OUTEST= data set contains one observation for each BY group containing the maximum likelihood estimates of the regression coefficients. If you also use the COVOUT option in the PROC LOGISTIC statement, there are additional observations containing the rows of the estimated covariance matrix. If you use the FORWARD, BACKWARD, or STEPWISE selection method, only the estimates of the parameters and covariance matrix for the final model are output to the OUTEST= data set.

Variables in the OUTEST= Data Set

The OUTEST= data set contains the following variables:

- any BY variables specified
- `_LINK_`, a character variable of length 8 with four possible values: CLOGLOG for the complementary log-log function, LOGIT for the logit function, NORMIT for the probit (alias normit) function, and GLOGIT for the generalized logit function.
- `_TYPE_`, a character variable of length 8 with two possible values: PARMS for parameter estimates or COV for covariance estimates. If an EXACT statement is also specified, then two other values are possible: EPARMMLE for the exact maximum likelihood estimates and EPARMMUE for the exact median unbiased estimates.
- `_NAME_`, a character variable containing the name of the response variable when `_TYPE_=PARMS`, EPARMMLE, and EPARMMUE, or the name of a model parameter when `_TYPE_=COV`
- `_STATUS_`, a character variable that indicates whether the estimates have converged
- one variable for each intercept parameter
- one variable for each slope parameter and one variable for the offset variable if the OFFSET= option is specified. If an effect is not included in the final model in a model building process, the corresponding parameter estimates and covariances are set to missing values.
- `_LNLIKE_`, the log likelihood

Parameter Names in the OUTEST= Data Set

If there are only two response categories in the entire data set, the intercept parameter is named `Intercept`. If there are more than two response categories in the entire data set, the intercept parameters are named `Intercept_XXX`, where `XXX` is the value (formatted if a format is applied) of the corresponding response category.

For continuous explanatory variables, the names of the parameters are the same as the corresponding variables. For class variables, the parameter names are obtained by concatenating the corresponding CLASS variable name with the CLASS category; see the `PARAM=` option in the CLASS statement and the “[CLASS Variable Parameterization](#)” section on page 2331 for more details. For interaction and nested effects, the parameter names are created by concatenating the names of each effect.

For the generalized logit model, names of parameters corresponding to each nonreference category contain `_XXX` as the suffix, where `XXX` is the value (formatted if a format is applied) of the corresponding nonreference category. For example, suppose the variable `Net3` represents the television network (ABC, CBS, and NBC) viewed at a certain time. The following code fits a generalized logit model with `Age` and `Gender` (a CLASS variable with values Female and Male) as explanatory variables.

```
proc logistic;
  class Gender;
  model Net3 = Age Gender / link=glogit;
run;
```

There are two logit functions, one contrasting ABC with NBC and the other contrasting CBS with NBC. For each logit, there are three parameters: an intercept parameter, a slope parameter for `Age`, and a slope parameter for `Gender` (since there are only two gender levels and the `EFFECT` parameterization is used by default). The names of the parameters and their descriptions are as follows.

<code>Intercept_ABC</code>	intercept parameter for the logit contrasting ABC with NBC
<code>Intercept_CBS</code>	intercept parameter for the logit contrasting CBS with NBC
<code>Age_ABC</code>	Age slope parameter for the logit contrasting ABC with NBC
<code>Age_CBS</code>	Age slope parameter for the logit contrasting CBS with NBC
<code>GenderFemale_ABC</code>	Gender=Female slope parameter for the logit contrasting ABC with NBC
<code>GenderFemale_CBS</code>	Gender=Female slope parameter for the logit contrasting CBS with NBC

INEST= Input Data Set

You can specify starting values for the iterative algorithm in the INEST= data set. The INEST= data set has the same structure as the OUTEST= data set but is not required to have all the variables or observations that appear in the OUTEST= data set.

The INEST= data set must contain the intercept variables (named Intercept for binary response models and Intercept, Intercept2, Intercept3, and so forth, for ordinal and nominal response models) and all explanatory variables in the MODEL statement. If BY processing is used, the INEST= data set should also include the BY variables, and there must be one observation for each BY group. If the INEST= data set also contains the _TYPE_ variable, only observations with _TYPE_ value 'PARMS' are used as starting values.

OUT= Output Data Set in the OUTPUT Statement

The OUT= data set in the OUTPUT statement contains all the variables in the input data set along with statistics you request using *keyword=name* options or the PREDPROBS= option in the OUTPUT statement. In addition, if you use the *single-trial* syntax and you request any of the XBETA=, STDXBETA=, PREDICTED=, LCL=, and UCL= options, the OUT= data set contains the automatic variable _LEVEL_. The value of _LEVEL_ identifies the response category upon which the computed values of XBETA=, STDXBETA=, PREDICTED=, LCL=, and UCL= are based.

When there are more than two response levels, only variables named by the XBETA=, STDXBETA=, PREDICTED=, LOWER=, and UPPER= options and the variables given by PREDPROBS=(INDIVIDUAL CUMULATIVE) have their values computed; the other variables have missing values. If you fit a generalized logit model, the cumulative predicted probabilities are not computed.

When there are only two response categories, each input observation produces one observation in the OUT= data set.

If there are more than two response categories and you only specify the PREDPROBS= option, then each input observation produces one observation in the OUT= data set. However, if you fit an ordinal (cumulative) model and specify options other than the PREDPROBS= options, each input observation generates as many output observations as one fewer than the number of response levels, and the predicted probabilities and their confidence limits correspond to the cumulative predicted probabilities. If you fit a generalized logit model and specify options other than the PREDPROBS= options, each input observation generates as many output observations as the number of response categories; the predicted probabilities and their confidence limits correspond to the probabilities of individual response categories.

For observations in which only the response variable is missing, values of the XBETA=, STDXBETA=, PREDICTED=, UPPER=, LOWER=, and the PREDPROBS= options are computed even though these observations do not affect the model fit. This enables, for instance, predicted probabilities to be computed for new observations.

OUT= Output Data Set in a SCORE Statement

The OUT= data set in a SCORE statement contains all the variables in the data set being scored. The data set being scored can be either the input DATA= data set in the PROC LOGISTIC statement or the DATA= data set in the SCORE statement. The DATA= data set in the SCORE statement may not contain a response variable.

If the data set being scored contains a response variable, then denote the *normalized* levels (left justified formatted values of 16 characters or less) of your response variable Y by Y_1, \dots, Y_{k+1} . For each response level, the OUT= data set also contains:

- F_Y, the normalized levels of the response variable Y in the data set being scored. If the *events/trials* syntax is used, the F_Y variable is not created.
- L_Y, the normalized levels that the observations are classified into. Note that an observation is classified into the level with the largest probability. If the *events/trials* syntax is used, the _INTO_ variable is created instead and it contains the values EVENT and NONEVENT.
- P_Y_i, the posterior probabilities of the normalized response level Y_i.
- If the CLM option is specified in the SCORE statement, the OUT= data set also includes:
 - LCL_Y_i, the lower 100(1- α)% confidence limits for P_Y_i
 - UCL_Y_i, the upper 100(1- α)% confidence limits for P_Y_i

OUTDIST= Output Data Set

The OUTDIST= data set contains every exact conditional distribution necessary to process the EXACT statement. For example, the following statements create one distribution for the x1 parameter and another for the x2 parameters, and produces the data set dist shown in [Figure 42.7](#):

```
proc logistic;
  class x2 / param=ref;
  model y=x1 x2;
  exact x1 x2/ outdist=dist;
proc print data=dist;
run;
```

Obs	x1	x20	x21	Count	Score	Prob
1	.	0	0	3	5.81151	0.03333
2	.	0	1	15	1.66031	0.16667
3	.	0	2	9	3.12728	0.10000
4	.	1	0	15	1.46523	0.16667
5	.	1	1	18	0.21675	0.20000
6	.	1	2	6	4.58644	0.06667
7	.	2	0	19	1.61869	0.21111
8	.	2	1	2	3.27293	0.02222
9	.	3	0	3	6.27189	0.03333
10	2	.	.	6	3.03030	0.12000
11	3	.	.	12	0.75758	0.24000
12	4	.	.	11	0.00000	0.22000
13	5	.	.	18	0.75758	0.36000
14	6	.	.	3	3.03030	0.06000

Figure 42.7. OUTDIST

The first nine observations in the `dist` data set contain an exact distribution for the parameters of the `x2` effect (hence the values for the `x1` parameter are missing), and the remaining five observations are for the `x1` parameter. If a joint distribution was created, there would be observations with values for both the `x1` and `x2` parameters. For CLASS variables, the corresponding parameters in the `dist` data set are identified by concatenating the variable name with the appropriate classification level.

The data set contains the possible sufficient statistics of the parameters for the effects specified in the EXACT statement, and the `Count` variable contains the number of different responses that yield these statistics. For example, there were 6 possible response vectors \mathbf{y} for which the dot product $\mathbf{y}'\mathbf{x}_1$ was equal to 2, and for which $\mathbf{y}'\mathbf{x}_{20}$, $\mathbf{y}'\mathbf{x}_{21}$, and $\mathbf{y}'\mathbf{1}$ were equal to their actual observed values (displayed in the “Sufficient Statistics” table). When hypothesis tests are performed on the parameters, the `Prob` variable contains the probability of obtaining that statistic (which is just the count divided by the total count), and the `Score` variable contains the score for that statistic. For more information, see the section “EXACT Statement Examples” on page 2302.

OUTROC= Output Data Set

The OUTROC= data set contains data necessary for producing the ROC curve, and can be created by specifying the `OUTROC=` option in the MODEL statement or the `OUTROC=` option in the SCORE statement: It has the following variables:

- any BY variables specified
- `_STEP_`, the model step number. This variable is not included if model selection is not requested.
- `_PROB_`, the estimated probability of an event. These estimated probabilities serve as cutpoints for predicting the response. Any observation with an estimated event probability that exceeds or equals `_PROB_` is predicted to be an event; otherwise, it is predicted to be a nonevent. Predicted probabilities

that are close to each other are grouped together, with the maximum allowable difference between the largest and smallest values less than a constant that is specified by the ROCEPS= option. The smallest estimated probability is used to represent the group.

- `_POS_`, the number of correctly predicted event responses
- `_NEG_`, the number of correctly predicted nonevent responses
- `_FALPOS_`, the number of falsely predicted event responses
- `_FALNEG_`, the number of falsely predicted nonevent responses
- `_SENSIT_`, the sensitivity, which is the proportion of event observations that were predicted to have an event response
- `_1MSPEC_`, one minus specificity, which is the proportion of nonevent observations that were predicted to have an event response

Note that none of these statistics are affected by the bias-correction method discussed in the “[Classification Table](#)” section on page 2352. An ROC curve is obtained by plotting `_SENSIT_` against `_1MSPEC_`. For more information, see the section “[Receiver Operating Characteristic Curves](#)” on page 2357.

Computational Resources

The memory needed to fit an unconditional model is approximately $24(p+2)^2$ bytes, where p is the number of parameters estimated. For cumulative response models with more than two response levels, a test of the parallel lines assumption requires an additional memory of approximately $4k^2(m+1)^2 + 24(m+2)^2$ bytes, where k is the number of response levels and m is the number of slope parameters. However, if this additional memory is not available, the procedure skips the test and finishes the other computations. You may need more memory if you use the SELECTION= option for model building.

The data that consist of relevant variables (including the design variables for model effects) and observations for fitting the model are stored in the utility file. If sufficient memory is available, such data will also be kept in memory; otherwise, the data are reread from the utility file for each evaluation of the likelihood function and its derivatives, with the resulting execution time of the procedure substantially increased.

If a conditional logistic regression is performed, then approximately $4(m^2 + m + 4) \max_h(m_h) + (8s_H + 36)H + 12s_H$ additional bytes of memory are needed, where m_h is the number of events in stratum h , H is the total number of strata, and s_H is the number of variables used to define the strata.

Computational Resources for Exact Conditional Logistic Regression

Many problems require a prohibitive amount of time and memory for exact computations, depending on the speed and memory available on your computer. For such problems, consider whether exact methods are really necessary. Stokes, Davis, and Koch (2000) suggest looking at exact p -values when the sample size is small and the approximate p -values from the unconditional analysis are less than 0.10, and they provide *rules of thumb* for determining when various models are valid.

A formula does not exist that can predict the amount of time and memory necessary to generate the exact conditional distributions for a particular problem. The time and memory required depends on several factors, including the total sample size, the number of parameters of interest, the number of nuisance parameters, and the order in which the parameters are processed. To provide a feel for how these factors affect performance, 19 data sets containing $\text{Nobs} \in \{10, \dots, 500\}$ observations consisting of up to 10 independent uniform binary covariates (X_1, \dots, X_N) and a binary response variable (Y), are generated and exact conditional distributions are created for X_1 conditional on the other covariates using the default `METHOD=NETWORK`. Figure 42.8 displays results obtained on a 400Mhz PC with 768MB RAM running Microsoft Windows NT.

```

data one;
  do obs=1 to HalfNobs;
    do Y=0 to 1;
      X1=round(ranuni(0));
      ...
      XN=round(ranuni(0));
      output;
    end;
  end;
options fullstimer;
proc logistic exactonly exactoptions(method=network maxtime=1200);
  class X1 ... XN / param=ref;
  model Y=X1 ... XN;
  exact X1 / outdist=dist;
run;

```

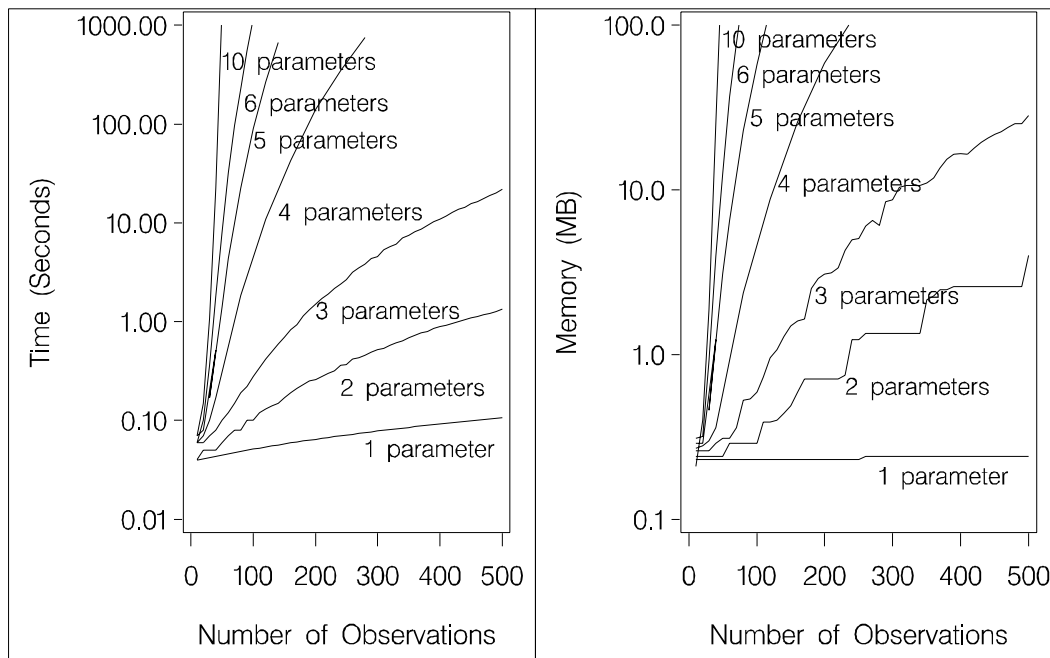

Figure 42.8. Mean Time and Memory Required

At any time while PROC LOGISTIC is deriving the distributions, you can terminate the computations by pressing the system interrupt key sequence (refer to the SAS Companion for your system) and choosing to stop computations. If you run out of memory, refer to the SAS Companion for your system to see how to allocate more.

You can use the EXACTOPTIONS option `MAXTIME=` to limit the total amount of time PROC LOGISTIC uses to derive all of the exact distributions. If PROC LOGISTIC does not finish within that time, the procedure terminates.

Calculation of frequencies are performed in the log-scale by default. This reduces the need to check for excessively large frequencies but can be slower than not scaling. You can turn off the log-scaling by specifying the `NOLOGSCALE` option in the MODEL statement. If a frequency in the exact distribution is larger than the largest integer that can be held in double-precision, a warning is printed to the LOG, but since inaccuracies due to adding small numbers to these large frequencies may have little-or-no effect on the statistics, the exact computations continue.

You can monitor the progress of the procedure by submitting your program with the EXACTOPTIONS option `STATUSTIME=`. If the procedure is too slow, you can try another method by specifying the EXACTOPTIONS option `METHOD=`, you can try reordering the variables in the MODEL statement (note that CLASS variables are always processed before continuous covariates), or you can try reparameterizing your classification variables, for example:

```
class class-variables / param=ref ref=first order=freq;
```

Displayed Output

If you use the NOPRINT option in the PROC LOGISTIC statement, the procedure does not display any output. Otherwise, the displayed output of the LOGISTIC procedure includes the following:

- “Model Information” table, which gives
 - name of the input Data Set
 - name and label of the Response Variable, if the *single-trial* syntax is used
 - number of Response Levels, if the *single-trial* syntax is used
 - name of the Events Variable, if the *events/trials* syntax is used
 - name of the Trials Variable, if the *events/trials* syntax is used
 - name of the Offset Variable, if the `OFFSET=` option is specified
 - name of the Frequency Variable, if the `FREQ` statement is specified
 - name of the Weight Variable, if the `WEIGHT` statement is specified
 - Number of Strata, if the `STRATA` statement is specified
 - Number of Strata Ignored and the total Frequency Ignored, if the `STRATA` statement is specified and at least one stratum has no events or no nonevents
 - Link Function

- Optimization Technique
- seed, if METHOD=NETWORKMC is specified
- “Number of Observations” table, which gives
 - Number of Observations read from the input data set
 - Number of Observations used in the analysis
 - Sum of Frequencies of all the observations read from the input data set
 - Sum of Frequencies of all the observations used in the analysis
 - Sum of Weights of all the observations read from the input data set
 - Sum of Weights of all the observations used in the analysis
 - Normalized Sum of Weights of all the observations used in the analysis, if the SCALE=WILLIAMS option is specified in the MODEL statement or the NORMALIZE option is specified in the WEIGHT statement.

An ODS OUTPUT data set created from this table contains all of the information in every row.

- “Response Profile” table, which gives, for each response level, the ordered value (an integer between one and the number of response levels, inclusive); the value of the response variable if the *single-trial* syntax is used or the values “Event” and “Nonevent” if the *events/trials* syntax is used; the count or frequency; and the sum of weights if the WEIGHT statement is specified
- “Class Level Information” table, which gives the level and the design variables for each CLASS explanatory variable
- “Descriptive Statistics for Continuous Explanatory Variables” table for continuous explanatory variables, the “Frequency Distribution of Class Variables,” and the “Weight Distribution of Class Variables” tables (if the WEIGHT statement is specified), if you specify the SIMPLE option in the PROC LOGISTIC statement. The “Descriptive Statistics for Continuous Explanatory Variables” table contains the mean, standard deviation, maximum and minimum of each continuous variable specified in the MODEL statement.
- “Maximum Likelihood Iterative Phase” table, if you use the ITPRINT option in the MODEL statement. This table gives the iteration number, the step size (in the scale of 1.0, .5, .25, and so on) or the ridge value, $-2 \log$ likelihood, and parameter estimates for each iteration. Also displayed are the last evaluation of the gradient vector and the last change in the $-2 \log$ likelihood.
- Pearson and deviance goodness-of-fit statistics, if you use the SCALE= option in the MODEL statement
- score test result for testing the parallel lines assumption, if an ordinal response model is fitted. If LINK=CLOGLOG or LINK=PROBIT, this test is labeled “Score Test for the Parallel Slopes Assumption.” The proportion odds assumption is a special case of the parallel lines assumption when LINK=LOGIT. In this case, the test is labeled “Score Test for the Proportional Odds Assumption”.
- “Model Fit Statistics” and “Testing Global Null Hypothesis: BETA=0” tables, which give the various criteria ($-2 \log L$, AIC, SC) based on the likelihood

for fitting a model with intercepts only and for fitting a model with intercepts and explanatory variables. If you specify the NOINT option, these statistics are calculated without considering the intercept parameters. The third column of the table gives the chi-square statistics and p -values for the -2 Log L statistic and for the Score statistic. These test the joint effect of the explanatory variables included in the model. The Score criterion is always missing for the models identified by the first two columns of the table. Note also that the first two rows of the Chi-Square column are always missing, since tests cannot be performed for AIC and SC.

- generalized R^2 measures for the fitted model, if you specify the RSQUARE option in the MODEL statement
- “Type 3 Analysis of Effects” table, if the model contains an effect involving a CLASS variable. This table gives the Wald Chi-square statistic, the degrees of freedom, and the p -value for each effect in the model
- “Analysis of Maximum Likelihood Estimates” table, which includes
 - parameter name, which also identifies the CLASS variable level and, for generalized logit models, a response variable column to identify the corresponding logit by displaying the nonreference level of the logit
 - maximum likelihood estimate of the parameter
 - estimated standard error of the parameter estimate, computed as the square root of the corresponding diagonal element of the estimated covariance matrix
 - Wald chi-square statistic, computed by squaring the ratio of the parameter estimate divided by its standard error estimate
 - p -value of the Wald chi-square statistic with respect to a chi-square distribution with one degree of freedom
 - standardized estimate for the slope parameter, if you specify the STB option in the MODEL statement. This estimate is given by $\hat{\beta}_i/(s/s_i)$, where s_i is the total sample standard deviation for the i th explanatory variable and

$$s = \begin{cases} \pi/\sqrt{3} & \text{Logistic} \\ 1 & \text{Normal} \\ \pi/\sqrt{6} & \text{Extreme-value} \end{cases}$$

Standardized estimates of the intercept parameters are set to missing.

- $e^{\hat{\beta}_i}$ for each slope parameter β_i , if you specify the EXPB option in the MODEL statement. For continuous variables, this is equivalent to the estimated odds ratio for a 1 unit change.
- label of the variable, if you specify the PARMLABEL option in the MODEL statement and if space permits. Due to constraints on the line size, the variable label may be suppressed in order to display the table in one panel. Use the SAS system option LINESIZE= to specify a larger line size to accommodate variable labels. A shorter line size can break the table into two panels allowing labels to be displayed.

- “Odds Ratio Estimates” table, which contains the odds ratio estimates and the corresponding 95% Wald confidence intervals. For continuous explanatory variables, these odds ratios correspond to a unit increase in the risk factors.
- “Association of Predicted Probabilities and Observed Responses” table, which includes a breakdown of the number of pairs with different responses, and four rank correlation indexes: Somers’ *D*, Goodman-Kruskal Gamma, and Kendall’s Tau-*a*, and *c*
- confidence intervals for all the parameters, if you use the CLPARM= option in the MODEL statement
- confidence intervals for all the odds ratios, if you use the CLODDS= option in the MODEL statement
- a summary of the model-building process, if you use a FORWARD, BACKWARD, or STEPWISE selection method. This summary gives the step number, the explanatory variables entered or removed at each step, the chi-square statistic, and the corresponding *p*-value on which the entry or removal of the variable is based (the score chi-square is used to determine entry; the Wald chi-square is used to determine removal)
- “Analysis of Variables Removed by Fast Backward Elimination” table, if you specify the FAST option in the MODEL statement. This table gives the approximate chi-square statistic for the variable removed, the corresponding *p*-value with respect to a chi-square distribution with one degree of freedom, the residual chi-square statistic for testing the joint significance of the variable and the preceding ones, the degrees of freedom, and the *p*-value of the residual chi-square with respect to a chi-square distribution with the corresponding degrees of freedom
- “Analysis of Effects not in the Model” table, if you specify the DETAILS option in the MODEL statement. This table gives the score chi-square statistic for testing the significance of each variable not in the model after adjusting for the variables already in the model, and the *p*-value of the chi-square statistic with respect to a chi-square distribution with one degree of freedom
- classification table, if you use the CTABLE option in the MODEL statement. For each prior event probability (labeled “Prob Event”) specified by the PEVENT= option and each cutpoint specified in the PPROB= option, the table gives the four entries of the 2×2 table of observed and predicted responses and the percentages of correct classification, sensitivity, specificity, false positive, and false negative. The columns labeled “Correct” give the number of correctly classified events and nonevents. “Incorrect Event” gives the number of nonevents incorrectly classified as events. “Incorrect Nonevent” gives the number of nonevents incorrectly classified as events.
- estimated covariance matrix of the parameter estimates, if you use the COVB option in the MODEL statement
- estimated correlation matrix of the parameter estimates, if you use the CORRB option in the MODEL statement
- “Contrast Test Results” table, if you specify a CONTRAST statement. This table gives the result of the Wald test for each CONTRAST specified. If you

specify the E option in the CONTRAST statement, then the contrast matrix is displayed. If you specify the ESTIMATE= option in the CONTRAST statement, then estimates and Wald tests for each contrast (row of the contrast matrix) or exponentiated contrast are produced.

- “Linear Hypothesis Testing” table, if you specify a TEST statement. This table gives the result of the Wald test for each TEST statement specified. If you specify the PRINT option in the TEST statement, then matrices used in the intermediate calculations are also displayed.
- results of the Hosmer and Lemeshow test for the goodness of fit of the fitted model, if you use the LACKFIT option in the MODEL statement
- “Regression Diagnostics” table, if you use the INFLUENCE option in the MODEL statement. This table gives, for each observation, the case number (which is the observation number), the values of the explanatory variables included in the model, the Pearson residual, the deviance residual, the diagonal element of the hat matrix, the standardized difference in the estimate for each parameter (*name* DFBETA, where *name* is either Intercept or the name of an explanatory variable), two confidence interval displacement diagnostics (C and CBAR), the change in the Pearson chi-square statistic (DIFCHISQ), and the change in the deviance (DIFDEV)

If you also specify the STRATA statement, then this table contains the case number (which is the observation number), the values of the explanatory variables included in the model, the estimated one-step Pearson residual, the estimated one-step diagonal element of the hat matrix, and the estimated one-step standardized difference in the estimate for each parameter.

- index plots of regression diagnostics, if you specify the IPLOTS option in the MODEL statement. These include plots of
 - Pearson residuals
 - deviance residuals
 - diagonal elements of the hat matrix
 - standardized differences in parameter estimates, DFBETA0 for the intercept estimate, DFBETA1 for the slope estimate of the first explanatory variable in the MODEL statement, and so on
 - confidence interval displacement diagnostics C
 - confidence interval displacement diagnostics CBAR
 - changes in the Pearson chi-square statistic
 - changes in the deviance
- if you specify a STRATA statement
 - “Strata Summary” table, which displays a pattern of the number of events and the number of non-events in a stratum, the number of strata having that pattern, and the total number of observations contained in those strata
 - “Strata Information” table, if you specify the INFO option on the STRATA statement. This table displays each stratum, its frequency, and the number of events and non-events in that stratum.

- if you specify an EXACT statement
 - “Sufficient Statistics” table, if you request an OUTDIST= data set. This table is displayed before printing any of the exact analysis results and lists the parameters and their observed sufficient statistics.
 - “Conditional Exact Tests” table, which provides two tests for the null hypothesis that the parameters for the specified effects are zero: the Exact Probability Test and the Exact Conditional Scores test. For each test, the test statistic, an exact p -value (the probability of obtaining a more extreme statistic than the observed, assuming the null hypothesis), and a mid p -value (which adjusts for the discreteness of the distribution) are displayed.
 - “Exact Parameter Estimates” table, if you specify the ESTIMATE, ESTIMATE=PARM, or ESTIMATE=BOTH options. This table gives individual parameter estimates for each variable (conditional on the values of all the other parameters in the model), confidence limits, and a two-sided p -value (twice the one-sided p -value) for testing that the parameter is zero.
 - “Exact Odds Ratios” table, if you specify the ESTIMATE=ODDS or ESTIMATE=BOTH options. This table gives odds ratio estimates for the individual parameters, confidence limits, and a two-sided p -value for testing that the odds ratio is 1.

ODS Table Names

PROC LOGISTIC assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

Table 42.2. ODS Tables Produced in PROC LOGISTIC

ODS Table Name	Description	Statement	Option
Association	Association of predicted probabilities and observed responses	MODEL	default
BestSubsets	Best subset selection	MODEL	SELECTION=SCORE
ClassFreq	Frequency breakdown of CLASS variables	PROC	Simple (with CLASS vars)
ClassLevelInfo	CLASS variable levels and design variables	MODEL	default (with CLASS vars)
Classification	Classification table	MODEL	CTABLE
ClassWgt	Weight breakdown of CLASS variables	PROC, WEIGHT	Simple (with CLASS vars)
CLOddsPL	Profile likelihood confidence limits for odds ratios	MODEL	CLODDS=PL
CLOddsWald	Wald’s confidence limits for odds ratios	MODEL	CLODDS=WALD

Table 42.2. (continued)

ODS Table Name	Description	Statement	Option
CLParmPL	Profile likelihood confidence limits for parameters	MODEL	CLPARAM=PL
CLParmWald	Wald's confidence limits for parameters	MODEL	CLPARAM=WALD
ContrastCoeff	L matrix from CONTRAST	CONTRAST	E
ContrastEstimate	Estimates from CONTRAST	CONTRAST	ESTIMATE=
ContrastTest	Wald test for CONTRAST	CONTRAST	default
ConvergenceStatus	Convergence status	MODEL	default
CorrB	Estimated correlation matrix of parameter estimators	MODEL	CORRB
CovB	Estimated covariance matrix of parameter estimators	MODEL	COVB
CumulativeModelTest	Test of the cumulative model assumption	MODEL	(ordinal response)
EffectNotInModel	Test for effects not in model	MODEL	SELECTION=S/F
ExactOddsRatio	Exact Odds Ratios	EXACT	ESTIMATE=ODDS, ESTIMATE=BOTH
ExactParmEst	Parameter Estimates	EXACT	ESTIMATE, ESTIMATE=PARM, ESTIMATE=BOTH
ExactTests	Conditional Exact Tests	EXACT	default
FastElimination	Fast backward elimination	MODEL	SELECTION=B,FAST
FitStatistics	Model fit statistics	MODEL	default
GlobalScore	Global score test	MODEL	NOFIT
GlobalTests	Test for global null hypothesis	MODEL	default
GoodnessOfFit	Pearson and deviance goodness-of-fit tests	MODEL	SCALE
IndexPlots	Batch capture of the index plots	MODEL	IPLOTS
Influence	Regression diagnostics	MODEL	INFLUENCE
IterHistory	Iteration history	MODEL	ITPRINT
LackFitChiSq	Hosmer-Lemeshow chi-square test results	MODEL	LACKFIT
LackFitPartition	Partition for the Hosmer-Lemeshow test	MODEL	LACKFIT
LastGradient	Last evaluation of gradient	MODEL	ITPRINT
LogLikeChange	Final change in the log likelihood	MODEL	ITPRINT
ModelBuildingSummary	Summary of model building	MODEL	SELECTION=B/F/S
ModelInfo	Model information	PROC	default
NObs	Number of Observations	PROC	default
OddsRatios	Odds ratios	MODEL	default

Table 42.2. (continued)

ODS Table Name	Description	Statement	Option
ParameterEstimates	Maximum likelihood estimates of model parameters	MODEL	default
RSquare	R-square	MODEL	RSQUARE
ResidualChiSq	Residual chi-square	MODEL	SELECTION=F/B
ResponseProfile	Response profile	PROC	default
SimpleStatistics	Summary statistics for explanatory variables	PROC	SIMPLE
StrataSummary	Number of strata with specific response frequencies	STRATA	default
StrataInfo	Event and non-event frequencies for each stratum	STRATA	INFO
SuffStats	Sufficient Statistics	EXACT	OUTDIST=
TestPrint1	$\mathbf{L}[\text{cov}(\mathbf{b})]\mathbf{L}'$ and $\mathbf{Lb-c}$	TEST	PRINT
TestPrint2	$\mathbf{Ginv}(\mathbf{L}[\text{cov}(\mathbf{b})]\mathbf{L}')$ and $\mathbf{Ginv}(\mathbf{L}[\text{cov}(\mathbf{b})]\mathbf{L}')(\mathbf{Lb-c})$	TEST	PRINT
TestStmts	Linear hypotheses testing results	TEST	default
Type3	Type 3 tests of effects	MODEL	default (with CLASS variables)

ODS Graphics (Experimental)

This section describes the use of ODS for creating graphics with the LOGISTIC procedure. These graphics are experimental in this release, meaning that both the graphical results and the syntax for specifying them are subject to change in a future release.

To request these graphs you must specify the ODS GRAPHICS statement in addition to options on the MODEL or GRAPHICS statement as described in the following sections. For more information on the ODS GRAPHICS statement, see Chapter 15, “Statistical Graphics Using ODS.”

MODEL Statement Options

If the INFLUENCE or IPLOTS option is specified in the MODEL statement, then the lineprinter plots are suppressed and ODS GRAPHICS versions of the plots are produced.

If you specify the OUTROC= option, and if ROCEPS= is not specified, then ROC curves are produced. If you also specify a SELECTION= method then an overlaid plot of all the ROC curves for each step of the selection process is displayed.

GRAPHICS Statement and Options**GRAPHICS options ;**

The GRAPHICS statement provides options for requesting and modifying certain graphical displays. This statement has no effect unless ODS GRAPHICS ON has been specified. The functionality of this statement may be replaced by alternative syntax in a future release.

The following options are available.

- DFBETAS** displays the DFBETAS versus Case Number plots. This acts like DFBETAS=_ALL_ in the OUTPUT statement. These plots are produced by default when the GRAPHICS statement is specified.
- HATDIAG** displays plots of DIFCHISQ, DIFDEV, and DFBETAS (when the DFBETAS option is specified) versus the hat diagonals.
- INFLUENCE | INDEX** displays the INFLUENCE plots with no DFBETAS. These plots are produced by default when the GRAPHICS statement is specified.
- PHAT** displays plots of DIFCHISQ, DIFDEV, and DFBETAS (when the DFBETAS option is specified) versus the predicted event probability.
- ALL** invokes the DFBETAS, HATDIAG, INFLUENCE, and PHAT options.
- NOINFLUENCE** suppresses the default INFLUENCE and DFBETAS plots.
- NOPANELS** unpanels the graphical displays and produces a series of plots which form the panelled display.
- ROC** displays the ROC curve. If the ROCEPS= option is specified on the MODEL statement then it must be equal to zero, otherwise no ROC curve is produced. If you also specify a SELECTION= method then an overlaid plot of all the ROC curves for each step of the selection process is displayed.
- ESTPROB(*fit-options*)** displays the fit curves for the model when only one continuous covariate is specified in the model. If you use events/trials syntax, then this displays the estimated event probability and the prediction limits versus the covariate with the observed proportions overlaid on the graph. If you use single-trial syntax, this displays the estimated event probability and the prediction limits versus the covariate with the observed responses overlaid on the graph. If you specify a polytomous logit model, then the estimated probabilities for each possible response level are graphed. If you have an OFFSET= variable with more than one value, then the prediction curves are replaced with error bars and the estimated probabilities are displayed at the observed covariate values.

The following *fit-options* are available with the ESTPROB option.

ALPHA=α	specifies the size of the prediction interval. The ALPHA= value specified on the PROC statement is the default. If neither ALPHA= value is specified, then ALPHA=0.05 by default.
GRIDSIZE=n	specifies the number of equally-spaced points at which the fit curve is computed. By default, GRIDSIZE=50.
OBSERVE	specifies that the fit curve should be computed at the observed values only.

See [Example 42.6](#) on page 2422 and [Example 42.7](#) on page 2429 for examples of the ODS graphical displays.

ODS Graph Names

PROC LOGISTIC assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in [Table 42.3](#).

To request these graphs you must specify the ODS GRAPHICS statement in addition to the options indicated in [Table 42.3](#). For more information on the ODS GRAPHICS statement, see [Chapter 15](#), “Statistical Graphics Using ODS.”

Table 42.3. ODS Graphics Produced by PROC LOGISTIC

ODS Graph Name	Plot Description	Statement	Option

0 1      .73 .73  .7  .398  .986
;

```

The data set `Remission` contains seven variables. The variable `remiss` is the cancer remission indicator variable with a value of 1 for remission and a value of 0 for nonremission. The other six variables are the risk factors thought to be related to cancer remission.

The following invocation of PROC LOGISTIC illustrates the use of [stepwise selection](#) to identify the prognostic factors for cancer remission. A significance level of 0.3 (`SLENTRY=0.3`) is required to allow a variable into the model, and a significance level of 0.35 (`SLSTAY=0.35`) is required for a variable to stay in the model. A detailed account of the variable selection process is requested by specifying the `DETAILS` option. The Hosmer and Lemeshow goodness-of-fit test for the final selected model is requested by specifying the `LACKFIT` option. The `OUTEST=` and `COVOUT` options in the PROC LOGISTIC statement create a data set that contains parameter estimates and their covariances for the final selected model. The response variable option `EVENT=` sets `remiss=1` (remission) to be Ordered Value 1 so that the probability of remission is modeled. The `OUTPUT` statement creates a data set that contains the cumulative predicted probabilities and the corresponding confidence limits, and the individual and cross validated predicted probabilities for each observation.

```

title 'Stepwise Regression on Cancer Remission Data';
proc logistic data=Remission outest=betas covout;
  model remiss(event='1')=cell smear infil li blast temp
    / selection=stepwise
      slentry=0.3
      slstay=0.35
      details
      lackfit;
  output out=pred p=phat lower=lcl upper=ucl
    predprob=(individual crossvalidate);
run;

proc print data=betas;
  title2 'Parameter Estimates and Covariance Matrix';
run;

proc print data=pred;
  title2 'Predicted Probabilities and 95% Confidence Limits';
run;

```

In stepwise selection, an attempt is made to remove any insignificant variables from the model before adding a significant variable to the model. Each addition or deletion of a variable to or from a model is listed as a separate step in the displayed output, and at each step a new model is fitted. Details of the model selection steps are shown in [Output 42.1.1 –Output 42.1.5](#).

Output 42.1.1. Startup Model

```

Stepwise Regression on Cancer Remission Data

Output 42.1.5. Summary of the Stepwise Selection

Summary of Stepwise Selection							
Step	Effect		DF	Number In	Score Chi-Square	Wald Chi-Square	Pr > ChiSq
	Entered	Removed					
1	li		1	1	7.9311		0.0049
2	temp		1	2	1.2591		0.2618
3	cell		1	3	1.4700		0.2254

Prior to the first step, the intercept-only model is fitted and individual score statistics for the potential variables are evaluated (Output 42.1.1). In Step 1 (Output 42.1.2), variable *li* is selected into the model since it is the most significant variable among those to be chosen ($p = 0.0049 < 0.3$). The intermediate model that contains an intercept and *li* is then fitted. *li* remains significant ($p = 0.0146 < 0.35$) and is not removed. In Step 2 (Output 42.1.3), variable *temp* is added to the model. The model then contains an intercept and variables *li* and *temp*. Both *li* and *temp* remain significant at 0.035 level; therefore, neither *li* nor *temp* is removed from the model. In Step 4 (Output 42.1.4), variable *cell* is added to the model. The model then contains an intercept and variables *li*, *temp*, and *cell*. None of these variables are removed from the model since all are significant at the 0.35 level. Finally, none of the remaining variables outside the model meet the entry criterion, and the stepwise selection is terminated. A summary of the stepwise selection is displayed in Output 42.1.5.

Output 42.1.6. Display of the LACKFIT Option

Partition for the Hosmer and Lemeshow Test						
Group	Total	remiss = 1		remiss = 0		
		Observed	Expected	Observed	Expected

The data set `pred` created by the `OUTPUT` statement is displayed in [Output 42.1.8](#). It contains all the variables in the input data set, the variable `phat` for the (cumulative) predicted probability, the variables `lcl` and `ucl` for the lower and upper confidence limits for the probability, and four other variables (viz., `IP_1`, `IP_0`, `XP_1`, and `XP_0`) for the `PREDPROBS=` option. The data set also contains the variable `_LEVEL_`, indicating the response value to which `phat`, `lcl`, and `ucl` refer. For instance, for the first row of the `OUTPUT` data set, the values of `_LEVEL_` and `phat`, `lcl`, and `ucl` are 1, 0.72265, 0.16892 and 0.97093, respectively; this means that the estimated probability that `remiss` ≤ 1 is 0.723 for the given explanatory variable values, and the corresponding 95% confidence interval is (0.16892, 0.97093). The variables `IP_1` and `IP_0` contain the predicted probabilities that `remiss`=1 and `remiss`=0, respectively. Note that values of `phat` and `IP_1` are identical since they both contain the probabilities that `remiss`=1. The variables `XP_1` and `XP_0` contain the cross validated predicted probabilities that `remiss`=1 and `remiss`=0, respectively.

Next, a different variable selection method is used to select prognostic factors for cancer remission, and an efficient algorithm is employed to eliminate insignificant variables from a model. The following SAS statements invoke PROC LOGISTIC to perform the backward elimination analysis.

```
title 'Backward Elimination on Cancer Remission Data';
proc logistic data=Remission;
    model remiss(event='1')=temp cell li smear blast
        / selection=backward fast slstay=0.2 ctable;
run;
```

The backward elimination analysis (SELECTION=BACKWARD) starts with a model that contains all explanatory variables given in the MODEL statement. By specifying the **FAST** option, PROC LOGISTIC eliminates insignificant variables without refitting the model repeatedly. This analysis uses a significance level of 0.2 (SLSTAY=0.2) to retain variables in the model, which is different from the previous stepwise analysis where SLSTAY=.35. The **CTABLE** option is specified to produce classifications of input observations based on the final selected model.

Output 42.1.9. Initial Step in Backward Elimination

```

Backward Elimination on Cancer Remission Data

The LOGISTIC Procedure

Model Information

Data Set                WORK.REMISSION

Results of the fast elimination analysis are shown in [Output 42.1.9](#) and [Output 42.1.10](#). Initially, a full model containing all six risk factors is fit to the data ([Output 42.1.9](#)). In the next step ([Output 42.1.10](#)), PROC LOGISTIC removes `blast`, `smear`, `cell`, and `temp` from the model all at once. This leaves `li` and the intercept as the only variables in the final model. Note that in this analysis, only parameter estimates for the final model are displayed because the `DETAILS` option has not been specified.

Note that you can also use the `FAST` option when `SELECTION=STEPWISE`. However, the `FAST` option operates only on backward elimination steps. In this example, the stepwise process only adds variables, so the `FAST` option would not be useful.

Output 42.1.11. Classifying Input Observations

Classification Table

Results of the CTABLE option are shown in [Output 42.1.11](#). Each row of the “Classification Table” corresponds to a cutpoint applied to the predicted probabilities, which is given in the Prob Level column. The 2×2 frequency tables of observed and predicted responses are given by the next four columns. For example, with a cutpoint of 0.5, 4 events and 16 nonevents were classified correctly. On the other hand, 2 nonevents were incorrectly classified as events and 5 events were incorrectly classi-

fied as nonevents. For this cutpoint, the correct classification rate is 20/27 (=74.1%), which is given in the sixth column. Accuracy of the classification is summarized by the sensitivity, specificity, and false positive and negative rates, which are displayed in the last four columns. You can control the number of cutpoints used, and their values, by using the `PPROB=` option.

Example 42.2. Logistic Modeling with Categorical Predictors

Consider a study of the analgesic effects of treatments on elderly patients with neuralgia. Two test treatments and a placebo are compared. The response variable is whether the patient reported pain or not. Researchers recorded age and gender of the patients and the duration of complaint before the treatment began. The data, consisting of 60 patients, are contained in the data set `Neuralgia`.

```

Data Neuralgia;
  input Treatment $ Sex $ Age Duration Pain $ @@;
  datalines;

```

The data set `Neuralgia` contains five variables: `Treatment`, `Sex`, `Age`, `Duration`, and `Pain`. The last variable, `Pain`, is the response variable. A specification of `Pain=Yes` indicates there was pain, and `Pain=No` indicates no pain. The variable `Treatment` is a categorical variable with three levels: A and B represent the two test treatments, and P represents the placebo treatment. The gender of the patients is given by the categorical variable `Sex`. The variable `Age` is the age of the patients, in years, when treatment began. The duration of complaint, in months, before the treatment began is given by the variable `Duration`. The following statements use the LOGISTIC procedure to fit a two-way logit with interaction model for the effect of `Treatment` and `Sex`, with `Age` and `Duration` as covariates. The categorical variables `Treatment` and `Sex` are declared in the `CLASS` statement.

```
proc logistic data=Neuralgia;
  class Treatment Sex;
  model Pain= Treatment Sex Treatment*Sex Age Duration / expb;
run;
```

In this analysis, PROC LOGISTIC models the probability of no pain (Pain=No). By default, effect coding is used to represent the CLASS variables. Two design variables are created for Treatment and one for Sex, as shown in [Output 42.2.1](#).

Output 42.2.1. Effect Coding of CLASS Variables

The LOGISTIC Procedure			
Class Level Information			
Class	Value	Design Variables	
Treatment	A	1	0
	B	0	1
	P	-1	-1
Sex	F	1	
	M	-1	

PROC LOGISTIC displays a table of the Type 3 analysis of effects based on the Wald test ([Output 42.2.2](#)). Note that the Treatment*Sex interaction and the duration of complaint are not statistically significant ($p = 0.9318$ and $p = 0.8752$, respectively). This indicates that there is no evidence that the treatments affect pain differently in men and women, and no evidence that the pain outcome is related to the duration of pain.

Output 42.2.2. Wald Tests of Individual Effects

Type 3 Analysis of Effects			
Effect	DF	Wald Chi-Square	Pr > ChiSq
Treatment	2	11.9886	0.0025
Sex	1	5.3104	0.0212
Treatment*Sex	2	0.1412	0.9318
Age	1	7.2744	0.0070
Duration	1	0.0247	0.8752

Parameter estimates are displayed in [Output 42.2.3](#). The Exp(Est) column contains the exponentiated parameter estimates requested with the EXPB option. These values may, but do not necessarily, represent odds ratios for the corresponding variables. For continuous explanatory variables, the Exp(Est) value corresponds to the odds ratio for a unit increase of the corresponding variable. For CLASS variables using the effect coding, the Exp(Est) values have no direct interpretation as a comparison of levels.

However, when the reference coding is used, the Exp(Est) values represent the odds ratio between the corresponding level and the last level. Following the parameter estimates table, PROC LOGISTIC displays the odds ratio estimates for those variables that are not involved in any interaction terms. If the variable is a CLASS variable, the odds ratio estimate comparing each level with the last level is computed regardless of the coding scheme. In this analysis, since the model contains the Treatment*Sex interaction term, the odds ratios for Treatment and Sex were not computed. The odds ratio estimates for Age and Duration are precisely the values given in the Exp(Est) column in the parameter estimates table.

Output 42.2.3. Parameter Estimates with Effect Coding

Analysis of Maximum Likelihood Estimates						
Parameter	DF	Estimate	Standard Error	Wald Chi-Square	Pr > ChiSq	Exp(Est)
Intercept	1	19.2236	7.1315	7.2661	0.0070	2.232E8
Treatment A	1	0.8483	0.5502	2.3773	0.1231	2.336
Treatment B	1	1.4949	0.6622	5.0956	0.0240	4.459
Sex F	1	0.9173	0.3981	5.3104	0.0212	2.503

Age	1	-0.2688	0.0996	7.2744	0.0070	0.764
Duration	1	0.00523	0.0333	0.0247	0.8752	1.005

Odds Ratio Estimates			
Effect	Point Estimate	95% Wald Confidence Limits	
Age	0.764	0.629	0.929
Duration	1.005	0.942	1.073

The following PROC LOGISTIC statements illustrate the use of forward selection on the data set Neuralgia to identify the effects that differentiate the two Pain responses. The option SELECTION=FORWARD is specified to carry out the forward selection. The term Treatment|Sex@2 illustrates another way to specify main effects and two-way interaction as is available in other procedures such as PROC GLM. (Note that, in this case, the “@2” is unnecessary because no interactions besides the two-way interaction are possible).

```
proc logistic data=Neuralgia;
  class Treatment Sex;
  model Pain=Treatment|Sex@2 Age Duration
    /selection=forward expb;
run;
```

Results of the forward selection process are summarized in Output 42.2.4. The variable Treatment is selected first, followed by Age and then Sex. The results are consistent with the previous analysis (Output 42.2.2) in which the Treatment*Sex interaction and Duration are not statistically significant.

Output 42.2.4. Effects Selected into the Model

The LOGISTIC Procedure					
Summary of Forward Selection					
Step	Effect Entered	DF	Number In	Score Chi-Square	Pr > ChiSq
1	Treatment	2	1	13.7143	0.0011
2	Age	1	2	10.6038	0.0011
3	Sex	1	3	5.9959	0.0143

[Output 42.2.5](#) shows the Type 3 analysis of effects, the parameter estimates, and the odds ratio estimates for the selected model. All three variables, **Treatment**, **Age**, and **Sex**, are statistically significant at the 0.05 level ($p = 0.0011$, $p = 0.0011$, and $p = 0.0143$, respectively). Since the selected model does not contain the **Treatment*Sex** interaction, odds ratios for **Treatment** and **Sex** are computed. The estimated odds ratio is 24.022 for treatment A versus placebo, 41.528 for Treatment B versus placebo, and 6.194 for female patients versus male patients. Note that these odds ratio estimates are not the same as the corresponding values in the Exp(Est) column in the parameter estimates table because effect coding was used. From [Output 42.2.5](#), it is evident that both Treatment A and Treatment B are better than the placebo in reducing pain; females tend to have better improvement than males; and younger patients are faring better than older patients.

Output 42.2.5. Type 3 Effects and Parameter Estimates with Effect Coding

Type 3 Analysis of Effects						
Effect	DF		Wald Chi-Square	Pr > ChiSq		
Treatment	2		12.6928	0.0018		
Sex	1		5.3013	0.0213		
Age	1		7.6314	0.0057		

Analysis of Maximum Likelihood Estimates						
Parameter	DF	Estimate	Standard Error	Wald Chi-Square	Pr > ChiSq	Exp(Est)
Intercept	1	19.0804	6.7882	7.9007	0.0049	1.9343E8
Treatment A	1	0.8772	0.5274	2.7662	0.0963	2.404
Treatment B	1	1.4246	0.6036	5.5711	0.0183	4.156
Sex F	1	0.9118	0.3960	5.3013	0.0213	2.489
Age	1	-0.2650	0.0959	7.6314	0.0057	0.767

Odds Ratio Estimates				
Effect		Point Estimate	95% Wald Confidence Limits	
Treatment A vs P		24.022	3.295	175.121
Treatment B vs P		41.528	4.500	383.262
Sex F vs M		6.194	1.312	29.248
Age		0.767	0.636	0.926

Finally, PROC LOGISTIC is invoked to refit the previously selected model using reference coding for the CLASS variables. Two CONTRAST statements are specified. The one labeled 'Pairwise' specifies three rows in the contrast matrix, L, for all the pairwise comparisons between the three levels of Treatment. The contrast labeled 'Female vs Male' compares female to male patients. The option ESTIMATE=EXP is specified in both CONTRAST statements to exponentiate the estimates of $L'\beta$. With the given specification of contrast coefficients, the first row of the 'Pairwise' CONTRAST statement corresponds to the odds ratio of A versus P, the second row corresponds to B versus P, and the third row corresponds to A versus B. There is only one row in the 'Female vs Male' CONTRAST statement, and it corresponds to the odds ratio comparing female to male patients.

```
proc logistic data=Neuralgia;
  class Treatment Sex /param=ref;
  model Pain= Treatment Sex age;
  contrast 'Pairwise' Treatment 1 0,
           Treatment 0 1,
           Treatment 1 -1 / estimate=exp;
  contrast 'Female vs Male' Sex 1 / estimate=exp;
run;
```

Output 42.2.6. Reference Coding of CLASS Variables

The LOGISTIC Procedure			
Class Level Information			
Class	Value	Design Variables	
Treatment	A	1	0
	B	0	1
	P	0	0
Sex	F	1	
	M	0	

The reference coding is shown in [Output 42.2.6](#). The Type 3 analysis of effects, the parameter estimates for the reference coding, and the odds ratio estimates are displayed in [Output 42.2.7](#). Although the parameter estimates are different (because of the different parameterizations), the “Type 3 Analysis of Effects” table and the “Odds Ratio” table remain the same as in [Output 42.2.5](#). With effect coding, the treatment A parameter estimate (0.8772) estimates the effect of treatment A compared to the average effect of treatments A, B, and placebo. The treatment A estimate (3.1790) under the reference coding estimates the difference in effect of treatment A and the placebo treatment.

Output 42.2.7. Type 3 Effects and Parameter Estimates with Reference Coding

Type 3 Analysis of Effects					
Effect	DF		Wald Chi-Square		Pr > ChiSq
Treatment	2		12.6928		0.0018
Sex	1		5.3013		0.0213
Age	1		7.6314		0.0057

Analysis of Maximum Likelihood Estimates					
Parameter	DF	Estimate	Standard Error	Wald Chi-Square	Pr > ChiSq
Intercept	1	15.8669	6.4056	6.1357	0.0132
Treatment A	1	3.1790	1.0135	9.8375	0.0017
Treatment B	1	3.7264	1.1339	10.8006	0.0010
Sex F	1	1.8235	0.7920	5.3013	0.0213
Age	1	-0.2650	0.0959	7.6314	0.0057

Odds Ratio Estimates			
Effect		Point Estimate	95% Wald Confidence Limits
Treatment A vs P		24.022	3.295 175.121
Treatment B vs P		41.528	4.500 383.262
Sex F vs M		6.194	1.312 29.248
Age		0.767	0.636 0.926

Output 42.2.8 contains two tables: the “Contrast Test Results” table and the “Contrast Rows Estimation and Testing Results” table. The former contains the overall Wald test for each CONTRAST statement. Although three rows are specified in the ‘Pairwise’ CONTRAST statement, there are only two degrees of freedom, and the Wald test result is identical to the Type 3 analysis of Treatment in Output 42.2.7. The latter table contains estimates and tests of individual contrast rows. The estimates for the first two rows of the ‘Pairwise’ CONTRAST statement are the same as those given in the “Odds Ratio Estimates” table (in Output 42.2.7). Both treatments A and B are highly effective over placebo in reducing pain. The third row estimates the odds ratio comparing A to B. The 95% confidence interval for this odds ratio is (0.0932, 3.5889), indicating that the pain reduction effects of these two test treatments are not that different. Again, the ‘Female vs Male’ contrast shows that female patients fared better in obtaining relief from pain than male patients.

Output 42.2.8. Results of CONTRAST Statements

Contrast Test Results						
Contrast	DF	Wald Chi-Square	Pr > ChiSq			
Pairwise	2	12.6928	0.0018			
Female vs Male	1	5.3013	0.0213			

Contrast Rows Estimation and Testing Results							
Contrast	Type	Row	Estimate	Standard Error	Alpha	Confidence Limits	
Pairwise	EXP	1	24.0218	24.3473	0.05	3.2951	175.1
Pairwise	EXP	2	41.5284	47.0877	0.05	4.4998	383.3
Pairwise	EXP	3	0.5784	0.5387	0.05	0.0932	3.5889
Female vs Male	EXP	1	6.1937	4.9053	0.05	1.3116	29.2476

Contrast Rows Estimation and Testing Results						
Contrast	Type	Row	Wald Chi-Square	Pr > ChiSq		
Pairwise	EXP	1	9.8375	0.0017		
Pairwise	EXP	2	10.8006	0.0010		
Pairwise	EXP	3	0.3455	0.5567		
Female vs Male	EXP	1	5.3013	0.0213		

Example 42.3. Ordinal Logistic Regression

Consider a study of the effects on taste of various cheese additives. Researchers tested four cheese additives and obtained 52 response ratings for each additive. Each response was measured on a scale of nine categories ranging from strong dislike (1) to excellent taste (9). The data, given in McCullagh and Nelder (1989, p. 175) in the form of a two-way frequency table of additive by rating, are saved in the data set Cheese.

```

data Cheese;
  do Additive = 1 to 4;
    do y = 1 to 9;
      input freq @@;
      output;
    end;
  end;
  label y='Taste Rating';
  datalines;
0 0 1 7 8 8 19 8 1
6 9 12 11 7 6 1 0 0
1 1 6 8 23 7 5 1 0
0 0 0 1 3 7 14 16 11
;

```

The data set **Cheese** contains the variables **y**, **Additive**, and **freq**. The variable **y** contains the response rating. The variable **Additive** specifies the cheese additive (1, 2, 3, or 4). The variable **freq** gives the frequency with which each additive received each rating.

The response variable **y** is ordinally scaled. A cumulative logit model is used to investigate the effects of the cheese additives on taste. The following SAS statements invoke PROC LOGISTIC to fit this model with **y** as the response variable and three indicator variables as explanatory variables, with the fourth additive as the reference level. With this parameterization, each **Additive** parameter compares an additive to the fourth additive. The **COVB** option produces the estimated covariance matrix.

```
proc logistic data=Cheese;
  freq freq;
  class Additive (param=ref ref='4');
  model y=Additive / covb;
  title1 'Multiple Response Cheese Tasting Experiment';
run;
```

Results of the analysis are shown in [Output 42.3.1](#), and the estimated covariance matrix is displayed in [Output 42.3.2](#).

Since the strong dislike ($y=1$) end of the rating scale is associated with lower Ordered Values in the Response Profile table, the probability of disliking the additives is modeled.

The score chi-square for testing the proportional odds assumption is 17.287, which is not significant with respect to a chi-square distribution with 21 degrees of freedom ($p = 0.694$). This indicates that the proportional odds model adequately fits the data. The positive value (1.6128) for the parameter estimate for **Additive1** indicates a tendency towards the lower-numbered categories of the first cheese additive relative to the fourth. In other words, the fourth additive is better in taste than the first additive. Each of the second and the third additives is less favorable than the fourth additive. The relative magnitudes of these slope estimates imply the preference ordering: fourth, first, third, second.

Example 42.4. Nominal Response Data: Generalized Logits Model

Over the course of one school year, third graders from three different schools are exposed to three different styles of mathematics instruction: a self-paced computer-learning style, a team approach, and a traditional class approach. The students are asked which style they prefer and their responses, classified by the type of program they are in (a regular school day versus a regular day supplemented with an afternoon school program) are displayed in [Table 42.4](#). The data set is from Stokes, Davis, and Koch (2000), and is also analyzed in the “Generalized Logits Model” section on page 824 of Chapter 22, “The CATMOD Procedure.”

Table 42.4. School Program Data

School	Program	Learning Style Preference		
		Self	Team	Class
1	Regular	10	17	26
1	Afternoon	5	12	50
2	Regular	21	17	26
2	Afternoon	16	12	36
3	Regular	15	15	16
3	Afternoon	12	12	20

The levels of the response variable (self, team, and class) have no essential ordering, so a logistic regression is performed on the generalized logits. The model to be fit is

$$\log\left(\frac{\pi_{hij}}{\pi_{hir}}\right) = \alpha_j + \mathbf{x}'_{hi}\beta_j$$

where π_{hij} is the probability that a student in school h and program i prefers teaching style j , $j \neq r$, and style r is the baseline style (in this case, class). There are separate sets of intercept parameters α_j and regression parameters β_j for each logit, and the matrix \mathbf{x}_{hi} is the set of explanatory variables for the h th population. Thus, two logits are modeled for each school and program combination: the logit comparing self to class and the logit comparing team to class.

The following statements create the data set `SCHOOL` and request the analysis. The `LINK=GLOGIT` option forms the generalized logits. The response variable option `ORDER=DATA` means that the response variable levels are ordered as they exist in the data set: self, team, and class; thus, the logits are formed by comparing self to class and by comparing team to class. The `ODS` statement suppresses the display of the maximum likelihood estimates. The results of this analysis are shown in [Output 42.4.1](#) through [Output 42.4.4](#).

Program regular	self	1	0.3737	0.1410	7.0272	0.0080
Program regular	team	1	0.3713	0.1353	7.5332	0.0061

Odds Ratio Estimates					
Effect	Style	Point Estimate	95% Wald Confidence Limits		
School 1 vs 3	self	0.269	0.127	0.570	
School 1 vs 3	team	0.519	0.267	1.010	
School 2 vs 3	self	0.793	0.413	1.522	
School 2 vs 3	team	0.622	0.317	1.219	
Program regular vs afternoon	self	2.112	1.215	3.670	
Program regular vs afternoon	team	2.101	1.237	3.571	

The parameter estimates, tests for individual parameters, and odds ratios are displayed in [Output 42.4.6](#). The Program variable has nearly the same effect on both logits, while School=1 has the largest effect of the schools.

Example 42.5. Stratified Sampling

Consider the hypothetical example in Fleiss (1981, pp. 6–7) in which a test is applied to a sample of 1,000 people known to have a disease and to another sample of 1,000 people known not to have the same disease. In the diseased sample, 950 test positive; in the nondiseased sample, only 10 test positive. If the true disease rate in the population is 1 in 100, specifying `PEVENT=0.01` results in the correct false positive and negative rates for the stratified sampling scheme. Omitting the `PEVENT=` option is equivalent to using the overall sample disease rate ($1000/2000 = 0.5$) as the value of the `PEVENT=` option, which would ignore the stratified sampling.

The SAS code is as follows:

```

data Screen;
  do Disease='Present','Absent';
    do Test=1,0;
      input Count @@;
      output;
    end;
  end;
  datalines;
950 50
10 990
;

```

```

proc logistic data=Screen;
  freq Count;
  model Disease(event='Present')=Test
    / pevent=.5 .01 ctable pprob=.5;
run;

```

The response variable option `EVENT=` indicates that `Disease='Present'` is the event. The `CTABLE` option is specified to produce a classification table. Specifying `PPROB=0.5` indicates a cutoff probability of 0.5. A list of two probabilities, 0.5 and 0.01, is specified for the `PEVENT=` option; 0.5 corresponds to the overall sample disease rate, and 0.01 corresponds to a true disease rate of 1 in 100.

The classification table is shown in [Output 42.5.1](#).

Output 42.5.1. False Positive and False Negative Rates

The LOGISTIC Procedure										
Classification Table										
Prob Event	Prob Level	Correct		Incorrect		Percentages				
		Event	Non- Event	Event	Non- Event	Correct	Sensi- tivity	Speci- ficity	False POS	False NEG
0.500	0.500	950	990	10	50	97.0	95.0	99.0	1.0	4.8
0.010	0.500	950	990	10	50	99.0	95.0	99.0	51.0	0.1

In the classification table, the column “Prob Level” represents the cutoff values (the settings of the `PPROB=` option) for predicting whether an observation is an event. The “Correct” columns list the numbers of subjects that are correctly predicted as events and nonevents, respectively, and the “Incorrect” columns list the number of nonevents incorrectly predicted as events and the number of events incorrectly predicted as nonevents, respectively. For `PEVENT=0.5`, the false positive rate is 1% and the false negative rate is 4.8%. These results ignore the fact that the samples were stratified and incorrectly assume that the overall sample proportion of disease (which is 0.5) estimates the true disease rate. For a true disease rate of 0.01, the false positive rate and the false negative rate are 51% and 0.1%, respectively, as shown on the second line of the classification table.

Example 42.6. Logistic Regression Diagnostics

In a controlled experiment to study the effect of the rate and volume of air inspired on a transient reflex vaso-constriction in the skin of the digits, 39 tests under various combinations of rate and volume of air inspired were obtained (Finney 1947). The end point of each test is whether or not vaso-constriction occurred. Pregibon (1981) uses this set of data to illustrate the diagnostic measures he proposes for detecting influential observations and to quantify their effects on various aspects of the maximum likelihood fit.

The vaso-constriction data are saved in the data set `vaso`:

```

data vaso;
  length Response $12;
  input Volume Rate Response @@;
  LogVolume=log(Volume);
  LogRate=log(Rate);
  datalines;

1.35 1.35 no_constrict   1.50 1.36 no_constrict
1.60 1.78 constrict      0.60 1.50 no_constrict
1.80 1.50 constrict      0.95 1.90 no_constrict
1.90 0.95 constrict      1.60 0.40 no_constrict
2.70 0.75 constrict      2.35 0.03 no_constrict
1.10 1.83 no_constrict   1.10 2.20 constrict
1.20 2.00 constrict      0.80 3.33 constrict
0.95 1.90 no_constrict   0.75 1.90 no_constrict
1.30 1.625 constrict
;

```

In the data set `vaso`, the variable `Response` represents the outcome of a test. The variable `LogVolume` represents the log of the volume of air intake, and the variable `LogRate` represents the log of the rate of air intake.

The following SAS statements invoke PROC LOGISTIC to fit a logistic regression model to the vaso-constriction data, where `Response` is the response variable, and `LogRate` and `LogVolume` are the explanatory variables. The `INFLUENCE` option and the `ILOTS` option are specified to display the regression diagnostics and the index plots.

```

ods html;
ods graphics on;

title 'Occurrence of Vaso-Constriction';
proc logistic data=vaso;
  model Response=LogRate LogVolume/influence iplots;
run;

ods graphics off;
ods html close;

```

Results of the model fit are shown in [Output 42.6.1](#). Both `LogRate` and `LogVolume` are statistically significant to the occurrence of vaso-constriction ($p = 0.0131$ and $p = 0.0055$, respectively). Their positive parameter estimates indicate that a higher

inspiration rate or a larger volume of air intake is likely to increase the probability of vaso-constriction.

The INFLUENCE option displays the values of the explanatory variables (LogRate and LogVolume) for each observation, a column for each diagnostic produced, and the *case number* which represents the sequence number of the observation (Output 42.6.2). Also produced (but not shown here) is a lineprinter plot where the vertical axis represents the case number and the horizontal axis represents the value of the diagnostic statistic.

The index plots produced by the IPLOTS option are essentially the same lineprinter plots as those produced by the INFLUENCE option with a 90-degree rotation and perhaps on a more refined scale. This version of the plots are not displayed here. The vertical axis of an index plot represents the value of the diagnostic and the horizontal axis represents the sequence (case number) of the observation. The index plots are useful for identification of extreme values.

Since the experimental ODS GRAPHICS statement is also specified, the lineprinter plots from the INFLUENCE and IPLOTS options are suppressed and graphical displays are produced as shown in Output 42.6.3 through Output 42.6.5. For general

information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the LOGISTIC procedure, see the “ODS Graphics” section on page 2388.

Output 42.6.3. Residuals, Hat Matrix, and CI Displacement C (Experimental)

Output 42.6.4. CI Displacement CBar, Change in Deviance and Pearson χ^2 , and DFBETAS for the Intercept (Experimental)

Output 42.6.5. DFBETAS for LogRate and LogVolume (Experimental)

The index plots of the Pearson residuals and the deviance residuals (Output 42.6.3) indicate that case 4 and case 18 are poorly accounted for by the model. The index plot of the diagonal elements of the hat matrix (Output 42.6.3) suggests that case 31 is an extreme point in the design space. The index plots of DFBETAS (Output 42.6.4 and Output 42.6.5) indicate that case 4 and case 18 are causing instability in all three parameter estimates. The other four index plots in Output 42.6.3 and Output 42.6.4 also point to these two cases as having a large impact on the coefficients and goodness of fit.

Example 42.7. ROC Curve, Customized Odds Ratios, Goodness-of-Fit Statistics, R-Square, and Confidence Limits

This example plots an ROC curve, estimates a customized odds ratio, produces the traditional goodness-of-fit analysis, displays the generalized R^2 measures for the fitted model, calculates the normal confidence intervals for the regression parameters, and produces an experimental display of the probability function and prediction curves for the fitted model. The data consist of three variables: n (number of subjects in a sample), $disease$ (number of diseased subjects in the sample), and age (age for the sample). A linear logistic regression model is used to study the effect of age on the probability of contracting the disease.

The SAS statements are as follows:

```

data Datal;
  input disease n age;
  datalines;
0 14 25
0 20 35
0 19 45
7 18 55
6 12 65
17 17 75
;

ods html;
ods graphics on;

proc logistic data=Datal;
  model disease/n=age / scale=none
    clparm=wald
    clodds=pl
    rsquare
    outroc=roc1;

  units age=10;
run;

ods graphics off;
ods html close;

```

The option `SCALE=NONE` is specified to produce the deviance and Pearson goodness-of-fit analysis without adjusting for overdispersion. The `RSQUARE` option is specified to produce generalized R^2 measures of the fitted model. The `CLPARG=WALD` option is specified to produce the Wald confidence intervals for the regression parameters. The `UNITS` statement is specified to produce customized odds ratio estimates for a change of 10 years in the `age` variable, and the `CLODDS=PL` option is specified to produce profile likelihood confidence limits for the odds ratio. The `OUTROC=` option outputs the data for the ROC curve to the SAS data set, `roc1`.

Results are shown in [Output 42.7.1](#) and [Output 42.7.2](#).

Output 42.7.1. Deviance and Pearson Goodness-of-Fit Analysis

Since the experimental ODS GRAPHICS statement is specified, a graphical display of the ROC curve is produced as shown in [Output 42.7.3](#). For general information about ODS graphics, see [Chapter 15, "Statistical Graphics Using ODS."](#) For specific information about the graphics available in the LOGISTIC procedure, see the "ODS Graphics" section on page 2388.

Output 42.7.3. Receiver Operating Characteristic Curve (Experimental)

Note that the area under the ROC curve is given by the statistic c in the “Association of Predicted Probabilities and Observed Responses” table. In this example, the area under the ROC curve is 0.953.

The ROC curve may also be displayed with the GLOT procedure by using the following code.

```
symbol1 i=join v=none c=black;
proc gplot data=roc1;
  title 'ROC Curve';
  plot _sensit*_lmspec=1 / vaxis=0 to 1 by .1 cframe=white;
run;
```

Because there is only one continuous covariate, if the experimental ODS GRAPHICS statement and the experimental GRAPHICS option ESTPROB are specified, then a graphical display of the estimated probability curve with bounding 95% prediction limits is displayed as shown in [Output 42.7.4](#).

```
ods html;  
ods graphics on;  
  
proc logistic data=Data1;  
  model disease/n=age / scale=none  
                        clparm=wald  
                        clodds=pl  
                        rsquare  
                        outroc=roc1;  
  
  units age=10;  
  graphics estprob;  
run;  
  
ods graphics off;  
ods html close;
```

Output 42.7.4. Estimated Probability and 95% Prediction Limits (Experimental)

Example 42.8. Goodness-of-Fit Tests and Subpopulations

A study is done to investigate the effects of two binary factors, **A** and **B**, on a binary response, **Y**. Subjects are randomly selected from subpopulations defined by the four possible combinations of levels of **A** and **B**. The number of subjects responding with each level of **Y** is recorded and entered into data set **A**.

```
data a;
  do A=0,1;
    do B=0,1;
      do Y=1,2;
        input F @@;
        output;
      end;
    end;
  end;
  datalines;
23 63 31 70 67 100 70 104
;
```

A full model is fit to examine the main effects of **A** and **B** as well as the interaction effect of **A** and **B**.

```
proc logistic data=a;
  freq F;
  model Y=A B A*B;
run;
```

Output 42.8.1. Full Model Fit

```

Pearson and Deviance goodness-of-fit tests cannot be obtained for this model since a full model containing four parameters is fit, leaving no residual degrees of freedom. For a binary response model, the goodness-of-fit tests have $m - q$ degrees of freedom, where m is the number of subpopulations and q is the number of model parameters. In the preceding model, $m = q = 4$, resulting in zero degrees of freedom for the tests.

Results of the model fit are shown in [Output 42.8.1](#). Notice that neither the A*B interaction nor the B main effect is significant. If a reduced model containing only the A effect is fit, two degrees of freedom become available for testing goodness of fit. Specifying the `SCALE=NONE` option requests the Pearson and deviance statistics. With *single-trial* syntax, the `AGGREGATE=` option is needed to define the subpopulations in the study. Specifying `AGGREGATE=(A B)` creates subpopulations of the four combinations of levels of A and B. Although the B effect is being dropped from the model, it is still needed to define the original subpopulations in the study. If `AGGREGATE=(A)` were specified, only two subpopulations would be created from the levels of A, resulting in $m = q = 2$ and zero degrees of freedom for the tests.

```
proc logistic data=a;
  freq F;
  model Y=A / scale=none aggregate=(A B);
run;
```

The goodness-of-fit tests ([Output 42.8.2](#)) show that dropping the **B** main effect and the **A*B** interaction simultaneously does not result in significant lack of fit of the model. The tests' large *p*-values indicate insufficient evidence for rejecting the null hypothesis that the model fits.

Example 42.9. Overdispersion

In a seed germination test, seeds of two cultivars were planted in pots of two soil conditions. The following SAS statements create the data set `seeds`, which contains the observed proportion of seeds that germinated for various combinations of cultivar and soil condition. Variable `n` represents the number of seeds planted in a pot, and variable `r` represents the number germinated. The indicator variables `cult` and `soil` represent the cultivar and soil condition, respectively.

```

data seeds;
  input pot n r cult soil;
  datalines;
1 16 8 0 0
2 51 26 0 0
3 45 23 0 0
4 39 10 0 0

;

```

PROC LOGISTIC is used to fit a logit model to the data, with cult, soil, and cult × soil interaction as explanatory variables. The option `SCALE=NONE` is specified to display goodness-of-fit statistics.

```

proc logistic data=seeds;
  model r/n=cult soil cult*soil/scale=none;
  title 'Full Model With SCALE=NONE';
run;

```

Output 42.9.1. Results of the Model Fit for the Two-Way Layout

Full Model With SCALE=NONE					
The LOGISTIC Procedure					
Deviance and Pearson Goodness-of-Fit Statistics					
Criterion	Value	DF	Value/DF	Pr > ChiSq	
Deviance	68.3465	16	4.2717	<.0001

Test	Chi-Square	DF	Pr > ChiSq		
Likelihood Ratio	49.8488	3	<.0001		
Score	49.1682	3	<.0001		
Wald	47.7623	3	<.0001		
Analysis of Maximum Likelihood Estimates					
Parameter	DF	Estimate	Standard Error	Wald Chi-Square	Pr > ChiSq
Intercept	1	-0.3788	0.1489	6.4730	0.0110
cult	1	-0.2956	0.2020	2.1412	0.1434
soil	1	0.9781	0.2128	21.1234	<.0001
cult*soil	1	-0.1239	0.2790	0.1973	0.6569

Results of fitting the full factorial model are shown in [Output 42.9.1](#). Both Pearson χ^2 and deviance are highly significant ($p < 0.0001$), suggesting that the model does not fit well. If the link function and the model specification are correct and if there are no outliers, then the lack of fit may be due to overdispersion. Without adjusting for the overdispersion, the standard errors are likely to be underestimated, causing the Wald tests to be too sensitive. In PROC LOGISTIC, there are three SCALE= options to accommodate overdispersion. With unequal sample sizes for the observations, SCALE=WILLIAMS is preferred. The Williams model estimates a scale parameter ϕ by equating the value of Pearson χ^2 for the full model to its approximate expected value. The full model considered here is the model with cultivar, soil condition, and their interaction. Using a full model reduces the risk of contaminating ϕ with lack of fit due to incorrect model specification.

```
proc logistic data=seeds;  
  model r/n=cult soil cult*soil / scale=williams;  
  title 'Full Model With SCALE=WILLIAMS';  
run;
```

Output 42.9.2. Williams' Model for Overdispersion

```

Full Model With SCALE=WILLIAMS

Percent Discordant		24.8	Gamma	0.343	
Percent Tied		24.6	Tau-a	0.129	
Pairs		204953	c	0.629	

Results using Williams' method are shown in [Output 42.9.2](#). The estimate of ϕ is 0.075941 and is given in the formula for the Weight Variable at the beginning of the displayed output. Since neither `cult` nor `cult × soil` is statistically significant ($p = 0.5290$ and $p = 0.9274$, respectively), a reduced model that contains only the soil condition factor is fitted, with the observations weighted by $1/(1+0.075941(N-1))$. This can be done conveniently in PROC LOGISTIC by including the scale estimate in the SCALE=WILLIAMS option as follows:

```
proc logistic data=seeds;
  model r/n=soil / scale=williams(0.075941);
  title 'Reduced Model With SCALE=WILLIAMS(0.075941)';
run;
```

Output 42.9.3. Reduced Model with Overdispersion Controlled

Reduced Model With SCALE=WILLIAMS(0.075941)					
The LOGISTIC Procedure					
Analysis of Maximum Likelihood Estimates					
Parameter	DF	Estimate	Standard Error	Wald Chi-Square	Pr > ChiSq
Intercept	1	-0.5249	0.2076	6.3949	0.0114
soil	1	0.7910	0.2902	7.4284	0.0064

Results of the reduced model fit are shown in [Output 42.9.3](#). Soil condition remains a significant factor ($p = 0.0064$) for the seed germination.

Example 42.10. Conditional Logistic Regression for Matched Pairs Data

In matched pairs, or *case-control*, studies, conditional logistic regression is used to investigate the relationship between an outcome of being an event (case) or a nonevent (control) and a set of prognostic factors.

The data in this example are a subset of the data from the Los Angeles Study of the Endometrial Cancer Data in Breslow and Day (1980). There are 63 matched pairs, each consisting of a case of endometrial cancer (*Outcome*=1) and a control (*Outcome*=0). The case and corresponding control have the same ID. Two prognostic factors are included: *Gall* (an indicator variable for gall bladder disease) and *Hyper* (an indicator variable for hypertension). The goal of the case-control analysis is to determine the relative risk for gall bladder disease, controlling for the effect of hypertension.

```

data Data1;
  do ID=1 to 63;
    do Outcome= 1 to 0 by -1;
      input Gall Hyper @@;
      output;
    end;
  end;
datalines;
0 0 0 0 0 0 0 0 0 1 0 1 0 0 1 0 1 0 0 1 0 0 1

1 0 1 0    0 1 0 0    1 0 0 0
;

```

There are several ways to approach this problem with PROC LOGISTIC.

- Specify the **STRATA** statement to perform a conditional logistic regression.
- Specify **EXACT** and **STRATA** statements to perform an exact conditional logistic regression on the original data set, if you believe the data set is too small or too sparse for the usual asymptotics to hold.
- Transform each matched pair into a single observation then specify a PROC LOGISTIC statement on this transformed data without a STRATA statement; this also performs a conditional logistic regression and produces essentially the same results.
- Specify an **EXACT** statement on the transformed data.

SAS statements and selected results for these four approaches are given in the remainder of this example.

Conditional Analysis Using the STRATA Statement

In the following SAS statements, PROC LOGISTIC is invoked with the ID variable declared in the **STRATA** statement to obtain the conditional logistic model estimates. Two models are fitted. The first model contains Gall as the only predictor variable, and the second model contains both Gall and Hyper as predictor variables. Because the option **CLODDS=Wald** is specified, PROC LOGISTIC computes a 95% Wald confidence interval for the odds ratio for each predictor variable.

```

proc logistic data=Data1;
  strata ID;
  model outcome(event='1')=Gall / clodds=Wald;
run;

proc logistic data=Data1;
  strata ID;
  model outcome(event='1')=Gall Hyper /clodds=Wald;
run;

```

Results from the two conditional logistic analyses are shown in [Output 42.10.1](#) and [Output 42.10.2](#). Note that there is only one response level listed in the “Response Profile” tables, and there is no intercept term in the “Analysis of Maximum Likelihood Estimates” tables.

Output 42.10.1. Conditional Logistic Regression (Gall as Risk Factor)

Output 42.10.2. (continued)

Conditional Analysis					
Convergence criterion (GCONV=1E-8) satisfied.					
Model Fit Statistics					
Criterion	Without Covariates		With Covariates		
AIC	87.337		86.788		
SC	87.337		92.460		
-2 Log L	87.337		82.788		
Testing Global Null Hypothesis: BETA=0					
Test	Chi-Square	DF	Pr > ChiSq		
Likelihood Ratio	4.5487	2	0.1029		
Score	4.3620	2	0.1129		
Wald	4.0060	2	0.1349		
Analysis of Maximum Likelihood Estimates					
Parameter	DF	Estimate	Standard Error	Wald Chi-Square	Pr > ChiSq
Gall	1	0.9704	0.5307	3.3432	0.0675
Hyper	1	0.3481	0.3770	0.8526	0.3558
Wald Confidence Interval for Adjusted Odds Ratios					
Effect	Unit	Estimate	95% Confidence Limits		
Gall	1.0000	2.639	0.933	7.468	
Hyper	1.0000	1.416	0.677	2.965	

In the first model, where **Gall** is the only predictor variable ([Output 42.10.1](#)), the odds ratio estimate for **Gall** is 2.60, which is marginally significant ($p=0.0694$) and which is an estimate of the relative risk for gall bladder disease. A 95% confidence interval for this relative risk is (0.927, 7.293).

In the second model, where both **Gall** and **Hyper** are present ([Output 42.10.2](#)), the odds ratio estimate for **Gall** is 2.639, which is an estimate of the relative risk for gall bladder disease adjusted for the effects of hypertension. A 95% confidence interval for this adjusted relative risk is (0.933, 7.468). Note that the adjusted values (accounting for hypertension) for gall bladder disease are not very different from the unadjusted values (ignoring hypertension). This is not surprising since the prognostic factor **Hyper** is highly statistically insignificant. The 95% Wald confidence interval for the odds ratio for **Hyper** is (0.677, 2.965), which contains unity with a p -value greater than 0.3.

Exact Analysis Using the STRATA Statement

When you believe there is not enough data or that the data are too sparse, you can perform a stratified exact conditional logistic regression. The following statements perform stratified exact conditional logistic regressions on the original data set by specifying both the **STRATA** and **EXACT** statements.

```
proc logistic data=Data1 exactonly;
  strata ID;
  model outcome(event='1')=Gall;
  exact Gall / estimate=both;
run;

proc logistic data=Data1 exactonly;
  strata ID;
  model outcome(event='1')=Gall Hyper;
  exact Gall Hyper / jointly estimate=both;
run;
```

Output 42.10.3. Exact Conditional Logistic Regression (Gall as Risk Factor)

The LOGISTIC Procedure				
Exact Conditional Analysis				
Conditional Exact Tests				
Effect	Test	Statistic	--- p-Value ---	
			Exact	Mid
Gall	Score	3.5556	0.0963	0.0799
	Probability	0.0327	0.0963	0.0799
Exact Parameter Estimates				
Parameter	Estimate	95% Confidence Limits		p-Value
Gall	0.9555	-0.1394	2.2316	0.0963
Exact Odds Ratios				
Parameter	Estimate	95% Confidence Limits		p-Value
Gall	2.600	0.870	9.315	0.0963

Output 42.10.4. Exact Conditional Logistic Regression (Gall and Hyper as Risk Factors)

The LOGISTIC Procedure				
Exact Conditional Analysis				
Conditional Exact Tests				
Effect	Test	Statistic	--- p-Value ---	
			Exact	Mid
Joint	Score	4.3620	0.1150	0.1134
	Probability	0.00316	0.1150	0.1134
Exact Parameter Estimates				
Parameter	Estimate	95% Confidence Limits		p-Value
Gall	0.9530	-0.1407	2.2292	0.0969
Hyper	0.3425	-0.4486	1.1657	0.4622
Exact Odds Ratios				
Parameter	Estimate	95% Confidence Limits		p-Value
Gall	2.593	0.869	9.293	0.0969
Hyper	1.408	0.639	3.208	0.4622

Note that the score statistics in the “Conditional Exact Tests” tables in [Output 42.10.3](#) and [Output 42.10.4](#) are identical to the score statistics in the conditional analyses in [Output 42.10.1](#) and [Output 42.10.2](#), respectively. The exact odds ratio confidence intervals are much wider than their conditional analysis counterparts, but the parameter estimates are similar. The exact analyses confirm the marginal significance of Gall and the insignificance of Hyper as predictor variables.

Conditional Analysis Using Transformed Data

When each matched set consists of one event and one nonevent, the conditional likelihood is given by

$$\prod_i (1 + \exp(-\beta'(\mathbf{x}_{i1} - \mathbf{x}_{i0})))^{-1}$$

where \mathbf{x}_{i1} and \mathbf{x}_{i0} are vectors representing the prognostic factors for the event and nonevent, respectively, of the i th matched set. This likelihood is identical to the likelihood of fitting a logistic regression model to a set of data with constant response, where the model contains no intercept term and has explanatory variables given by $\mathbf{d}_i = \mathbf{x}_{i1} - \mathbf{x}_{i0}$ (Breslow 1982).

To apply this method, each matched pair is transformed into a single observation, where the variables `Gall` and `Hyper` contain the differences between the corresponding values for the case and the control (case – control). The variable `Outcome`, which will be used as the response variable in the logistic regression model, is given a constant value of 0 (which is the `Outcome` value for the control, although any constant, numeric or character, will do).

```
data Data2;
  set Data1;
  drop id1 gall1 hyper1;
  retain id1 gall1 hyper1 0;
  if (ID = id1) then do;
    Gall=gall1-Gall; Hyper=hyper1-Hyper;
    output;
  end;
  else do;
    id1=ID; gall1=Gall; hyper1=Hyper;
  end;
run;
```

Note that there are 63 observations in the data set, one for each matched pair. The variable `Outcome` has a constant value of 0.

In the following SAS statements, PROC LOGISTIC is invoked with the `NOINT` option to obtain the conditional logistic model estimates. Because the option `CLODDS=PL` is specified, PROC LOGISTIC computes a 95% profile likelihood confidence interval for the odds ratio for each predictor variable; note that profile likelihood confidence intervals are not currently available when a STRATA statement is specified.

```
proc logistic data=Data2;
  model outcome=Gall / noint clodds=PL;
run;

proc logistic data=Data2;
  model outcome=Gall Hyper / noint clodds=PL;
run;
```

The results are not displayed here.

Exact Analysis Using Transformed Data

Sometimes the original data set in a matched-pairs study may be too large for the exact methods to handle. In such cases it may be possible to use the transformed data set. The following code performs exact conditional logistic regressions on the transformed data set. The results are not displayed here.

```

proc logistic data=Data2 exactonly;
  model outcome=Gall / noint;
  exact Gall / estimate=both;
run;
proc logistic data=Data2 exactonly;
  model outcome=Gall Hyper / noint;
  exact Gall Hyper / jointonly estimate=both;
run;

```

Example 42.11. Complementary Log-Log Model for Infection Rates

Antibodies produced in response to an infectious disease like malaria remain in the body after the individual has recovered from the disease. A serological test detects the presence or absence of such antibodies. An individual with such antibodies is termed seropositive. In areas where the disease is endemic, the inhabitants are at fairly constant risk of infection. The probability of an individual never having been infected in Y years is $\exp(-\mu Y)$, where μ is the mean number of infections per year (refer to the appendix of Draper, Voller, and Carpenter 1972). Rather than estimating the unknown μ , it is of interest to epidemiologists to estimate the probability of a person living in the area being infected in one year. This infection rate γ is given by

$$\gamma = 1 - e^{-\mu}$$

The following statements create the data set `sero`, which contains the results of a serological survey of malarial infection. Individuals of nine age groups (`Group`) were tested. Variable `A` represents the midpoint of the age range for each age group. Variable `N` represents the number of individuals tested in each age group, and variable `R` represents the number of individuals that are seropositive.

```

data sero;
  input Group A N R;
  X=log(A);
  label X='Log of Midpoint of Age Range';
  datalines;
1  1.5  123  8
2  4.0  132  6
3  7.5  182 18
4 12.5  140 14
5 17.5  138 20
6 25.0  161 39
7 35.0  133 19
8 47.0   92 25
9 60.0   74 44
;

```

For the i th group with age midpoint A_i , the probability of being seropositive is $p_i = 1 - \exp(-\mu A_i)$. It follows that

$$\log(-\log(1 - p_i)) = \log(\mu) + \log(A_i)$$

By fitting a binomial model with a complementary log-log link function and by using $X=\log(A)$ as an offset term, you can estimate $\beta_0 = \log(\mu)$ as an intercept parameter. The following SAS statements invoke PROC LOGISTIC to compute the maximum likelihood estimate of β_0 . The **LINK=CLOGLOG** option is specified to request the complementary log-log link function. Also specified is the **CLPARM=PL** option, which requests the profile likelihood confidence limits for β_0 .

```
proc logistic data=sero;
  model R/N= / offset=X
          link=cloglog
          clparm=pl

Results of fitting this constant risk model are shown in [Output 42.11.1](#). The maximum likelihood estimate of $\beta_0 = \log(\mu)$ and its estimated standard error are $\hat{\beta}_0 = -4.6605$ and $\hat{\sigma}_{\hat{\beta}_0} = 0.0725$, respectively. The infection rate is estimated as

$$\hat{\gamma} = 1 - e^{-\hat{\mu}} = 1 - e^{-e^{\hat{\beta}_0}} = 1 - e^{-e^{-4.6605}} = 0.00942$$

The 95% confidence interval for γ , obtained by back-transforming the 95% confidence interval for β_0 , is (0.0082, 0.0108); that is, there is a 95% chance that, in repeated sampling, the interval of 8 to 11 infections per thousand individuals contains the true infection rate.

The goodness of fit statistics for the constant risk model are statistically significant ($p < 0.0001$), indicating that the assumption of constant risk of infection is not correct. You can fit a more extensive model by allowing a separate risk of infection for each age group. Suppose μ_i is the mean number of infections per year for the i th age group. The probability of seropositive for the i th group with age midpoint A_i is $p_i = 1 - \exp(-\mu_i A_i)$, so that

$$\log(-\log(1 - p_i)) = \log(\mu_i) + \log(A_i)$$

In the following statements, a complementary log-log model is fit containing Group as an explanatory classification variable with the GLM coding (so that a dummy variable is created for each age group), no intercept term, and X=log(A) as an offset

term. The ODS OUTPUT statement saves the estimates and their 95% profile likelihood confidence limits to ClparmPL data set. Note that $\log(\mu_i)$ is the regression parameter associated with $\text{Group}=i$.

```

Group 9	-4.1965	-4.5164	-3.9037

Results of fitting the model with a separate risk of infection are shown in [Output 42.11.2](#). For the first age group ($\text{Group}=1$), the point estimate of $\log(\mu_1)$ is -3.1048 , which transforms into an infection rate of $1 - \exp(-\exp(-3.1048)) = 0.0438$. A 95% confidence interval for this infection rate is obtained by transforming the 95% confidence interval for $\log(\mu_1)$. For the first age group, the lower and upper confidence limits are $1 - \exp(-\exp(-3.8880)) = 0.0203$ and $1 - \exp(-\exp(-2.4833)) = 0.0801$, respectively; that is, there is a 95% chance that, in repeated sampling, the interval of 20 to 80 infections per thousand individuals contains the true infection rate.

The following statements perform this transformation on the estimates and confidence limits saved in the ClparmPL data set; the resulting estimated infection rates in one year's time for each age group are displayed in Table 42.5. Note that the infection rate for the first age group is high compared to the other age groups.

```
data ClparmPL;
  set ClparmPL;
  Estimate=round( 1000*( 1-exp(-exp(Estimate)) ) );
  LowerCL =round( 1000*( 1-exp(-exp(LowerCL )) ) );
  UpperCL =round( 1000*( 1-exp(-exp(UpperCL )) ) );
run;
```

Example 42.12. Complementary Log-Log Model for Interval-Censored Survival Times

Often survival times are not observed more precisely than the interval (for instance, a day) within which the event occurred. Survival data of this form are known as grouped or interval-censored data. A discrete analogue of the continuous proportional hazards model (Prentice and Gloeckler 1978; Allison 1982) is used to investigate the relationship between these survival times and a set of explanatory variables.

Suppose T_i is the discrete survival time variable of the i th subject with covariates \mathbf{x}_i . The discrete-time hazard rate λ_{it} is defined as

$$\lambda_{it} = \Pr(T_i = t \mid T_i \geq t, \mathbf{x}_i), \quad t = 1, 2, \dots$$

Using elementary properties of conditional probabilities, it can be shown that

$$\Pr(T_i = t) = \lambda_{it} \prod_{j=1}^{t-1} (1 - \lambda_{ij}) \quad \text{and} \quad \Pr(T_i > t) = \prod_{j=1}^t (1 - \lambda_{ij})$$

Suppose t_i is the observed survival time of the i th subject. Suppose $\delta_i = 1$ if $T_i = t_i$ is an event time and 0 otherwise. The likelihood for the grouped survival data is given by

$$\begin{aligned} L &= \prod_i [\Pr(T_i = t_i)]^{\delta_i} [\Pr(T_i > t_i)]^{1-\delta_i} \\ &= \prod_i \left(\frac{\lambda_{it_i}}{1 - \lambda_{it_i}} \right)^{\delta_i} \prod_{j=1}^{t_i} (1 - \lambda_{ij}) \\ &= \prod_i \prod_{j=1}^{t_i} \left(\frac{\lambda_{ij}}{1 - \lambda_{ij}} \right)^{y_{ij}} (1 - \lambda_{ij}) \end{aligned}$$

where $y_{ij} = 1$ if the i th subject experienced an event at time $T_i = j$ and 0 otherwise.

Note that the likelihood L for the grouped survival data is the same as the likelihood of a binary response model with event probabilities λ_{ij} . If the data are generated by a continuous-time proportional hazards model, Prentice and Gloeckler (1978) have shown that

$$\lambda_{ij} = 1 - \exp(-\exp(\alpha_j + \beta' \mathbf{x}_i))$$

where the coefficient vector β is identical to that of the continuous-time proportional hazards model, and α_j is a constant related to the conditional survival probability in the interval defined by $T_i = j$ at $\mathbf{x}_i = \mathbf{0}$. The grouped data survival model is therefore equivalent to the binary response model with complementary log-log link function. To fit the grouped survival model using PROC LOGISTIC, you must treat each discrete time unit for each subject as a separate observation. For each of these observations, the response is dichotomous, corresponding to whether or not the subject died in the time unit.

Consider a study of the effect of insecticide on flour-beetles. Four different concentrations of an insecticide were sprayed on separate groups of flour-beetles. The numbers of male and female flour-beetles dying in successive intervals were saved in the data set `beetles`.

```

The data set `beetles` contains four variables: `time`, `sex`, `conc`, and `freq`. `time` represents the interval death time; for example, `time=2` is the interval between day 1 and day 2. Insects surviving the duration (13 days) of the experiment are given a `time` value of 14. The variable `sex` represents the sex of the insects (1=male, 2=female), `conc` represents the concentration of the insecticide (mg/cm^2), and `freq` represents the frequency of the observations.

To use PROC LOGISTIC with the grouped survival data, you must expand the data so that each beetle has a separate record for each day of survival. A beetle that died in the third day (`time=3`) would contribute three observations to the analysis, one for each day it was alive at the beginning of the day. A beetle that survives the 13-day duration of the experiment (`time=14`) would contribute 13 observations.

A new data set `days` that contains the beetle-day observations is created from the data set `beetles`. In addition to the variables `sex`, `conc` and `freq`, the data set contains an outcome variable `y` and 13 indicator variables `day1`, `day2`, . . . , `day13`. `y` has a value of 1 if the observation corresponds to the day that the beetle died and has a value of 0 otherwise. An observation for the first day will have a value of 1 for `day1` and a value of 0 for `day2–day13`; an observation for the second day will have a value of 1 for `day2` and a value of 0 for `day1` and `day2–day13`. For instance, [Output 42.12.1](#) shows an observation in the `beetles` data set with `time=3`, and [Output 42.12.2](#) shows the corresponding beetle-day observations in the data set `days`.

```

data days;
  retain day1-day13 0;
  array dd[13] day1-day13;
  set beetles;
  if time = 14 then do day=1 to 13;
    y=0; dd[day]=1;
    output;
    dd[day]=0;
  end;
  else do day=1 to time;
    if day=time then y=1;
    else y=0;
    dd[day]=1;
    output;
    dd[day]=0;
  end;
end;

```

The following SAS statements invoke PROC LOGISTIC to fit a complementary log-log model for binary data with response variable Y and explanatory variables day1–day13, sex, and conc. Specifying the **EVENT=** option ensures that the event (y=1) probability is modeled. The coefficients of day1–day13 can be used to estimate the baseline survival function. The **NOINT** option is specified to prevent any redundancy in estimating the coefficients of day1–day13. The Newton-Raphson algorithm is used for the maximum likelihood estimation of the parameters.

```

proc logistic data=days outest=est1;

day10	1	-5.1350	0.7315	49.2805	<.0001
day11	1	-5.1131	0.7313	48.8834	<.0001
day12	1	-5.1029	0.7313	48.6920	<.0001
day13	1	-5.0951	0.7313	48.5467	<.0001
sex	1	-0.5651	0.1141	24.5477	<.0001
conc	1	3.0918	0.2288	182.5665	<.0001

Results of the model fit are given in [Output 42.12.3](#). Both `sex` and `conc` are statistically significant for the survival of beetles sprayed by the insecticide. Female beetles are more resilient to the chemical than male beetles, and increased concentration increases the effectiveness of the insecticide.

The coefficients of `day1`–`day13` are the maximum likelihood estimates of $\alpha_1, \dots, \alpha_{13}$, respectively. The baseline survivor function $S_0(t)$ is estimated by

$$\hat{S}_0(t) = \widehat{\Pr}(T > t) = \prod_{j \leq t} \exp(-\exp(\hat{\alpha}_j))$$

and the survivor function for a given covariate pattern (`sex`= x_1 and `conc`= x_2) is estimated by

$$y\hat{S}(t) = [\hat{S}_0(t)]^{\exp(-0.5651x_1 + 3.0918x_2)}$$

The following statements compute the survivor curves for male and female flour-beetles exposed to the insecticide of concentrations 0.20 mg/cm² and 0.80 mg/cm². The Gplot procedure in SAS/GRAPH software is used to plot the survival curves. Instead of plotting them as step functions, the SPLINE option is used to smooth the curves. These smoothed survival curves are displayed in [Output 42.12.4](#).

```

legend1 label=none frame cframe=white cborder=black position=center
value=(justify=center);
run;
axis1 label=(angle=90 'Survival Function');
proc gplot data=one;
plot (s_m20 s_f20 s_m80 s_f80) * day
/ overlay legend=legend1 vaxis=axis1;
symbol1 v=circle i=spline c=black height=.8;
symbol2 v=diamond i=spline c=black height=.8;
symbol3 v=triangle i=spline c=black height=.8;
symbol4 v=square i=spline c=black height=.8;
run;

```

The probability of survival is displayed on the vertical axis. Notice that most of the insecticide effect occurs by day 6 for both the high and low concentrations.

Output 42.12.4. Predicted Survival at Concentrations of 0.20 and 0.80 mg/cm²

Example 42.13. Scoring Data Sets with the SCORE Statement

This example first illustrates the syntax used for scoring data sets, then uses a previously scored data set to score a new data set. A generalized logit model is fit to the remote-sensing data set used in Example 25.4 on page 1231 of Chapter 25, “The DISCRIM Procedure,” to illustrate discrimination and classification methods. The response variable is Crop and the prognostic factors are x1 through x4.

```
data Crops;
  length Crop $ 10;
  infile datalines truncover;
  input Crop $ @@;
  do i=1 to 3;
    input x1-x4 @@;
    if (x1 ^= .) then output;

```

You can specify a **SCORE** statement to score the Crops data using the fitted model. The data together with the predicted values are saved into the data set Score1.

```
proc logistic data=Crops;
  model Crop=x1-x4 / link=glogit;
  score out=Score1;
run;
```

The **OUTMODEL=** option saves the fitted model information in a data set. In the following statements, the model is again fit, the data and the predicted values are saved into the data set Score2, and the model information is saved in the permanent SAS data set sasuser.CropModel.

```
proc logistic data=Crops outmodel=sasuser.CropModel;
  model Crop=x1-x4 / link=glogit;
  score data=Crops out=Score2;
run;
```

To score data without refitting the model, specify the `INMODEL=` option to identify a previously saved SAS data set of model information. In the following statements, the model is read from the `sasuser.CropModel` data set, and the data and the predicted values are saved into the data set `Score3`.

```
proc logistic inmodel=sasuser.CropModel;
  score data=Crops out=Score3;
run;
```

To set prior probabilities on the responses, specify the `PRIOR=` option to identify a SAS data set containing the response levels and their priors. In the following statements, the `Prior` data set contains the values of the response variable (because this example uses single-trial `MODEL` syntax) and a `_PRIOR_` variable containing values proportional to the default priors. The model is fit, then the data and the predicted values are saved into the data set `Score4`.

```
data Prior;
  input Crop $ 1-10 _PRIOR_;
  datalines;
Clover      11
Corn        7
Cotton      6
Soybeans    6
Sugarbeets  6
;

proc logistic inmodel=sasuser.CropModel;
  score data=Crops prior=prior out=Score4;
run;
```

The data sets `Score1`, `Score2`, `Score3`, and `Score4` are identical.

The following statements display the results of scoring the `Crops` data set in [Output 42.13.1](#).

```
proc freq data=Score1;
  table F_Crop*I_Crop / nocol nocum nopercent;
run;
```

Output 42.13.1. Classification of Data used for Scoring

Chapter 43

The MDS Procedure

Overview

Multidimensional scaling (MDS) is a class of methods that estimates the coordinates of a set of objects in a space of specified dimensionality that come from data measuring the distances between pairs of objects. A variety of models can be used that include different ways of computing distances and various functions relating the distances to the actual data. The MDS procedure fits two- and three-way, metric and nonmetric multidimensional scaling models. PROC MDS shares many of the features of the ALSCAL procedure (Young, Lewyckyj, and Takane 1986; Young 1982), as well as some features of the MLSCALE procedure (Ramsay 1986). Both PROC ALSCAL and PROC MLSCALE are described in the *SUGI Supplemental Library User's Guide, Version 5 Edition*.

The data for the MDS procedure consist of one or more square symmetric or asymmetric matrices of similarities or dissimilarities between *objects* or *stimuli* (Kruskal and Wish 1978, pp. 7–11). Such data are also called *proximity* data. In psychometric applications, each matrix typically corresponds to a *subject*, and models that fit different parameters for each subject are called *individual difference* models.

Missing values are allowed. In particular, if the data are all missing except within some off-diagonal rectangle, the analysis is called *unfolding*. There are, however, many difficulties intrinsic to unfolding models (Heiser, 1981). PROC MDS does not perform external unfolding; for analyses requiring external unfolding, use the TRANSREG procedure instead.

The MDS procedure estimates the following parameters by nonlinear least squares:

configuration	the coordinates of each object in a Euclidean (Kruskal and Wish 1978, pp. 17–19) or weighted Euclidean space (Kruskal and Wish 1978, pp. 61–63) of one or more dimensions
dimension coefficients	for each data matrix, the coefficients that multiply each coordinate of the <i>common</i> or <i>group</i> weighted Euclidean space to yield the <i>individual</i> unweighted Euclidean space. These coefficients are the square roots of the <i>subject weights</i> (Kruskal and Wish 1978, pp. 61–63). A plot of the dimension coefficients is directly interpretable in that it shows how a unit square in the group space is transformed to a rectangle in each individual space. A plot of subject weights has no such simple interpretation. The weighted Euclidean model is related to the INDSCAL model (Carroll and Chang 1970).

transformation parameters intercept, slope, or exponent in a linear, affine, or power transformation relating the distances to the data (Kruskal and Wish 1978, pp. 19–22). For a nonmetric analysis, monotone transformations involving no explicit parameters are used (Kruskal and Wish 1978, pp. 22–25). For a discussion of metric versus nonmetric transformations, refer to Kruskal and Wish (1978, pp. 76–78).

Depending on the LEVEL= option, PROC MDS fits either a regression model of the form

$$fit(datum) = fit(trans(distance)) + error$$

or a measurement model of the form

$$fit(trans(datum)) = fit(distance) + error$$

where

<i>fit</i>	is a predetermined power or logarithmic transformation specified by the FIT= option.
<i>trans</i>	is an estimated (“optimal”) linear, affine, power, or monotone transformation specified by the LEVEL= option.
<i>datum</i>	is a measure of the similarity or dissimilarity of two objects or stimuli.
<i>distance</i>	is a distance computed from the estimated coordinates of the two objects and estimated dimension coefficients in a space of one or more dimensions. If there are no dimension coefficients (COEF=IDENTITY), this is an unweighted Euclidean distance. If dimension coefficients are used (COEF=DIAGONAL), this is a weighted Euclidean distance where the weights are the squares of the dimension coefficients; alternatively, you can multiply each dimension by its coefficient and compute an unweighted Euclidean distance.
<i>error</i>	is an error term assumed to have an approximately normal distribution and to be independently and identically distributed for all data. Under these assumptions, least-squares estimation is statistically appropriate.

For an introduction to multidimensional scaling, refer to Kruskal and Wish (1978) and Arabie, Carroll, and DeSarbo (1987). A more advanced treatment is given by Young (1987). Many practical issues of data collection and analysis are discussed in Schiffman, Reynolds, and Young (1981). The fundamentals of psychological measurement, including both unidimensional and multidimensional scaling, are expounded by Torgerson (1958). Nonlinear least-squares estimation of PROC MDS models is discussed in Null and Sarle (1982).

Getting Started

The simplest application of PROC MDS is to reconstruct a map from a table of distances between points on the map (Kruskal and Wish 1978, pp. 7–9). For example, the following DATA step reads a table of flying mileages between ten U.S. cities:

```
data city;
  title 'Analysis of Flying Mileages Between Ten U.S. Cities';
  input (atlanta chicago denver houston losangeles
        miami newyork sanfran seattle washdc) (5.)
        @56 city $15.;
  datalines;
    0 Atlanta
  587 0 Chicago
 1212 920 0 Denver
  701 940 879 0 Houston
 1936 1745 831 1374 0 Los Angeles
  604 1188 1726 968 2339 0 Miami
  748 713 1631 1420 2451 1092 0 New York
 2139 1858 949 1645 347 2594 2571 0 San Francisco
 2182 1737 1021 1891 959 2734 2408 678 0 Seattle
  543 597 1494 1220 2300 923 205 2442 2329 0 Washington D.C.
;
```

Since the flying mileages are very good approximations to Euclidean distance, no transformation is needed to convert distances from the model to data. The analysis can therefore be done at the absolute level of measurement, as displayed in the following PROC MDS step (LEVEL=ABSOLUTE). An output data set containing the estimated configuration (coordinates on the map) is created with the OUT= option and then used to display the map using the %PLOTIT macro. The ID statement copies the names of the cities to the OUT= data set so that they can be used on the plot. The following statements produce [Figure 43.1](#):

```
proc mds data=city level=absolute out=out;
  id city;
run;
```

By default, PROC MDS displays only the iteration history. In this example, only one iteration is required. The badness-of-fit criterion 0.001689 indicates that the data fit the model extremely well.

```

Analysis of Flying Mileages Between Ten U.S. Cities

Multidimensional Scaling: Data=WORK.CITY.DATA
Shape=TRIANGLE Condition=MATRIX Level=ABSOLUTE
Coef=IDENTITY Dimension=2 Formula=1 Fit=1

Gconverge=0.01 Maxiter=100 Over=1 Ridge=0.0001

```

Iteration	Type	Badness- of-Fit Criterion	Change in Criterion	Convergence Measure
0	Initial	0.003273	.	0.8562
1	Lev-Mar	0.001689	0.001584	0.005128

```

Convergence criterion is satisfied.

```

Figure 43.1. Iteration History from PROC MDS

In order for the plot to represent the geometry of the configuration correctly, the axes must be scaled so that a given physical distance on one axis represents the same number of units as the same physical distance on the other axis. You can use the %PLOTIT macro to obtain such a scaling by specifying the VTOH= option. The VTOH= option indicates the ratio of the vertical distance between lines to the horizontal distance between characters; obtaining a suitable value may require some experimentation. The %PLOTIT macro can create graphical scatter plots with iteratively derived optimal label placement. See [Appendix B, “Using the %PLOTIT Macro,”](#) for more information on the %PLOTIT macro.

The following statements produce [Figure 43.2](#):

```

%plotit(data=out, datatype=mds, labelvar=city,
        vtoh=1.75, labfont=swissb);
run;

```

While PROC MDS can recover the relative positions of the cities, it cannot determine absolute location or orientation. In this case, north is toward the bottom of the plot.

Figure 43.2. Plot of Estimated Configuration Using the %PLOTIT Macro

Syntax

You can specify the following statements with the MDS procedure:

```

PROC MDS < options > ;
  VAR variables ;
  INVAR variables ;
  ID | OBJECT variable ;
  MATRIX | SUBJECT variable ;
  WEIGHT variables ;
  BY variables ;

```

The PROC MDS statement is required. All other statements are optional.

PROC MDS Statement

PROC MDS < options > ;

By default, the only result produced by the MDS procedure is the iteration history. Hence, you should always specify one or more options for output data sets (OUT=, OUTFIT=, and OUTRES=) or displayed output (such as PFINAL). PROC MDS does not produce any plots; to produce plots, use the output data sets with PROC PLOT or PROC GPLOT.

The types of estimates written to the OUT= data set are determined by the OCONFIG, OCOEF, OTRANS, and OCRIT options. If you do not specify any of these four options, the estimates of all the parameters of the PROC MDS model and the value of the badness-of-fit criterion appear in the OUT= data set. If you specify one or more of these options, only the information requested by the specified options appear in the OUT= data set. Also, the OITER option causes these statistics to be written to the OUT= data set after initialization and on each iteration, as well as after the iterations have terminated.

Displayed output is controlled by the interaction of the PCONFIG, PCOEF, PTRANS, PFIT, and PFITROW options with the PININ, PINIT, PITER, and PFINAL options. The PCONFIG, PCOEF, PTRANS, PFIT, and PFITROW options specify *which* estimates and fit statistics are to be displayed. The PININ, PINIT, PITER, and PFINAL options specify *when* the estimates and fit statistics are to be displayed. If you specify at least one of the PCONFIG, PCOEF, PTRANS, PFIT and PFITROW options but none of the PININ, PINIT, PITER, and PFINAL options, the final results (PFINAL) are displayed. If you specify at least one of the PININ, PINIT, PITER, and PFINAL options but none of the PCONFIG, PCOEF, PTRANS, PFIT and PFITROW options, all estimates (PCONFIG, PCOEF, PTRANS) and the fit statistics for each matrix and for the entire sample (PFIT) are displayed. If you do not specify any of these nine options, no estimates or fit statistics are displayed (except the badness-of-fit criterion in the iteration history).

ALTERNATE | ALT=NONE | NO | N

ALTERNATE | ALT=MATRIX | MAT | M | SUBJECT | SUB | S

ALTERNATE | ALT=ROW | R <=n>

determines what form of alternating-least-squares algorithm is used. The default depends on the amount of memory available. The following ALTERNATE= options are listed in order of decreasing memory requirements:

ALT=NONE causes all parameters to be adjusted simultaneously on each iteration. This option is usually best for a small number of subjects and objects.

ALT=MATRIX adjusts all the parameters for the first subject, then all the parameters for the second subject, and so on, and finally adjusts all parameters that do not correspond to a subject, such as coordinates and unconditional transformations. This option usually works best for a large number of subjects with a small number of objects.

ALT=ROW treats subject parameters the same way as the **ALTERNATE=MATRIX** option but also includes separate stages for unconditional parameters and for subsets of the objects. The **ALT=ROW** option usually works best for a large number of objects.

Specifying **ALT=ROW=*n*** divides the objects into subsets of *n* objects each, except possibly for one subset when *n* does not divide the number of objects evenly. If you omit **=*n***, the number of objects in the subsets is determined from the amount of memory available. The smaller the value of *n*, the less memory is required.

When you specify the **LEVEL=ORDINAL** option, the monotone transformation is always computed in a separate stage and is listed as a separate iteration in the iteration history. In this case, estimation is done by iteratively reweighted least squares. The weights are recomputed according to the **FORMULA=** option on each monotone iteration; hence, it is possible for the badness-of-fit criterion to increase after a monotone iteration.

COEF=IDENTITY | IDEN | I
COEF=DIAGONAL | DIAG | D

specifies the type of matrix for the dimension coefficients.

COEF=IDENTITY is the default, which yields Euclidean distances.

COEF=DIAGONAL produces weighted Euclidean distances, in which each subject is allowed differential weights for the dimensions. The dimension coefficients that PROC MDS outputs are related to the square roots of what are called subject weights in PROC ALSCAL; the normalization in PROC MDS also differs from that in PROC ALSCAL. The weighted Euclidean model is related to the INDSCAL model (Carroll and Chang 1970).

CONDITION | COND=UN | U
CONDITION | COND=MATRIX | MAT | M | SUBJECT | SUB | S
CONDITION | COND=ROW | R

specifies the conditionality of the data (Young 1987, pp. 60–63). The default is **CONDITION=MATRIX**.

The data are divided into disjoint subsets called *partitions*. Within each partition, a separate transformation is applied, as specified by the **LEVEL=** option.

COND=UN puts all the data into a single partition.

COND=MATRIX makes each data matrix a partition.

COND=ROW makes each row of each data matrix a partition.

The `CONDITION=` option also determines the default value for the `SHAPE=` option. If you specify the `CONDITION=ROW` option and omit the `SHAPE=` option, each data matrix is stored as a square and possibly asymmetric matrix. If you specify the `CONDITION=UN` or `CONDITION=MATRIX` option and omit the `SHAPE=` option, only one triangle is stored. See the [SHAPE= option](#) on page 2484 for details.

CONVERGE | CONV=*p*

sets both the gradient convergence criterion and the monotone convergence criterion to p , where $0 \leq p \leq 1$. The default is `CONVERGE=.01`; smaller values may greatly increase the number of iterations required. Values less than .0001 may be impossible to satisfy because of the limits of machine precision. See the [GCONVERGE=](#) (page 2480) and [MCONVERGE=](#) (page 2481) options.

CUTOFF=*n*

causes data less than n to be replaced by missing values. The default is `CUTOFF=0`.

DATA=*SAS-data-set*

specifies the SAS data set containing one or more square matrices to be analyzed. In typical psychometric data, each matrix contains judgments from one subject, so there is a one-to-one correspondence between data matrices and subjects.

The data matrices contain similarity or dissimilarity measurements to be modeled and, optionally, weights for these data. The data are generally assumed to be dissimilarities unless you use the `SIMILAR` option. However, if there are nonmissing diagonal values and these values are predominantly larger than the off-diagonal values, the data are assumed to be similarities and are treated as if the `SIMILAR` option is specified. The diagonal elements are not otherwise used in fitting the model.

Each matrix must have exactly the same number of observations as the number of variables specified by the `VAR` statement or determined by defaults. This number is the number of objects or stimuli.

The first observation and variable are assumed to contain data for the first object, the second observation and variable are assumed to contain data for the second object, and so on.

When there are two or more matrices, the observations in each matrix must correspond to the same objects in the same order as in the first matrix.

The matrices can be symmetric or asymmetric, as specified by the `SHAPE=` option.

DECIMALS | DEC=*n*

specifies how many decimal places to use when displaying the parameter estimates and fit statistics. The default is `DECIMALS=2`, which is generally reasonable except in conjunction with the `LEVEL=ABSOLUTE` option and very large or very small data.

DIMENSION | DIMENS | DIM=*n* < TO *m* < BY=*i* >>

specifies the number of dimensions to use in the MDS model, where $1 \leq n, m < \text{number of objects}$. The parameter i can be either positive or negative but not zero. If you specify different values for n and m , a separate model is fitted for each requested dimension. If you specify only `DIMENSION= n` , then only n dimensions are

fitted. The default is DIMENSION=2 if there are three or more objects; otherwise, DIMENSION=1 is the only valid specification. The analyses for each number of dimensions are done independently. For information on choosing the dimensionality, refer to Kruskal and Wish (1978, pp. 48–60).

EPSILON | EPS=*n*

specifies a number n , $0 < n < 1$, that determines the amount added to squared distances computed from the model to avoid numerical problems such as division by 0. This amount is computed as ϵ equal to n times the mean squared distance in the initial configuration. The distance in the MDS model is thus computed as

$$distance = \sqrt{sqdist + \epsilon}$$

where *sqdist* is the squared Euclidean distance or the weighted squared Euclidean distance.

The default is EPSILON=1E–12, which is small enough to have no practical effect on the estimates unless the FIT= value is nonpositive and there are dissimilarities that are very close to 0. Hence, when the FIT= value is nonpositive, dissimilarities less than n times 100 times the maximum dissimilarity are disallowed.

FIT=DISTANCE | DIS | D

FIT=SQUARED | SQU | S

FIT=LOG | L

FIT=*n*

specifies a predetermined (not estimated) transformation to apply to both sides of the MDS model before the error term is added.

The default is FIT=DISTANCE or, equivalently, FIT=1, which fits data to distances.

The option FIT=SQUARED or FIT=2 fits squared data to squared distances. This gives greater importance to large data and distances and lesser importance to small data and distances in fitting the model.

The FIT=LOG or FIT=0 option fits log data to log distances. This gives lesser importance to large data and distances and greater importance to small data and distances in fitting the model.

In general, the FIT= n option fits n th-power data to n th-power distances. Values of n that are large in absolute value can cause floating-point overflows.

If the FIT= value is 0 or negative, the data must be strictly positive (see the EPSILON= option). Negative data may produce strange results with any value other than FIT=1.

FORMULA | FOR=0 | OLS | O

FORMULA | FOR=1 | USS | U

FORMULA | FOR=2 | CSS | C

determines how the badness-of-fit criterion is standardized in correspondence with stress formulas 1 and 2 (Kruskal and Wish 1978, pp. 24–26). The default is FORMULA=1 unless you specify FIT=LOG, in which case the default is FORMULA=2. Data partitions are defined by the CONDITION= option.

- FORMULA=0** fits a regression model by ordinary least squares (Null and Sarle 1982) without standardizing the partitions; this option cannot be used with the **LEVEL=ORDINAL** option. The badness-of-fit criterion is the square root of the error sum of squares.
- FORMULA=1** standardizes each partition by the uncorrected sum of squares of the (possibly transformed) data; this option should not be used with the **FIT=LOG** option. With the **FIT=DISTANCE** and **LEVEL=ORDINAL** options, this is equivalent to Kruskal's stress formula 1 or an obvious generalization thereof. With the **FIT=SQUARED** and **LEVEL=ORDINAL** options, this is equivalent to Young's s-stress formula 1 or an obvious generalization thereof. The badness-of-fit criterion is analogous to $\sqrt{1 - R^2}$, where R is a multiple correlation about the origin.
- FORMULA=2** standardizes each partition by the corrected sum of squares of the (possibly transformed) data; this option is the recommended method for unfolding. With the **FIT=DISTANCE** and **LEVEL=ORDINAL** options, this is equivalent to Kruskal's stress formula 2 or an obvious generalization thereof. With the **FIT=SQUARED** and **LEVEL=ORDINAL** options, this is equivalent to Young's s-stress formula 2 or an obvious generalization thereof. The badness-of-fit criterion is analogous to $\sqrt{1 - R^2}$, where R is a multiple correlation computed with a denominator corrected for the mean.

GCONVERGE | GCONV= p

sets the gradient convergence criterion to p , where $0 \leq p \leq 1$. The default is **GCONVERGE=0.01**; smaller values may greatly increase the number of iterations required. Values less than 0.0001 may be impossible to satisfy because of the limits of machine precision.

The gradient convergence measure is the multiple correlation of the Jacobian matrix with the residual vector, uncorrected for the mean. See the **CONVERGE=** (page 2478) and **MCONVERGE=** (page 2481) options.

INAV=DATA | D**INAV=SSCP | S**

affects the computation of initial coordinates. The default is **INAV=DATA**.

INAV=DATA computes a weighted average of the data matrices. Its value is estimated only if an element is missing from every data matrix. The weighted average of the data matrices with missing values filled in is then converted to a scalar products matrix (or what would be a scalar products matrix if the fit were perfect), from which the initial coordinates are computed.

INAV=SSCP estimates missing values in each data matrix and converts each data matrix to a scalar products matrix. The initial coordinates are computed from the unweighted average of the scalar products matrices.

INITIAL | IN=SAS-data-set

specifies a SAS data set containing initial values for some or all of the parameters of the MDS model. If the INITIAL= option is omitted, the initial values are computed from the data.

LEVEL=ABSOLUTE | ABS | A**LEVEL=RATIO | RAT | R****LEVEL=INTERVAL | INT | I****LEVEL=LOGINTERVAL | LOG | L****LEVEL=ORDINAL | ORD | O**

specifies the measurement level of the data and hence the type of estimated (optimal) transformations applied to the data or distances (Young 1987, pp. 57–60; Krantz et. al. 1971, pp. 9–12) within each partition as specified by the CONDITION= option. LEVEL=ORDINAL specifies a nonmetric analysis, while all other LEVEL= options specify metric analyses. The default is LEVEL=ORDINAL.

LEVEL=ABSOLUTE allows no optimal transformations. Hence, the distinction between regression and measurement models is irrelevant.

LEVEL=RATIO fits a regression model in which the distances are multiplied by a slope parameter in each partition (a linear transformation). In this case, the regression model is equivalent to the measurement model with the slope parameter reciprocated.

LEVEL=INTERVAL fits a regression model in which the distances are multiplied by a slope parameter and added to an intercept parameter in each partition (an affine transformation). In this case, the regression and measurement models differ if there is more than one partition.

LEVEL=LOGINTERVAL fits a regression model in which the distances are raised to a power and multiplied by a slope parameter in each partition (a power transformation).

LEVEL=ORDINAL fits a measurement model in which a least-squares monotone increasing transformation is applied to the data in each partition. At the ordinal measurement level, the regression and measurement models differ.

MAXITER | ITER=*n*

specifies the maximum number of iterations, where $n \geq 0$. The default is MAXITER=100.

MCONVERGE | MCONV=*p*

sets the monotone convergence criterion to p , where $0 \leq p \leq 1$, for use with the LEVEL=ORDINAL option. The default is MCONVERGE=0.01; if you want greater precision, MCONVERGE=0.001 is usually reasonable, but smaller values may greatly increase the number of iterations required.

The monotone convergence criterion is the Euclidean norm of the change in the optimally scaled data divided by the Euclidean norm of the optimally scaled data, averaged across partitions defined by the `CONDITION=` option. See the `CONVERGE=` (page 2478) and `GCONVERGE=` (page 2480) options.

MINCRIT | CRITMIN=*n*

causes iteration to terminate when the badness-of-fit criterion is less than or equal to *n*, where $n \geq 0$. The default is `MINCRIT=1E-6`.

NEGATIVE

allows slopes or powers to be negative with the `LEVEL=RATIO`, `INTERVAL`, or `LOGINTERVAL` option.

NONORM

suppresses normalization of the initial and final estimates.

NOPHIST | NOPRINT | NOP

suppresses the output of the iteration history.

NOULB

causes missing data to be estimated during initialization by the average nonmissing value, where the average is computed according to the `FIT=` option. Otherwise, missing data are estimated by interpolating between the Rabinowitz (1976) upper and lower bounds.

OCOEF

writes the dimension coefficients to the `OUT=` data set. See the `OUT=` option for interactions with other options.

OCONFIG

writes the coordinates of the objects to the `OUT=` data set. See the `OUT=` option for interactions with other options.

OCRIT

writes the badness-of-fit criterion to the `OUT=` data set. See the `OUT=` option for interactions with other options.

OITER | OUTITER

writes current values to the output data sets after initialization and on every iteration. Otherwise, only the final values are written to any output data sets. See the `OUT=`, `OUTFIT=`, and `OUTRES=` options.

OTRANS

writes the transformation parameter estimates to the `OUT=` data set if any such estimates are computed. There are no transformation parameters with the `LEVEL=ORDINAL` option. See the `OUT=` option for interactions with other options.

OUT=SAS-data-set

creates a SAS data set containing, by default, the estimates of all the parameters of the PROC MDS model and the value of the badness-of-fit criterion. However, if you specify one or more of the `OCONFIG`, `OCOEF`, `OTRANS`, and `OCRIT` options, only

the information requested by the specified options appears in the OUT= data set. See also the OITER option.

OUTFIT=SAS-data-set

creates a SAS data set containing goodness-of-fit and badness-of-fit measures for each partition as well as for the entire data set. See also the OITER option.

OUTRES=SAS-data-set

creates a SAS data set containing one observation for each nonmissing datum from the DATA= data set. Each observation contains the original datum, the estimated distance computed from the MDS model, transformed data and distances, and the residual. See also the OITER option.

OVER=*n*

specifies the maximum overrelaxation factor, where $n \geq 1$. Values between 1 and 2 are generally reasonable. The default is OVER=2 with the LEVEL=ORDINAL, ALTERNATE=MATRIX, or ALTERNATE=ROW option; otherwise, the default is OVER=1. Use this option only if you have convergence problems.

PCOEF

produces the estimated dimension coefficients.

PCONFIG

produces the estimated coordinates of the objects in the configuration.

PDATA

displays each data matrix.

PFINAL

displays final estimates.

PFIT

displays the badness-of-fit criterion and various types of correlations between the data and fitted values for each data matrix, as well as for the entire sample.

PFITROW

displays the badness-of-fit criterion and various types of correlations between the data and fitted values for each row as well as for each data matrix and for the entire sample. This option works only with the CONDITION=ROW option.

PINAVDATA

displays the sum of the weights and the weighted average of the data matrices computed during initialization with the INAV=DATA option.

PINEIGVAL

displays the eigenvalues computed during initialization.

PINEIGVEC

displays the eigenvectors computed during initialization.

PININ

displays values read from the INITIAL= data set. Since these values may be incomplete, the PFIT and PFITROW options do not apply.

PINIT

displays initial values.

PITER

displays estimates on each iteration.

PTRANS

displays the estimated transformation parameters if any are computed. There are no transformation parameters with the LEVEL=ORDINAL option.

RANDOM<=*seed*>

causes initial coordinate values to be pseudorandom numbers. In one dimension, the pseudorandom numbers are uniformly distributed on an interval. In two or more dimensions, the pseudorandom numbers are uniformly distributed on the circumference of a circle or the surface of a (hyper)sphere.

RIDGE=*n*

specifies the initial ridge value, where $n \geq 0$. The default is RIDGE=1E-4.

If you get a floating-point overflow in the first few iterations, specify a larger value such as RIDGE=0.01 or RIDGE=1 or RIDGE=100.

If you know that the initial estimates are very good, using RIDGE=0 may speed convergence.

SHAPE=TRIANGULAR | TRIANGLE | TRI | T**SHAPE=SQUARE | SQU | S**

determines whether the entire data matrix for each subject or only one triangle of the matrix is stored and analyzed. If you specify the CONDITION=ROW option, the default is SHAPE=SQUARE. Otherwise, the default is SHAPE=TRIANGLE.

SHAPE=SQUARE causes the entire matrix to be stored and analyzed. The matrix can be asymmetric.

SHAPE=TRIANGLE causes only one triangle to be stored. However, PROC MDS reads both upper and lower triangles to look for nonmissing values and to symmetrize the data if needed. If corresponding elements in the upper and lower triangles both contain nonmissing values, only the average of the two values is stored and analyzed (Kruskal and Wish 1978, p. 74). Also, if an OUTRES= data set is requested, only the average of the two corresponding elements is output.

SIMILAR | SIM<=*max*>

causes the data to be treated as similarity measurements rather than dissimilarities. If =*max* is not specified, each datum is converted to a dissimilarity by subtracting it from the maximum value in the data set or BY group. If =*max* is specified, each

datum is subtracted from the maximum of *max* and the data. The diagonal data are included in computing these maxima.

By default, the data are assumed to be dissimilarities unless there are nonmissing diagonal values and these values are predominantly larger than the off-diagonal values. In this case, the data are assumed to be similarities and are treated as if the SIMILAR option is specified.

SINGULAR=*p*

specifies the singularity criterion p , $0 \leq p \leq 1$. The default is SINGULAR=1E-8.

UNTIE

allows tied data to be assigned different optimally scaled values with the LEVEL=ORDINAL option. Otherwise, tied data are assigned equal optimally scaled values. The UNTIE option has no effect with values of the LEVEL= option other than LEVEL=ORDINAL.

BY Statement

BY variables ;

You can specify a BY statement with PROC MDS to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the MDS procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure.

If the INITIAL= data set contains the BY variables, the BY groups must appear in the same order as in the DATA= data set. If the BY variables are not in the INITIAL= data set, the entire data set is used to provide initial values for each BY group in the DATA= data set.

For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

ID Statement

ID | **OBJECT** | **OBJ** *variable* ;

The ID statement specifies a variable in the DATA= data set that contains descriptive labels for the objects. The labels are used in the output and are copied to the OUT= data set. If there is more than one data matrix, only the ID values from the observations containing the first data matrix are used.

The ID variable is not used to establish any correspondence between observations and variables.

If the ID statement is omitted, the variable labels or names are used as object labels.

INVAR Statement

INVAR *variables* ;

The INVAR statement specifies the numeric variables in the INITIAL= data set that contain initial parameter estimates. The first variable corresponds to the first dimension, the second variable to the second dimension, and so on.

If the INVAR statement is omitted, the variables DIM1, . . . , DIM m are used, where m is the maximum number of dimensions.

MATRIX Statement

MATRIX | **MAT** | **SUBJECT** | **SUB** *variable* ;

The MATRIX statement specifies a variable in the DATA= data set that contains descriptive labels for the data matrices or subjects. The labels are used in the output and are copied to the OUT= and OUTRES= data sets. Only the first observation from each data matrix is used to obtain the label for that matrix.

If the MATRIX statement is omitted, the matrices are labeled 1, 2, 3, and so on.

VAR Statement

VAR *variables* ;

The VAR statement specifies the numeric variables in the DATA= data set that contain similarity or dissimilarity measurements on a set of objects or stimuli. Each variable corresponds to one object.

If the VAR statement is omitted, all numeric variables that are not specified in another statement are used.

To analyze a subset of the objects in a data set, you can specify the variable names corresponding to the columns in the subset, but you must also use a DATA step or a WHERE clause to specify the rows in the subset. PROC MDS expects to read one or more square matrices, and you must ensure that the rows in the data set correctly correspond to the columns in number and order.

WEIGHT Statement

WEIGHT *variables* ;

The WEIGHT statement specifies numeric variables in the DATA= data set that contain weights for each similarity or dissimilarity measurement. These weights are used to compute weighted least-squares estimates. The number of WEIGHT variables must be the same as the number of VAR variables, and the variables in the WEIGHT statement must be in the same order as the corresponding variables in the VAR statement.

If the WEIGHT statement is omitted, all data within a partition are assigned equal weights.

Data with 0 or negative weights are ignored in fitting the model but are included in the OUTRES= data set and in monotone transformations.

Details

Formulas

The following notation is used:

A_p	intercept for partition p
B_p	slope for partition p
C_p	power for partition p
D_{rcs}	distance computed from the model between objects r and c for subject s
F_{rcs}	data weight for objects r and c for subject s obtained from the c th WEIGHT variable, or 1 if there is no WEIGHT statement
f	value of the FIT= option
N	number of objects
O_{rcs}	observed dissimilarity between objects r and c for subject s
P_{rcs}	partition index for objects r and c for subject s
Q_{rcs}	dissimilarity after applying any applicable estimated transformation for objects r and c for subject s
R_{rcs}	residual for objects r and c for subject s
S_p	standardization factor for partition p
$T_p(\cdot)$	estimated transformation for partition p
V_{sd}	coefficient for subject s on dimension d
X_{nd}	coordinate for object n on dimension d

Summations are taken over nonmissing values.

Distances are computed from the model as

$$\begin{aligned}
 D_{rcs} &= \sqrt{\sum_d (X_{rd} - X_{cd})^2} && \text{for COEF=IDENTITY:} \\
 & && \text{Euclidean distance} \\
 &= \sqrt{\sum_d V_{sd}^2 (X_{rd} - X_{cd})^2} && \text{for COEF=DIAGONAL:} \\
 & && \text{weighted Euclidean distance}
 \end{aligned}$$

Partition indexes are

$$\begin{aligned}
 P_{rcs} &= 1 && \text{for CONDITION=UN} \\
 &= s && \text{for CONDITION=MATRIX} \\
 &= (s-1)N + r && \text{for CONDITION=ROW}
 \end{aligned}$$

The estimated transformation for each partition is

$$\begin{aligned}
 T_p(d) &= d && \text{for LEVEL=ABSOLUTE} \\
 &= B_p d && \text{for LEVEL=RATIO} \\
 &= A_p + B_p d && \text{for LEVEL=INTERVAL} \\
 &= B_p d^{C_p} && \text{for LEVEL=LOGINTERVAL}
 \end{aligned}$$

For LEVEL=ORDINAL, $T_p(\cdot)$ is computed as a least-squares monotone transformation.

For LEVEL=ABSOLUTE, RATIO, or INTERVAL, the residuals are computed as

$$\begin{aligned}
 Q_{rcs} &= O_{rcs} \\
 R_{rcs} &= Q_{rcs}^f - [T_{P_{rcs}}(D_{rcs})]^f
 \end{aligned}$$

For LEVEL=ORDINAL, the residuals are computed as

$$\begin{aligned}
 Q_{rcs} &= T_{P_{rcs}}(O_{rcs}) \\
 R_{rcs} &= Q_{rcs}^f - D_{rcs}^f
 \end{aligned}$$

If f is 0, then natural logarithms are used in place of the f th powers.

For each partition, let

$$U_p = \frac{\sum_{r,c,s} F_{rcs}}{\sum_{r,c,s|P_{rcs}=p} F_{rcs}}$$

and

$$\bar{Q}_p = \frac{\sum_{r,c,s|P_{rcs}=p} Q_{rcs} F_{rcs}}{\sum_{r,c,s|P_{rcs}=p} F_{rcs}}$$

Then the standardization factor for each partition is

$$\begin{aligned}
 S_p &= 1 && \text{for FORMULA=0} \\
 &= U_p \sum_{r,c,s|P_{rcs}=p} Q_{rcs}^2 F_{rcs} && \text{for FORMULA=1} \\
 &= U_p \sum_{r,c,s|P_{rcs}=p} (Q_{rcs} - \bar{Q}_p)^2 F_{rcs} && \text{for FORMULA=2}
 \end{aligned}$$

The badness-of-fit criterion that the MDS procedure tries to minimize is

$$\sqrt{\sum_{r,c,s} \frac{R_{rcs}^2 F_{rcs}}{S_{P_{rcs}}}}$$

OUT= Data Set

The OUT= data set contains the following variables:

- BY variables, if any
- `_ITER_` (if the OUTITER option is specified), a numeric variable containing the iteration number
- `_DIMENS_`, a numeric variable containing the number of dimensions
- `_MATRIX_` or the variable in the MATRIX statement, identifying the data matrix or subject to which the observation pertains. This variable contains a missing value for observations that pertain to the data set as a whole and not to a particular matrix, such as the coordinates (`_TYPE_='CONFIG'`).
- `_TYPE_`, a character variable of length 10 identifying the type of information in the observation

The values of `_TYPE_` are as follows:

CONFIG	the estimated coordinates of the configuration of objects
DIAGCOEF	the estimated dimension coefficients for COEF=DIAGONAL
INTERCEPT	the estimated intercept parameters
SLOPE	the estimated slope parameters
POWER	the estimated power parameters
CRITERION	the badness-of-fit criterion

- `_LABEL_` or the variable in the ID statement, containing the variable label or value of the ID variable of the object to which the observation pertains. This variable contains a missing value for observations that do not pertain to a particular object or dimension.
- `_NAME_`, a character variable of length 8 containing the variable name of the object or dimension to which the observation pertains. This variable contains a missing value for observations that do not pertain to a particular object or dimension.
- DIM1, . . . , DIM m , where m is the maximum number of dimensions

OUTFIT= Data Set

The OUTFIT= data set contains various measures of goodness and badness of fit. There is one observation for the entire sample plus one observation for each matrix. For the CONDITION=ROW option, there is also one observation for each row.

The OUTFIT= data set contains the following variables:

- BY variables, if any
- `_ITER_` (if the OUTITER option is specified), a numeric variable containing the iteration number
- `_DIMENS_`, a numeric variable containing the number of dimensions
- `_MATRIX_` or the variable in the MATRIX statement, identifying the data matrix or subject to which the observation pertains
- `_LABEL_` or the variable in the ID statement, containing the variable label or value of the ID variable of the object to which the observation pertains when CONDITION=ROW
- `_NAME_`, a character variable of length 8 containing the variable name of the object or dimension to which the observation pertains when CONDITION=ROW
- N, the number of nonmissing data
- WEIGHT, the weight of the partition
- CRITER, the badness-of-fit criterion
- DISCORR, the correlation between the transformed data and the distances for LEVEL=ORDINAL or the correlation between the data and the transformed distances otherwise
- UDISCORR, the correlation uncorrected for the mean between the transformed data and the distances for LEVEL=ORDINAL or the correlation between the data and the transformed distances otherwise
- FITCORR, the correlation between the fit-transformed data and the fit-transformed distances
- UFITCORR, the correlation uncorrected for the mean between the fit-transformed data and the fit-transformed distances

OUTRES= Data Set

The OUTRES= data set has one observation for each nonmissing datum. It contains the following variables:

- BY variables, if any
- `_ITER_` (if the OUTITER option is specified), a numeric variable containing the iteration number
- `_DIMENS_`, a numeric variable containing the number of dimensions

- `_MATRIX_` or the variable in the `MATRIX` statement, identifying the data matrix or subject to which the observation pertains
- `_ROW_`, containing the variable label or value of the ID variable of the row to which the observation pertains
- `_COL_`, containing the variable label or value of the ID variable of the column to which the observation pertains
- `DATA`, the original datum
- `TRANDATA`, the optimally transformed datum when `LEVEL=ORDINAL`
- `DISTANCE`, the distance computed from the PROC MDS model
- `TRANSDIST`, the optimally transformed distance when the `LEVEL=` option is not `ORDINAL` or `ABSOLUTE`
- `FITDATA`, the datum further transformed according to the `FIT=` option
- `FITDIST`, the distance further transformed according to the `FIT=` option
- `WEIGHT`, the combined weight of the datum based on the `WEIGHT` variable(s), if any, and the standardization specified by the `FORMULA=` option
- `RESIDUAL`, `FITDATA` minus `FITDIST`

To cause a datum to appear in the `OUTRES=` data set, yet be ignored in fitting the model, give the datum a nonmissing value but a 0 weight (see “[WEIGHT Statement](#)”).

INITIAL= Data Set

The `INITIAL=` data set has the same structure as the `OUT=` data set but is not required to have all of the variables or observations that appear in the `OUT=` data set. You can use an `OUT=` data set previously created by PROC MDS (without the `OUTITER` option) as an `INITIAL=` data set in a subsequent invocation of the procedure.

The only variables that are required are `DIM1, . . . , DIM m` (where m is the maximum number of dimensions) or equivalent variables specified in the `INVAR` statement. If these are the only variables, then all the observations are assumed to contain coordinates of the configuration; you cannot read dimension coefficients or transformation parameters.

To read initial values for the dimension coefficients or transformation parameters, the `INITIAL=` data set must contain the `_TYPE_` variable and either the variable specified in the `ID` statement or, if no `ID` statement is used, the variable `_NAME_`. In addition, if there is more than one data matrix, either the variable specified in the `MATRIX` statement or, if no `MATRIX` statement is used, the variable `_MATRIX_` or `_MATNUM_` is required.

If the `INITIAL=` data set contains the variable `_DIMENS_`, initial values are obtained from observations with the corresponding number of dimensions. If there is no `_DIMENS_` variable, the same observations are used for each number of dimensions analyzed.

If you want PROC MDS to read initial values from some but not all of the observations in the INITIAL= data set, use the WHERE= data set option to select the desired observations.

Missing Values

Missing data in the similarity or dissimilarity matrices are ignored in fitting the model and are omitted from the OUTRES= data set. Any matrix that is completely missing is omitted from the analysis.

Missing weights are treated as 0.

Missing values are also allowed in the INITIAL= data set, but a large number of missing values may yield a degenerate initial configuration.

Normalization of the Estimates

In multidimensional scaling models, the parameter estimates are not uniquely determined; the estimates can be transformed in various ways without changing their badness of fit. The initial and final estimates from PROC MDS are, therefore, normalized (unless you specify the NONORM option) to make it easier to compare results from different analyses.

The configuration always has a mean of 0 for each dimension.

With the COEF=IDENTITY option, the configuration is rotated to a principal-axis orientation. Unless you specify the LEVEL=ABSOLUTE option, the entire configuration is scaled so that the root-mean-square element is 1, and the transformations are adjusted to compensate.

With the COEF=DIAGONAL option, each dimension is scaled to a root-mean-square value of 1, and the dimension coefficients are adjusted to compensate. Unless you specify the LEVEL=ABSOLUTE option, the dimension coefficients are normalized as follows. If you specify the CONDITION=UN option, all of the dimension coefficients are scaled to a root-mean-square value of 1. For other values of the CONDITION= option, the dimension coefficients are scaled separately for each subject to a root-mean-square value of 1. In either case, the transformations are adjusted to compensate.

Each dimension is reflected to give a positive rank correlation with the order of the objects in the data set.

For the LEVEL=ORDINAL option, if the intercept, slope, or power parameters are fitted, the transformed data are normalized to eliminate these parameters if possible.

Comparison with the ALSCAL Procedure

The MDS procedure generally produces results similar to those from the ALSCAL procedure (Young, Lewyckyj, and Takane 1986; Young 1982) if you use the following options in PROC MDS:

- FIT=SQUARED
- FORMULA=1 except for unfolding data, which require FORMULA=2
- PFINAL to get output similar to that from PROC ALSCAL

Unlike PROC ALSCAL, PROC MDS produces no plots, so you must use output data sets and PROC PLOT or PROC GPLOT.

The MDS and ALSCAL procedures may sometimes produce different results for the following reasons:

- With the LEVEL=INTERVAL option, PROC MDS fits a regression model while PROC ALSCAL fits a measurement model. These models are not equivalent if there is more than one partition, although the differences in the parameter estimates are usually minor.
- PROC MDS and PROC ALSCAL use different algorithms for initialization and optimization. Hence, different local optima may be found by PROC MDS and PROC ALSCAL for some data sets with poor fit. Using the INAV=SSCP option causes the initial estimates from PROC MDS to be more like those from PROC ALSCAL.
- The default convergence criteria in PROC MDS are more strict than those in PROC ALSCAL. The convergence measure in PROC ALSCAL may cause PROC ALSCAL to stop iterating because progress is slow rather than because a local optimum has been reached. Even if you run PROC ALSCAL with a very small convergence criterion and a very large iteration limit, PROC ALSCAL may never achieve the same degree of precision as PROC MDS. For most applications, this problem is of no practical consequence since two- or three-digit precision is sufficient. If the model does not fit well, obtaining higher precision may require hundreds of iterations.

PROC MDS accepts some PROC ALSCAL options as synonyms for the preceding options, as displayed in [Table 43.1](#).

Table 43.1. PROC MDS Options Compared to PROC ALSCAL Options

PROC ALSCAL Option	Accepted by PROC MDS?	Related PROC MDS Option or Comments
CONDITION=	Yes	
CONVERGE=	Yes	Convergence measures are not comparable
CUTOFF=	Yes	
DATA=	Yes	

Table 43.1. (continued)

PROC ALSCAL Option	Accepted by PROC MDS?	Related PROC MDS Option or Comments
DEGREE=	No	
DIMENS=	Yes	
DIRECTIONS=	No	
HEADER	Yes	Default in PROC MDS
IN=	Yes	
ITER=	Yes	MAXITER=

SHAPE=RECTANGU	No	Use SHAPE=TRIANGLE with extra missing values to fill out the matrix.
SIMILAR	Yes	
TIESTORE=	Yes	Ignored by PROC MDS
UNTIE	Yes	

Comparison with the MLSCALE Procedure

Running the MDS procedure with the options

```
proc mds fit=log level=loginterval ... ;
```

generally produces results similar to using the MLSCALE procedure (Ramsay 1986) with the options

```
proc mlscale stvarnce=constant suvarnce=constant ... ;
```

Alternatively, using the FIT=DISTANCE option in the PROC MDS statement produces results similar to specifying the NORMAL option in the PROC MLSCALE statement.

The MDS procedure uses the least-squares method of estimation. The least-squares method is equivalent to the maximum-likelihood method if the error terms are assumed to be independent and identically distributed normal random variables. Unlike PROC MLSCALE, PROC MDS does not provide any options for unequal error variances.

PROC MDS accepts some PROC MLSCALE options as synonyms for the options described previously, as displayed in [Table 43.2](#).

Table 43.2. PROC MDS Options Compared to PROC MLSCALE Options

Displayed Output

Unless you specify the NOPHIST option, PROC MDS displays the iteration history containing

- Iteration number
- Type of iteration:

Initial	initial configuration
Monotone	monotone transformation
Gau-New	Gauss-Newton step
Lev-Mar	Levenberg-Marquardt step
- Badness-of-Fit Criterion
- Change in Criterion
- Convergence Measures:

Monotone	the Euclidean norm of the change in the optimally scaled data divided by the Euclidean norm of the optimally scaled data, averaged across partitions
Gradient	the multiple correlation of the Jacobian matrix with the residual vector, uncorrected for the mean

Depending on what options are specified, PROC MDS may also display the following tables:

- Data Matrix and possibly Weight Matrix for each subject
- Eigenvalues from the computation of the initial coordinates
- Sum of Data Weights and Pooled Data Matrix computed during initialization with INAV=DATA

- Configuration, the estimated coordinates of the objects
- Dimension Coefficients
- A table of transformation parameters, including one or more of the following:
 - Intercept
 - Slope
 - Power
- A table of fit statistics for each matrix and possibly each row, including
 - Number of Nonmissing Data
 - Weight of the matrix or row, allowing for both observation weights and standardization factors
 - Badness-of-Fit Criterion
 - Distance Correlation computed between the distances and data with optimal transformation
 - Uncorrected Distance Correlation not corrected for the mean
 - Fit Correlation computed after applying the FIT= transformation to both distances and data
 - Uncorrected Fit Correlation not corrected for the mean

ODS Table Names

PROC MDS assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

Table 43.3. ODS Tables Produced in PROC MDS

ODS Table Name	Description	Option
ConvergenceStatus	Convergence status	default
DimensionCoef	Dimension coefficients	PCOEF w/COEF= not IDENTITY
FitMeasures	Measures of fit	PFIT
IterHistory	Iteration history	default
PConfig	Estimated coordinates of the objects in the configuration	PCONFIG
PData	Data matrices	PDATA
PInAvData	Initial sum of weights and weighted average of data matrices with INAV=DATA	PINAVDATA
PInEigval	Initial eigenvalues	PINEIGVAL
PInEigvec	Initial eigenvectors	PINEIGVEC
PInWeight	Initialization weights	PINWEIGHT
Transformations	Transformation parameters	PTRANS w/LEVEL=RATIO, INTERVAL, LOGINTERVAL

Example

Example 43.1. Jacobowitz Body Parts Data from Children and Adults

Jacobowitz (1975) collected conditional rank-order data regarding perceived similarity of parts of the body from children of ages 6, 8, and 10 years and from college sophomores. The following analysis includes data from 15 children (6-year-olds) and 15 sophomores. The method of data collection and some results of an analysis are also described by Young (1987, pp. 4–10). A portion of the data is included below. See “Mds Documentation Examples” in the SAS/STAT Sample Program Library for the complete data set.

The OUTRES= data set is used to produce a plot showing the overall fit of the model, with the transformed data on the vertical axis and the distances from the model on the horizontal axis. If the model fits perfectly, all points lie on a diagonal line from lower left to upper right. The vertical departure of each point from this diagonal line represents the residual of the corresponding observation. The HAXIS and VAXIS options in the PLOT statement specify that the horizontal and vertical axes use the definitions AXIS2 and AXIS1, respectively. The identical ORDER= options in each of these AXIS statements make physical distances on each axis comparable.

The following statements produce [Output 43.1.2](#):

```

title1 'Plot of Over-All Fit';
axis1 label=(angle=90 rotate=0) minor=none

```

```

order=(0 to 5 by 1);
axis2 minor=none order=(0 to 5 by 1);

proc gplot data=res;
  plot fitdata*fitdist/vaxis=axis1 haxis=axis2
      frame cframe=ligr;
run;

```

Output 43.1.2. Plot of Over-All Fit for Body Parts Data

The OUT= data set is used to plot the configuration and dimension coefficients using the %PLOTIT macro. Again it is necessary to use the VTOH= option to make the axes commensurable. The configuration is plotted by selecting observations having _TYPE_='CONFIG' with a WHERE statement and by using the _NAME_ variable to identify each body part on the plot.

The dimension coefficients are plotted by selecting observations having _TYPE_='DIAGCOEF' and by using the Subject variable to distinguish children from adults on the plot. The following statements produce [Output 43.1.3](#):

```

title1 'Plot of configuration';
%plotit(data=out(where=( _type_='CONFIG' )), datatype=mds,
        labelvar=_name_, vtoh=1.75);
%plotit(data=out(where=( _type_='CONFIG' )), datatype=mds,
        plotvars=dim3 dim1, labelvar=_name_, vtoh=1.75);
run;

title1 'Plot of Dimension Coefficients for Each Subject';
%plotit(data=out(where=( _type_='DIAGCOEF' )), symtype=vector,
        symbols='',datatype=mds, place=0, labelvar=subject,

```

```

vehead=, ls=100, plotopts=hzero vzero);

%plotit(data=out(where=(_type_='DIAGCOEF')),
plotvars=dim3 dim1, symtime=vector, symbols='',
datatype=mds, place=0, labelvar=subject, ls=100,
vehead=, plotopts=hzero vzero);
run;

```

The configuration displayed in [Output 43.1.3](#) has a tripodal shape with **Body** at the apex. The three legs of the tripod can be distinguished in the plot of dimension 2 by dimension 1, which shows three distinct clusters with **Body** in the center. Dimension 1 separates head parts from arm and leg parts. Dimension 2 separates arm parts from leg parts. The plot of dimension 3 by dimension 1 shows the tripod from the side. Dimension 3 distinguishes the more inclusive body parts (at the top) from the less inclusive body parts (at the bottom).

Output 43.1.3. Plot of Configuration for Body Parts Data

The plots of dimension coefficients in [Output 43.1.4](#) show that children differ from adults primarily in the emphasis given to dimension 2. Children give about the same weight (approximately 1) to each dimension. Adults are much more variable than children, but all have coefficients less than 1.0 for dimension 2, with an average of about 0.7. Referring back to the configuration plot, you can see that adults consider arm parts to be more similar to leg parts than do children. Many adults also give a high weight to dimension 1, indicating that they consider head parts to be more dissimilar from arm and leg parts than do children. Dimension 3 shows considerable variability for both children and adults.

Output 43.1.4. Plot of Dimension Coefficients for Body Parts Data

Chapter 44

The MI Procedure

Overview

The MI procedure performs multiple imputation of missing data. Missing values are an issue in a substantial number of statistical analyses. Most SAS statistical procedures exclude observations with any missing variable values from the analysis. These observations are called incomplete cases. While analyzing only complete cases has its simplicity, the information contained in the incomplete cases is lost. This approach also ignores possible systematic differences between the complete cases and the incomplete cases, and the resulting inference may not be applicable to the population of all cases, especially with a small number of complete cases.

Some SAS procedures use all the available cases in an analysis, that is, cases with useful information. For example, the CORR procedure estimates a variable mean by using all cases with nonmissing values for this variable, ignoring the possible missing values in other variables. PROC CORR also estimates a correlation by using all cases with nonmissing values for this pair of variables. This makes better use of the available data than use only the complete cases, but the resulting correlation matrix may not be positive definite.

Another strategy for handling missing data is single imputation, which substitutes a value for each missing value. Standard statistical procedures for complete data analysis can then be used with the filled-in data set. For example, each missing value can be imputed with the variable mean of the complete cases, or it can be imputed with the mean conditional on observed values of other variables. This approach treats missing values as if they were known in the complete-data analysis. However, single imputation does not reflect the uncertainty about the predictions of the unknown missing values, and the resulting estimated variances of the parameter estimates will be biased toward zero (Rubin 1987, p. 13).

Instead of filling in a single value for each missing value, multiple imputation (Rubin 1976; 1987) replaces each missing value with a set of plausible values that represent the uncertainty about the right value to impute. The multiply imputed data sets are then analyzed by using standard procedures for complete data and combining the results from these analyses. No matter which complete-data analysis is used, the process of combining results from different data sets is essentially the same.

Multiple imputation does not attempt to estimate each missing value through simulated values. Instead, it draws a random sample of the missing values from its distribution. This process results in valid statistical inferences that properly reflect the uncertainty due to missing values; for example, confidence intervals with the correct probability coverage.

Multiple imputation inference involves three distinct phases:

1. The missing data are filled in m times to generate m complete data sets.
2. The m complete data sets are analyzed using standard statistical analyses.
3. The results from the m complete data sets are combined to produce inferential results.

The MI procedure creates multiply imputed data sets for incomplete multivariate data. It uses methods that incorporate appropriate variability across the m imputations. The method of choice depends on the patterns of missingness.

For data sets with monotone missing patterns, either a parametric method that assumes multivariate normality or a nonparametric method is appropriate. Parametric methods available include the regression method (Rubin 1987, pp. 166–167) and the predictive mean matching method (Heitjan and Little 1991; Schenker and Taylor 1996). The nonparametric method is the propensity score method (Rubin 1987, pp. 124, 158; Lavori, Dawson, and Shera 1995).

For data sets with arbitrary missing patterns, a Markov Chain Monte Carlo (MCMC) method (Schafer 1997) that assumes multivariate normality is used to impute all missing values or just enough missing values to make the imputed data sets have monotone missing patterns.

Once the m complete data sets are analyzed using standard SAS procedures, the MIANALYZE procedure can be used to generate valid statistical inferences about these parameters by combining results from the m analyses.

Often, as few as three to five imputations are adequate in multiple imputation (Rubin 1996, p. 480). The relative efficiency of the small m imputation estimator is high for cases with little missing information (Rubin 1987, p. 114). Also see the [“Multiple Imputation Efficiency”](#) section on page 2562.

Multiple imputation inference assumes that the model (variables) you used to analyze the multiply imputed data (the analyst’s model) is the same as the model used to impute missing values in multiple imputation (the imputer’s model). But in practice, the two models may not be the same. The consequences for different scenarios (Schafer 1997, pp. 139–143) are discussed in the [“Imputer’s Model Versus Analyst’s Model”](#) section on page 2563.

In SAS 9, an experimental CLASS statement has been added to specify classification variables, which can be used either as covariates for imputed variables or as imputed variables for data sets with monotone missing patterns. The CLASS statement must be used in conjunction with the MONOTONE statement.

Experimental graphics using ODS are now available with the MI procedure. For more information, see the [“ODS Graphics”](#) section on page 2567.

Getting Started

Consider the following Fitness data set that has been altered to contain an arbitrary pattern of missingness:

```
*----- Data on Physical Fitness -----*
| These measurements were made on men involved in a physical |
| fitness course at N.C. State University.                   |
| Only selected variables of                                |
| Oxygen (oxygen intake, ml per kg body weight per minute), |
| Runtime (time to run 1.5 miles in minutes), and          |
| RunPulse (heart rate while running) are used.            |
| Certain values were changed to missing for the analysis.  |
*-----*
data FitMiss;
  input Oxygen RunTime RunPulse @@;
  datalines;
44.609 11.37 178      45.313 10.07 185
54.297  8.65 156      59.571  .      .

47.467 10.50 170
;
```

Suppose that the data are multivariate normally distributed and the missing data are missing at random (MAR). That is, the probability that an observation is missing can depend on the observed variable values of the individual, but not on the missing variable values of the individual. See the “[Statistical Assumptions for Multiple Imputation](#)” section on page 2537 for a detailed description of the MAR assumption.

The following statements invoke the MI procedure and impute missing values for the FitMiss data set.

```
proc mi data=FitMiss seed=501213 mu0=50 10 180 out=outmi;
  var Oxygen RunTime RunPulse;
run;
```

The MI Procedure	
Model Information	
Data Set	WORK.FITMISS
Method	MCMC
Multiple Imputation Chain	Single Chain
Initial Estimates for MCMC	EM Posterior Mode
Start	Starting Value
Prior	Jeffreys
Number of Imputations	5
Number of Burn-in Iterations	200
Number of Iterations	100
Seed for random number generator	501213

Figure 44.1. Model Information

The “Model Information” table displayed in [Figure 44.1](#) describes the method used in the multiple imputation process. By default, the procedure uses the Markov Chain Monte Carlo (MCMC) method with a single chain to create five imputations. The posterior mode, the highest observed-data posterior density, with a noninformative prior, is computed from the EM algorithm and is used as the starting value for the chain.

The MI procedure takes 200 burn-in iterations before the first imputation and 100 iterations between imputations. In a Markov chain, the information in the current iteration has influence on the state of the next iteration. The burn-in iterations are iterations in the beginning of each chain that are used both to eliminate the series of dependence on the starting value of the chain and to achieve the stationary distribution. The between-imputation iterations in a single chain are used to eliminate the series of dependence between the two imputations.

The MI Procedure					
Missing Data Patterns					
Group	Oxygen	Run Time	Run Pulse	Freq	Percent
1	X	X	X	21	67.74
2	X	X	.	4	12.90
3	X	.	.	3	9.68
4	.	X	X	1	3.23
5	.	X	.	2	6.45

Missing Data Patterns

Group	Oxygen	RunTime	RunPulse
1	46.353810	10.809524	171.666667
2	47.109500	10.137500	.
3	52.461667	.	.
4	.	11.950000	176.000000
5	.	9.885000	.

Figure 44.2. Missing Data Patterns

The “Missing Data Patterns” table displayed in [Figure 44.2](#) lists distinct missing data patterns with corresponding frequencies and percents. Here, an “X” means that the variable is observed in the corresponding group and a “.” means that the variable is missing. The table also displays group-specific variable means. The MI procedure sorts the data into groups based on whether an individual’s value is observed or missing for each variable to be analyzed. For a detailed description of missing data patterns, see the “Missing Data Patterns” section on page 2538.

The MI Procedure				
Multiple Imputation Variance Information				
-----Variance-----				
Variable	Between	Within	Total	DF
Oxygen	0.056930	0.954041	1.022356	25.549
RunTime	0.000811	0.064496	0.065469	27.721
RunPulse	0.922032	3.269089	4.375528	15.753

Multiple Imputation Variance Information			
Variable	Relative Increase in Variance	Fraction Missing Information	Relative Efficiency
Oxygen	0.071606	0.068898	0.986408
RunTime	0.015084	0.014968	0.997015
RunPulse	0.338455	0.275664	0.947748

Figure 44.3. Variance Information

After the completion of m imputations, the “Multiple Imputation Variance Information” table shown in [Figure 44.3](#) displays the between-imputation variance, within-imputation variance, and total variance for combining complete-data inferences. It also displays the degrees of freedom for the total variance. The relative increase in variance due to missing values, the fraction of missing information, and the relative efficiency (in units of variance) for each variable are also displayed. A detailed description of these statistics is provided in the “[Combining Inferences from Multiply Imputed Data Sets](#)” section on page 2561.

The following “Multiple Imputation Parameter Estimates” table shown in [Figure 44.4](#) displays the estimated mean and standard error of the mean for each variable. The inferences are based on the t distribution. The table also displays a 95% confidence interval for the mean and a t statistic with the associated p -value for the hypothesis that the population mean is equal to the value specified with the MU0= option. A detailed description of these statistics is provided in the “[Combining Inferences from Multiply Imputed Data Sets](#)” section on page 2561.

The MI Procedure					
Multiple Imputation Parameter Estimates					
Variable	Mean	Std Error	95% Confidence Limits		DF
Oxygen	47.094040	1.011116	45.0139	49.1742	25.549
RunTime	10.572073	0.255870	10.0477	11.0964	27.721
RunPulse	171.787793	2.091776	167.3478	176.2278	15.753
Multiple Imputation Parameter Estimates					
Variable	Minimum	Maximum	Mu0	t for H0: Mean=Mu0	Pr > t
Oxygen	46.783898	47.395550	50.000000	-2.87	0.0081
RunTime	10.526392	10.599616	10.000000	2.24	0.0336
RunPulse	170.774818	173.122002	180.000000	-3.93	0.0012

Figure 44.4. Parameter Estimates

In addition to the output tables, the procedure also creates a data set with imputed values. The imputed data sets are stored in the `outmi` data set, with the index variable `_Imputation_` indicating the imputation numbers. The data set can now be analyzed using standard statistical procedures with `_Imputation_` as a BY variable.

The following statements list the first ten observations of data set `outmi`.

```
proc print data=outmi (obs=10);
    title 'First 10 Observations of the Imputed Data Set';
run;
```

First 10 Observations of the Imputed Data Set				
Obs	_Imputation_	Oxygen	RunTime	Run Pulse
1	1	44.6090	11.3700	178.000
2	1	45.3130	10.0700	185.000
3	1	54.2970	8.6500	156.000
4	1	59.5710	8.0747	155.925
5	1	49.8740	9.2200	176.837
6	1	44.8110	11.6300	176.000
7	1	42.8857	11.9500	176.000
8	1	46.9992	10.8500	173.099
9	1	39.4420	13.0800	174.000
10	1	60.0550	8.6300	170.000

Figure 44.5. Imputed Data Set

The table displayed in [Figure 44.5](#) shows that the precision of the imputed values differs from the precision of the observed values. You can use the ROUND= option to make the imputed values consistent with the observed values.

Syntax

The following statements are available in PROC MI.

```

PROC MI < options > ;
  BY variables ;
  CLASS variables ;
  EM < options > ;
  FREQ variable ;
  MCMC < options > ;
  MONOTONE < options > ;
  TRANSFORM transform ( variables < / options > )
    < ... transform ( variables < / options > ) > ;
  VAR variables ;

```

The BY statement specifies groups in which separate multiple imputation analyses are performed.

The CLASS statement lists the classification variables in the VAR statement. Classification variables can be either character or numeric.

The EM statement uses the EM algorithm to compute the maximum likelihood estimate (MLE) of the data with missing values, assuming a multivariate normal distribution for the data.

The FREQ statement specifies the variable that represents the frequency of occurrence for other values in the observation.

The MCMC statement uses a Markov chain Monte Carlo method to impute values for a data set with an arbitrary missing pattern, assuming a multivariate normal distribution for the data.

The MONOTONE statement specifies monotone methods to impute continuous and CLASS variables for a data set with a monotone missing pattern. Note that you can use either an MCMC statement or a MONOTONE statement, but not both. When neither of these two statements is specified, the MCMC method with its default options is used.

The TRANSFORM statement lists the variables to be transformed before the imputation process. The imputed values of these transformed variables will be reverse-transformed to the original forms before the imputation.

The VAR statement lists the numeric variables to be analyzed. If you omit the VAR statement, all numeric variables not listed in other statements are used.

The PROC MI statement is the only required statement for the MI procedure. The rest of this section provides detailed syntax information for each of these statements, beginning with the PROC MI statement. The remaining statements are in alphabetical order.

PROC MI Statement

PROC MI < options > ;

The following table summarizes the options available in the PROC MI statement.

Table 44.1. Summary of PROC MI Options

Tasks	Options
Specify data sets	
input data set	DATA=
output data set with imputed values	OUT=
Specify imputation details	
number of imputations	NIMPUTE=
seed to begin random number generator	SEED=
units to round imputed variable values	ROUND=
maximum values for imputed variable values	MAXIMUM=
minimum values for imputed variable values	MINIMUM=
maximum number of iterations to impute values in the specified range	MINMAXITER=
singularity tolerance	SINGULAR=
Specify statistical analysis	
level for the confidence interval, $(1 - \alpha)$	ALPHA=
means under the null hypothesis	MU0=
Control printed output	
suppress all displayed output	NOPRINT
displays univariate statistics and correlations	SIMPLE

The following options can be used in the PROC MI statement (in alphabetical order):

ALPHA= α

specifies that confidence limits be constructed for the mean estimates with confidence level $100(1 - \alpha)\%$, where $0 < \alpha < 1$. The default is ALPHA=0.05.

DATA=SAS-data-set

names the SAS data set to be analyzed by PROC MI. By default, the procedure uses the most recently created SAS data set.

MAXIMUM=numbers

specifies maximum values for imputed variables. When an intended imputed value is greater than the maximum, PROC MI redraws another value for imputation. If only one number is specified, that number is used for all variables. If more than one number is specified, you must use a VAR statement, and the specified numbers must correspond to variables in the VAR statement. The default number is a missing value, which indicates no restriction on the maximum for the corresponding variable

The MAXIMUM= option is related to the MINIMUM= and ROUND= options, which are used to make the imputed values more consistent with the observed variable values. These options are applicable only if you use the MCMC method or the monotone regression method.

When specifying a maximum for the first variable only, you must also specify a missing value after the maximum. Otherwise, the maximum is used for all variables. For example, the MAXIMUM= 100 . option sets a maximum of 100 for the first analysis variable only and no maximum for the remaining variables. The MAXIMUM= . 100 option sets a maximum of 100 for the second analysis variable only and no maximum for the other variables.

MINIMUM=numbers

specifies the minimum values for imputed variables. When an intended imputed value is less than the minimum, PROC MI redraws another value for imputation. If only one number is specified, that number is used for all variables. If more than one number is specified, you must use a VAR statement, and the specified numbers must correspond to variables in the VAR statement. The default number is a missing value, which indicates no restriction on the minimum for the corresponding variable

MINMAXITER=number

specifies the maximum number of iterations for imputed values to be in the specified range when the option MINIMUM or MAXIMUM is also specified. The default is MINMAXITER=100.

MU0=numbers

THETA0=numbers

specifies the parameter values μ_0 under the null hypothesis $\mu = \mu_0$ for the population means corresponding to the analysis variables. Each hypothesis is tested with a t test. If only one number is specified, that number is used for all variables. If more than one number is specified, you must use a VAR statement, and the specified numbers must correspond to variables in the VAR statement. The default is MU0=0.

If a variable is transformed as specified in a TRANSFORM statement, then the same transformation for that variable is also applied to its corresponding specified MU0= value in the t test. If the parameter values μ_0 for a transformed variable is not specified, then a value of zero is used for the resulting μ_0 after transformation.

NIMPUTE=number

specifies the number of imputations. The default is NIMPUTE=5. You can specify NIMPUTE=0 to skip the imputation. In this case, only tables of model information, missing data patterns, descriptive statistics (SIMPLE option), and MLE from the EM algorithm (EM statement) are displayed.

NOPRINT

suppresses the display of all output. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 14, “Using the Output Delivery System,” for more information.

OUT=SAS-data-set

creates an output SAS data set containing imputation results. The data set includes an index variable, `_Imputation_`, to identify the imputation number. For each imputation, the data set contains all variables in the input data set with missing values being replaced by the imputed values. See the “Output Data Sets” section on page 2559 for a description of this data set.

ROUND=numbers

specifies the units to round variables in the imputation. If only one number is specified, that number is used for all continuous variables. If more than one number is specified, you must use a VAR statement, and the specified numbers must correspond to variables in the VAR statement. When the CLASS variables are listed in the VAR statement, their corresponding roundoff units are not used. The default number is a missing value, which indicates no rounding for imputed variables.

When specifying a roundoff unit for the first variable only, you must also specify a missing value after the roundoff unit. Otherwise, the roundoff unit is used for all variables. For example, the option “ROUND= 10 .” sets a roundoff unit of 10 for the first analysis variable only and no rounding for the remaining variables. The option “ROUND= . 10” sets a roundoff unit of 10 for the second analysis variable only and no rounding for other variables.

The ROUND= option sets the precision of imputed values. For example, with a roundoff unit of 0.001, each value is rounded to the nearest multiple of 0.001. That is, each value has three significant digits after the decimal point. See Example 44.3 for an illustration of this option.

SEED=number

specifies a positive integer to start the pseudo-random number generator. The default is a value generated from reading the time of day from the computer’s clock. However, in order to duplicate the results under identical situations, you must use the same value of the seed explicitly in subsequent runs of the MI procedure.

The seed information is displayed in the “Model Information” table so that the results can be reproduced by specifying this seed with the SEED= option. You need to specify the same seed number in the future to reproduce the results.

SIMPLE

displays simple descriptive univariate statistics and pairwise correlations from available cases. For a detailed description of these statistics, see the “Descriptive Statistics” section on page 2535.

SINGULAR= p

specifies the criterion for determining the singularity of a covariance matrix based on standardized variables, where $0 < p < 1$. The default is SINGULAR=1E-8.

Suppose that \mathbf{S} is a covariance matrix and v is the number of variables in \mathbf{S} . Based on the spectral decomposition $\mathbf{S} = \mathbf{\Gamma}\mathbf{\Lambda}\mathbf{\Gamma}'$, where $\mathbf{\Lambda}$ is a diagonal matrix of eigenvalues λ_j , $j = 1, \dots, v$, where $\lambda_i \geq \lambda_j$ when $i < j$, and $\mathbf{\Gamma}$ is a matrix with the corresponding orthonormal eigenvectors of \mathbf{S} as columns, \mathbf{S} is considered singular when an eigenvalue λ_j is less than $p\bar{\lambda}$, where the average $\bar{\lambda} = \sum_{k=1}^v \lambda_k / v$.

BY Statement

BY variables ;

You can specify a BY statement with PROC MI to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the MI procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure.

For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

CLASS Statement (Experimental)

CLASS *variables* ;

The CLASS statement specifies the classification variables in the VAR statement. Classification variables can be either character or numeric. The CLASS statement must be used in conjunction with the MONOTONE statement.

Class levels are determined from the formatted values of the CLASS variables. Refer to the chapter titled “The FORMAT Procedure” in the *SAS Procedures Guide*.

EM Statement

EM < *options* > ;

The expectation-maximization (EM) algorithm is a technique for maximum likelihood estimation in parametric models for incomplete data. The EM statement uses the EM algorithm to compute the MLE for (μ, Σ) , the means and covariance matrix, of a multivariate normal distribution from the input data set with missing values. Either the means and covariances from complete cases or the means and standard deviations from available cases can be used as the initial estimates for the EM algorithm. You can also specify the correlations for the estimates from available cases.

You can also use the EM statement with the NIMPUTE=0 option in the PROC statement to compute the EM estimates without multiple imputation, as shown in [Example 44.1](#) in the “Examples” section on page 2568.

The following seven options are available with the EM statement.

CONVERGE=*p*

XCONV=*p*

sets the convergence criterion. The value must be between 0 and 1. The iterations are considered to have converged when the change in the parameter estimates between iteration steps is less than p for each parameter. That is, for each of the means and covariances. For each parameter, the change is a relative change if the parameter is greater than 0.01 in absolute value; otherwise, it is an absolute change. By default, CONVERGE=1E-4.

INITIAL=CC | AC | AC(R=*r*)

sets the initial estimates for the EM algorithm. The INITIAL=CC option uses the means and covariances from complete cases, the INITIAL=AC option uses the means and standard deviations from available cases and the correlations are set to zero, and the INITIAL=AC(R= r) option uses the means and standard deviations from available cases with correlation r , where $-1/(p-1) < r < 1$ and p is the number of variables to be analyzed. The default is INITIAL=AC.

ITPRINT

prints the iteration history in the EM algorithm.

MAXITER=number

specifies the maximum number of iterations used in the EM algorithm. The default is MAXITER=200.

OUT=SAS-data-set

creates an output SAS data set containing results from the EM algorithm. The data set contains all variables in the input data set with missing values being replaced by the expected values from the EM algorithm. See the “[Output Data Sets](#)” section on page 2559 for a description of this data set.

OUTEM=SAS-data-set

creates an output SAS data set of TYPE=COV containing the MLE of the parameter vector (μ , Σ). These estimates are computed with the EM algorithm. See the “[Output Data Sets](#)” section on page 2559 for a description of this output data set.

OUTITER < (options) > =SAS-data-set

creates an output SAS data set of TYPE=COV containing parameters for each iteration. The data set includes a variable named `_Iteration_` to identify the iteration number. The parameters in the output data set depend on the options specified. You can specify the MEAN and COV options to output the mean and covariance parameters. When no options are specified, the output data set contains the mean parameters for each iteration. See the “[Output Data Sets](#)” section on page 2559 for a description of this data set.

FREQ Statement

FREQ *variable* ;

If one variable in your input data set represents the frequency of occurrence for other values in the observation, specify the variable name in a FREQ statement. PROC MI then treats the data set as if each observation appears n times, where n is the value of the FREQ variable for the observation. If the value of the FREQ variable is less than one, the observation is not used in the analysis. Only the integer portion of the value is used. The total number of observations is considered to be equal to the sum of the FREQ variable when PROC MI calculates significance probabilities.

MCMC Statement

MCMC < *options* > ;

The MCMC statement specifies the details of the MCMC method for imputation.

The following table summarizes the options available for the MCMC statement.

Table 44.2. Summary of Options in MCMC

Tasks	Options
Specify data sets	
input parameter estimates for imputations	INEST=
output parameter estimates used in imputations	OUTEST=
output parameter estimates used in iterations	OUTITER=
Specify imputation details	
monotone/full imputation	IMPUTE=
single/multiple chain	CHAIN=
number of burn-in iterations for each chain	NBITER=
number of iterations between imputations in a chain	NITER=
initial parameter estimates for MCMC	INITIAL=
prior parameter information	PRIOR=
starting parameters	START=
Specify output graphics	
displays time-series plots	TIMEPLOT=
displays autocorrelation plots	ACFPLOT=
graphics catalog name for saving graphics output	GOUT=
Control printed output	
displays worst linear function	WLF
displays initial parameter values for MCMC	DISPLAYINIT

The following options are available for the MCMC statement (in alphabetical order):

ACFPLOT < (*options* < / *display-options* >) >

displays the autocorrelation function plots of parameters from iterations.

The available options are:

COV < (< *variables* > < *variable1*variable2* > < ... *variable1*variable2* >) >

displays plots of variances for variables in the list and covariances for pairs of variables in the list. When the option COV is specified without variables, variances for all variables and covariances for all pairs of variables are used.

MEAN < (*variables*) >

displays plots of means for variables in the list. When the option MEAN is specified without variables, all variables are used.

WLF

displays the plot for the worst linear function.

When the ACFPLOT is specified without the preceding options, the procedure displays plots of means for all variables that are used.

The display-options provide additional information for the autocorrelation function plots. The available display-options are:

CCONF=*color*

specifies the color of the displayed confidence limits. The default is CCONF=BLACK.

CFRAME=*color*

specifies the color for filling the area enclosed by the axes and the frame. By default, this area is not filled.

CNEEDLES=*color*

specifies the color of the vertical line segments (needles) that connect autocorrelations to the reference line. The default is CNEEDLES=BLACK.

CREF=*color*

specifies the color of the displayed reference line. The default is CREF=BLACK.

CSYMBOL=*color*

specifies the color of the displayed data points. The default is CSYMBOL=BLACK.

HSYMBOL=*number*

specifies the height for data points in percentage screen units. The default is HSYMBOL=1.

LCONF=*linetype*

specifies the line type for the displayed confidence limits. The default is LCONF=1, a solid line.

LOG

requests that the logarithmic transformations of parameters be used to compute the autocorrelations. It's generally used for the variances of variables. When a parameter has values less than or equal to zero, the corresponding plot is not created.

LREF=*linetype*

specifies the line type for the displayed reference line. The default is LREF=3, a dashed line.

NLAG=*number*

specifies the maximum lag of the series. The default is NLAG=20. The autocorrelations at each lag are displayed in the graph.

SYMBOL=*value*

specifies the symbol for data points in percentage screen units. The default is SYMBOL=STAR.

TITLE=*'string'*

specifies the title to be displayed in the autocorrelation function plots. The default is TITLE='Autocorrelation Plot'.

WCONF=number

specifies the width for the displayed confidence limits in percentage screen units. If you specify the WCONF=0 option, the confidence limits are not displayed. The default is WCONF=1.

WNEEDLES=number

specifies the width for the displayed needles that connect autocorrelations to the reference line in percentage screen units. If you specify the WNEEDLES=0 option, the needles are not displayed. The default is WNEEDLES=1.

WREF=number

specifies the width for the displayed reference line in percentage screen units. If you specify the WREF=0 option, the reference line is not displayed. The default is WREF=1.

For example, the statement

```
acfplot( mean( y1) cov(y1) /log);
```

requests autocorrelation function plots for the means and variances of the variable *y1*, respectively. Logarithmic transformations of both the means and variances are used in the plots. For a detailed description of the autocorrelation function plot, see the “[Autocorrelation Function Plot](#)” section on page 2557; refer also to Schafer (1997, pp. 120-126) and the *SAS/ETS User’s Guide*.

CHAIN=SINGLE | MULTIPLE

specifies whether a single chain is used for all imputations or a separate chain is used for each imputation. The default is CHAIN=SINGLE.

DISPLAYINIT

displays initial parameter values in the MCMC process for each imputation.

GOUT=graphics-catalog

specifies the graphics catalog for saving graphics output from PROC MI. The default is WORK.GSEG. For more information, refer to the chapter “The GREPLAY Procedure” in *SAS/GRAPH Software: Reference*.

IMPUTE=FULL | MONOTONE

specifies whether a full-data imputation is used for all missing values or a monotone-data imputation is used for a subset of missing values to make the imputed data sets have a monotone missing pattern. The default is IMPUTE=FULL. When IMPUTE=MONOTONE is specified, the order in the VAR statement is used to complete the monotone pattern.

INEST=SAS-data-set

names a SAS data set of TYPE=EST containing parameter estimates for imputations. These estimates are used to impute values for observations in the DATA= data set. A detailed description of the data set is provided in the “[Input Data Sets](#)” section on page 2558.

INITIAL=EM < (options) >

INITIAL=INPUT=SAS-data-set

specifies the initial mean and covariance estimates for the MCMC process. The default is INITIAL=EM.

You can specify INITIAL=INPUT=SAS-data-set to read the initial estimates of the mean and covariance matrix for each imputation from a SAS data set. See the “[Input Data Sets](#)” section on page 2558 for a description of this data set.

With INITIAL=EM, PROC MI derives parameter estimates for a posterior mode, the highest observed-data posterior density, from the EM algorithm. The MLE from EM is used to start the EM algorithm for the posterior mode, and the resulting EM estimates are used to begin the MCMC process. The prior information specified in the PRIOR= option is also used in the process to compute the posterior mode.

The following four options are available with INITIAL=EM.

BOOTSTRAP < =number >

requests bootstrap resampling, which uses a simple random sample with replacement from the input data set for the initial estimate. You can explicitly specify the number of observations in the random sample. Alternatively, you can implicitly specify the number of observations in the random sample by specifying the proportion p , $0 < p \leq 1$, to request $[np]$ observations in the random sample, where n is the number of observations in the data set and $[np]$ is the integer part of np . This produces an overdispersed initial estimate that provides different starting values for the MCMC process. If you specify the BOOTSTRAP option without the number, $p=0.75$ is used by default.

CONVERGE= p

XCONV= p

sets the convergence criterion. The value must be between 0 and 1. The iterations are considered to have converged when the change in the parameter estimates between iteration steps is less than p for each parameter. That is, for each of the means and covariances. For each parameter, the change is a relative change if the parameter is greater than 0.01 in absolute value; otherwise, it is an absolute change. By default, CONVERGE=1E-4.

ITPRINT

prints the iteration history in the EM algorithm for the posterior mode.

MAXITER= $number$

specifies the maximum number of iterations used in the EM algorithm. The default is MAXITER=200.

NBITER=number

specifies the number of burn-in iterations before the first imputation in each chain. The default is NBITER=200.

NITER=number

specifies the number of iterations between imputations in a single chain. The default is NITER=100.

OUTEST=SAS-data-set

creates an output SAS data set of TYPE=EST. The data set contains parameter estimates used in each imputation. The data set also includes a variable named `_Imputation_` to identify the imputation number. See the “[Output Data Sets](#)” section on page 2559 for a description of this data set.

OUTITER < (options) > =SAS-data-set

creates an output SAS data set of TYPE=COV containing parameters used in the imputation step for each iteration. The data set includes variables named `_Imputation_` and `_Iteration_` to identify the imputation number and iteration number.

The parameters in the output data set depend on the options specified. You can specify options MEAN, STD, COV, LR, LR_POST, and WLF to output parameters of means, standard deviations, covariances, -2 log LR statistic, -2 log LR statistic of the posterior mode, and the worst linear function. When no options are specified, the output data set contains the mean parameters used in the imputation step for each iteration. See the “[Output Data Sets](#)” section on page 2559 for a description of this data set.

PRIOR=name

specifies the prior information for the means and covariances. Valid values for *name* are as follows:

JEFFREYS	specifies a noninformative prior.
RIDGE=number	specifies a ridge prior.
INPUT=SAS-data-set	specifies a data set containing prior information.

For a detailed description of the prior information, see the “[Bayesian Estimation of the Mean Vector and Covariance Matrix](#)” section on page 2549 and the “[Posterior Step](#)” section on page 2550. If you do not specify the PRIOR= option, the default is PRIOR=JEFFREYS.

The PRIOR=INPUT= option specifies a TYPE=COV data set from which the prior information of the mean vector and the covariance matrix is read. See the “[Input Data Sets](#)” section on page 2558 for a description of this data set.

START=VALUE | DIST

specifies that the initial parameter estimates are used as either the starting value (START=VALUE) or as the starting distribution (START=DIST) in the first imputation step of each chain. If the IMPUTE=MONOTONE option is specified, then START=VALUE is used in the procedure. The default is START=VALUE.

TIMEPLOT < (*options* < / *display-options* >) >

displays the time-series plots of parameters from iterations.

The available options are:

COV < (< *variables* > < *variable1*variable2* > < . . . *variable1*variable2* >) >

displays plots of variances for variables in the list and covariances for pairs of variables in the list. When the option COV is specified without variables, variances for all variables and covariances for all pairs of variables are used.

MEAN < (*variables*) >

displays plots of means for variables in the list. When the option MEAN is specified without variables, all variables are used.

WLF

displays the plot for the worst linear function.

When the TIMEPLOT is specified without the preceding options, the procedure displays plots of means for all variables are used.

The display-options provide additional information for the time-series plots. The available display-options are:

CCONNECT=*color*

specifies the color for the line segments that connect data points in the time-series plots. The default is CCONNECT=BLACK.

CFRAME=*color*

specifies the color for filling the area enclosed by the axes and the frame. By default, this area is not filled.

CSYMBOL=*color*

specifies the color of the data points to be displayed in the time-series plots. The default is CSYMBOL=BLACK.

HSYMBOL=*number*

specifies the height for data points in percentage screen units. The default is HSYMBOL=1.

LCONNECT=*linetype*

specifies the line type for the line segments that connect data points in the time-series plots. The default is LCONNECT=1, a solid line.

LOG

requests that the logarithmic transformations of parameters be used. It's generally used for the variances of variables. When a parameter value is less than or equal to zero, the value is not displayed in the corresponding plot.

SYMBOL=*value*

specifies the symbol for data points in percentage screen units. The default is SYMBOL=PLUS.

TITLE=*'string'*

specifies the title to be displayed in the time-series plots. The default is TITLE='Time-series Plot for Iterations'.

WCONNECT=number

specifies the width for the line segments that connect data points in the time-series plots in percentage screen units. If you specify the WCONNECT=0 option, the data points are not connected. The default is WCONNECT=1.

For a detailed description of the time-series plot, see the “[Time-Series Plot](#)” section on page 2556 and Schafer (1997, pp. 120–126).

WLF

displays the worst linear function of parameters. This scalar function of parameters μ and Σ is “worst” in the sense that its values from iterations converge most slowly among parameters. For a detailed description of this statistic, see the “[Worst Linear Function of Parameters](#)” section on page 2556.

MONOTONE Statement

MONOTONE < *method* < (< *imputed* < = *effects* > > < / *options* >) >
>

< ... *method* < (< *imputed* < = *effects* > > < / *options* >) > > ;

The MONOTONE statement specifies imputation methods for data sets with monotone missingness. You must also specify a VAR statement and the data set must have a monotone missing pattern with variables ordered in the VAR list. When both MONOTONE and MCMC statements are specified, the MONOTONE statement is not used.

For each method, you can specify the imputed variables and optionally, a set of the effects to impute these variables. Each effect is a variable or a combination of variables preceding the imputed variable in the VAR statement. The syntax for specification of effects is the same as for the GLM procedure. See [Chapter 32, “The GLM Procedure,”](#) for more information.

One general form of an effect involving several variables is

$$X1 * X2 * A * B * C (D E)$$

where A, B, C, D, and E are class variables and X1 and X2 are continuous variables.

If no covariates are specified, then all preceding variables are used as the covariates. That is, each preceding continuous variable is used as a regressor effect, and each preceding class variable is used as a main effect. For the discriminant function method, only the continuous variables can be used as covariate effects.

When a method for continuous variables is specified without imputed variables, the method is used for all continuous variables in the VAR statement that are not specified in other methods. Similarly, when a method for class variables is specified without imputed variables, the method is used for all class variables in the VAR statement that are not specified in other methods.

When a MONOTONE statement is used without specifying any methods, the regression method is used for all continuous variables and the discriminant function method

is used for all class variables. The preceding variables of each imputed variable in the VAR statement are used as the covariates.

With a MONOTONE statement, the variables are imputed sequentially in the order given by the VAR statement. For a continuous variable, you can use a regression method, a regression predicted mean matching method, or a propensity score method to impute missing values.

For a nominal class variable, you can use a discriminant function method to impute missing values without using the ordering of the class levels. For an ordinal class variable, you can use a logistic regression method to impute missing values using the ordering of the class levels. For a binary class variable, either a discriminant function method or a logistic regression method can be used.

Note that except for the regression method, all other methods impute values from the observed observation values. You can specify the following methods in a MONOTONE statement.

DISCRIM < (*imputed* < = *effects* > < / *options* >) >

specifies the discriminant function method of class variables. Only the continuous variables are allowed as covariate effects. The available options are DETAILS, PCOV=, and PRIOR=. The DETAILS option displays the group means and pooled covariance matrix used in each imputation. The PCOV= option specifies the pooled covariance used in the discriminant method. Valid values for the PCOV= option are:

FIXED	uses the observed-data pooled covariance matrix for each imputation.
POSTERIOR	draws a pooled covariance matrix from its posterior distribution.

The default is PCOV=POSTERIOR. See the “[Discriminant Function Method for Monotone Missing Data](#)” section on page 2544 for a detailed description of the method.

The PRIOR= option specifies the prior probabilities of group membership. Valid values for the PRIOR= option are:

EQUAL	set the prior probabilities equal for all groups.
PROPORTIONAL	set the prior probabilities proportion to the group sample sizes.
JEFFREYS < = <i>c</i> >	specifies a noninformative prior, $0 < c < 1$. If the number <i>c</i> is not specified, JEFFREYS=0.5.
RIDGE < = <i>d</i> >	specifies a ridge prior, $d > 0$. If the number <i>d</i> is not specified, RIDGE=0.25.

The default is PRIOR=JEFFREYS. See the “[Discriminant Function Method for Monotone Missing Data](#)” section on page 2544 for a detailed description of the method.

LOGISTIC < (*imputed* < = *effects* > < / *options* >) >

specifies the logistic regression method of class variables. The available options are DETAILS, ORDER=, and DESCENDING. The DETAILS option displays the regression coefficients in the logistic regression model used in each imputation.

When the imputed variable has more than two response levels, the ordinal logistic regression method is used. The ORDER= option specifies the sorting order for the levels of the response variable. Valid values for the ORDER= option are:

DATA	sorts by the order of appearance in the input data set
FORMATTED	sorts by their external formatted values
FREQ	sorts by the descending frequency counts
INTERNAL	sorts by the unformatted values

By default, ORDER=FORMATTED.

The option DESCENDING reverses the sorting order for the levels of the response variables.

See the [“Logistic Regression Method for Monotone Missing Data”](#) section on page 2546 for a detailed description of the method.

REG | REGRESSION < (*imputed* < = *effects* > < / **DETAILS** >) >

specifies the regression method of continuous variables. The DETAILS option displays the regression coefficients in the regression model used in each imputation.

With a regression method, the MAXIMUM=, MINIMUM=, and ROUND= options can be used to make the imputed values more consistent with the observed variable values.

See the [“Regression Method for Monotone Missing Data”](#) section on page 2541 for a detailed description of the method.

REGPMM < (*imputed* < = *effects* > < / *options* >) >

REGPREDMEANMATCH < (*imputed* < = *effects* > < / *options* >) >

specifies the predictive mean matching method for continuous variables. This method is similar to the regression method except that it imputes a value randomly from a set of observed values whose predicted values are closest to the predicted value for the missing value from the simulated regression model (Heitjan and Little 1991; Schenker and Taylor 1996).

The available options are DETAILS and K=. The DETAILS option displays the regression coefficients in the regression model used in each imputation. The K= option specifies the number of closest observations to be used in the selection. The default is K=5.

Note that an optimal K= value is currently not available in the literature on multiple imputation. The default K=5 is experimental and may change in future releases.

See the [“Predictive Mean Matching Method for Monotone Missing Data”](#) section on page 2542 for a detailed description of the method.

PROPENSITY < (*imputed* < = *effects* > < / *options* >) >

specifies the propensity scores method of variables. Each variable is either a class variable or a continuous variable. The available options are DETAILS and NGROUPS=. The DETAILS option displays the regression coefficients in the logistic regression model for propensity scores. The NGROUPS= option specifies the number of groups created based on propensity scores. The default is NGROUPS=5.

See the “Propensity Score Method for Monotone Missing Data” section on page 2543 for a detailed description of the method.

With a MONOTONE statement, the missing values of a variable are imputed when the variable is either explicitly specified in the method or implicitly specified when a method is specified without imputed variables. These variables are imputed sequentially in the order specified in the VAR statement. For example, the following MI procedure

```
proc mi;
  class c1;
  var y1 y2 c1 y3;
  monotone reg(y3= y1 y2 c1) logistic(c1= y1 y2 y1*y2);
run;
```

uses the logistic regression method to impute variable *c1* from effects *y1*, *y2*, and $y1 * y2$ first, then uses the regression method to impute variable *y3* from effects *y1*, *y2*, and *c1*. The variables *y1* and *y2* are not imputed since *y1* is the leading variable in the VAR statement and *y2* is not specified as an imputed variable in the MONOTONE statement.

TRANSFORM Statement

TRANSFORM *transform* (*variables* < / *options* >)

< ... *transform* (*variables* < / *options* >) > ;

The TRANSFORM statement lists the transformations and their associated variables to be transformed. The options are transformation options that provide additional information for the transformation.

The MI procedure assumes that the data are from a multivariate normal distribution when either the regression method or the MCMC method is used. When some variables in a data set are clearly non-normal, it is useful to transform these variables to conform to the multivariate normality assumption. With a TRANSFORM statement, variables are transformed before the imputation process and these transformed variable values are displayed in all of the results. When you specify an OUT= option, the variable values are back-transformed to create the imputed data set.

The following transformations can be used in the TRANSFORM statement.

BOXCOX

specifies the Box-Cox transformation of variables. The variable *Y* is transformed to $\frac{(Y+c)^{\lambda}-1}{\lambda}$, where *c* is a constant such that each value of $Y + c$ must be positive and the constant $\lambda > 0$.

EXP

specifies the exponential transformation of variables. The variable Y is transformed to $e^{(Y+c)}$, where c is a constant.

LOG

specifies the logarithmic transformation of variables. The variable Y is transformed to $\log(Y + c)$, where c is a constant such that each value of $Y + c$ must be positive.

LOGIT

specifies the logit transformation of variables. The variable Y is transformed to $\log\left(\frac{Y/c}{1-Y/c}\right)$, where the constant $c > 0$ and the values of Y/c must be between 0 and 1.

POWER

specifies the power transformation of variables. The variable Y is transformed to $(Y + c)^\lambda$, where c is a constant such that each value of $Y + c$ must be positive and the constant $\lambda \neq 0$.

The following options provide the constant c and λ values in the transformations.

C=number

specifies the c value in the transformation. The default is $c = 1$ for logit transformation and $c = 0$ for other transformations.

LAMBDA=number

specifies the λ value in the power and Box-Cox transformations. You must specify the λ value for these two transformations.

For example, the statement

```
transform log(y1) power(y2/c=1 lambda=.5);
```

requests that variables $\log(y1)$, a logarithmic transformation for the variable $y1$, and $\sqrt{y2 + 1}$, a power transformation for the variable $y2$, be used in the imputation.

If the `MU0=` option is used to specify a parameter value μ_0 for a transformed variable, the same transformation for the variable is also applied to its corresponding `MU0=` value in the t test. Otherwise, $\mu_0 = 0$ is used for the transformed variable. See [Example 44.10](#) for a usage of the `TRANSFORM` statement.

VAR Statement

```
VAR variables;
```

The `VAR` statement lists the variables to be analyzed. The variables can be either character or numeric. If you omit the `VAR` statement, all continuous variables not mentioned in other statements are used. The `VAR` statement is required if you specify a `MONOTONE` statement, an `IMPUTE=MONOTONE` option in the `MCMC` statement, or more than one number in the `MU0=`, `MAXIMUM=`, `MINIMUM=`, or `ROUND=` option.

The character variables are allowed only when they are specified as `CLASS` variables and the `MONOTONE` statement is also specified.

Details

Descriptive Statistics

Suppose $\mathbf{Y} = (\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_n)'$ is the $(n \times p)$ matrix of complete data, which may not be fully observed, n_0 is the number of observations fully observed, and n_j is the number of observations with observed values for variable Y_j .

With complete cases, the sample mean vector is

$$\bar{\mathbf{y}} = \frac{1}{n_0} \sum \mathbf{y}_i$$

and the CSSCP matrix is

$$\sum (\mathbf{y}_i - \bar{\mathbf{y}})(\mathbf{y}_i - \bar{\mathbf{y}})'$$

where each summation is over the fully observed observations.

The sample covariance matrix is

$$\mathbf{S} = \frac{1}{n_0 - 1} \sum (\mathbf{y}_i - \bar{\mathbf{y}})(\mathbf{y}_i - \bar{\mathbf{y}})'$$

and is an unbiased estimate of the covariance matrix.

The correlation matrix \mathbf{R} containing the Pearson product-moment correlations of the variables is derived by scaling the corresponding covariance matrix:

$$\mathbf{R} = \mathbf{D}^{-1} \mathbf{S} \mathbf{D}^{-1}$$

where \mathbf{D} is a diagonal matrix whose diagonal elements are the square roots of the diagonal elements of \mathbf{S} .

With available cases, the corrected sum of squares for variable Y_j is

$$\sum (y_{ji} - \bar{y}_j)^2$$

where $\bar{y}_j = \frac{1}{n_j} \sum y_{ji}$ is the sample mean and each summation is over observations with observed values for variable Y_j .

The variance is

$$s_{jj}^2 = \frac{1}{n_j - 1} \sum (y_{ji} - \bar{y}_j)^2$$

The correlations for available cases contain pairwise correlations for each pair of variables. Each correlation is computed from all observations that have nonmissing values for the corresponding pair of variables.

EM Algorithm for Data with Missing Values

The EM algorithm (Dempster, Laird, and Rubin 1977) is a technique that finds maximum likelihood estimates in parametric models for incomplete data. The books by Little and Rubin (1987), Schafer (1997), and McLachlan and Krishnan (1997) provide detailed description and applications of the EM algorithm.

The EM algorithm is an iterative procedure that finds the MLE of the parameter vector by repeating the following steps:

1. The expectation E-step:

Given a set of parameter estimates, such as a mean vector and covariance matrix for a multivariate normal distribution, the E-step calculates the conditional expectation of the complete-data log likelihood given the observed data and the parameter estimates.

2. The maximization M-step:

Given a complete-data log likelihood, the M-step finds the parameter estimates to maximize the complete-data log likelihood from the E-step.

The two steps are iterated until the iterations converge.

In the EM process, the observed-data log likelihood is non-decreasing at each iteration. For multivariate normal data, suppose there are G groups with distinct missing patterns. Then the observed-data log likelihood being maximized can be expressed as

$$\log L(\boldsymbol{\theta}|Y_{obs}) = \sum_{g=1}^G \log L_g(\boldsymbol{\theta}|Y_{obs})$$

where $\log L_g(\boldsymbol{\theta}|Y_{obs})$ is the observed-data log likelihood from the g_{th} group, and

$$\log L_g(\boldsymbol{\theta}|Y_{obs}) = -\frac{n_g}{2} \log |\boldsymbol{\Sigma}_g| - \frac{1}{2} \sum_{ig} (\mathbf{y}_{ig} - \boldsymbol{\mu}_g)' \boldsymbol{\Sigma}_g^{-1} (\mathbf{y}_{ig} - \boldsymbol{\mu}_g)$$

where n_g is the number of observations in the g_{th} group, the summation is over observations in the g_{th} group, \mathbf{y}_{ig} is a vector of observed values corresponding to observed variables, $\boldsymbol{\mu}_g$ is the corresponding mean vector, and $\boldsymbol{\Sigma}_g$ is the associated covariance matrix.

A sample covariance matrix is computed at each step of the EM algorithm. If the covariance matrix is singular, the linearly dependent variables for the observed data are excluded from the likelihood function. That is, for each observation with linear dependency among its observed variables, the dependent variables are excluded from the likelihood function. Note that this may result in an unexpected change in the likelihood between iterations prior to the final convergence.

Refer to Schafer (1997, pp. 163–181) for a detailed description of the EM algorithm for multivariate normal data.

PROC MI uses the means and standard deviations from available cases as the initial estimates for the EM algorithm. The correlations are set to zero. It provides a good

starting value with positive definite covariance matrix. For a discussion of suggested starting values for the algorithm, see Schafer (1997, p. 169).

You can specify the convergence criterion with the CONVERGE= option in the EM statement. The iterations are considered to have converged when the maximum change in the parameter estimates between iteration steps is less than the value specified. You can also specify the maximum number of iterations used in the EM algorithm with the MAXITER= option.

The MI procedure displays tables of the initial parameter estimates used to begin the EM process and the MLE parameter estimates derived from EM. You can also display the EM iteration history with the ITPRINT option. PROC MI lists the iteration number, the likelihood $-2 \text{ Log } L$, and the parameter values μ at each iteration. You can also save the MLE derived from the EM algorithm in a SAS data set specified with the OUTEM= option.

Statistical Assumptions for Multiple Imputation

The MI procedure assumes that the data are from a continuous multivariate distribution and contain missing values that can occur for any of the variables. It also assumes that the data are from a multivariate normal distribution when either the regression method or the MCMC method is used.

Suppose \mathbf{Y} is the $n \times p$ matrix of complete data, which is not fully observed, and denote the observed part of \mathbf{Y} by \mathbf{Y}_{obs} and the missing part by \mathbf{Y}_{mis} . The SAS MI and MIANALYZE procedures assume that the missing data are missing at random (MAR), that is, the probability that an observation is missing can depend on \mathbf{Y}_{obs} , but not on \mathbf{Y}_{mis} (Rubin 1976; 1987, p. 53).

To be more precise, suppose that \mathbf{R} is the $n \times p$ matrix of response indicators whose elements are zero or one depending on whether the corresponding elements of \mathbf{Y} are missing or observed. Then the MAR assumption is that the distribution of \mathbf{R} can depend on \mathbf{Y}_{obs} but not on \mathbf{Y}_{mis} .

$$\text{pr}(\mathbf{R} | \mathbf{Y}_{obs}, \mathbf{Y}_{mis}) = \text{pr}(\mathbf{R} | \mathbf{Y}_{obs})$$

For example, consider a trivariate data set with variables Y_1 and Y_2 fully observed, and a variable Y_3 that has missing values. MAR assumes that the probability that Y_3 is missing for an individual can be related to the individual's values of variables Y_1 and Y_2 , but not to its value of Y_3 . On the other hand, if a complete case and an incomplete case for Y_3 with exactly the same values for variables Y_1 and Y_2 have systematically different values, then there exists a response bias for Y_3 , and MAR is violated.

The MAR assumption is not the same as missing completely at random (MCAR), which is a special case of MAR. Under the MCAR assumption, the missing data values are a simple random sample of all data values; the missingness does not depend on the values of any variables in the data set.

Although the MAR assumption cannot be verified with the data and it can be questionable in some situations, the assumption becomes more plausible as more variables are included in the imputation model (Schafer 1997, pp. 27–28; van Buuren, Boshuizen, and Knook, 1999, p. 687).

Furthermore, the MI and MIANALYZE procedures assume that the parameters θ of the data model and the parameters ϕ of the model for the missing data indicators are distinct. That is, knowing the values of θ does not provide any additional information about ϕ , and vice versa. If both the MAR and distinctness assumptions are satisfied, the missing-data mechanism is said to be ignorable (Rubin 1987, pp. 50–54; Schafer 1997, pp. 10–11).

Missing Data Patterns

The MI procedure sorts the data into groups based on whether an individual's value is observed or missing for each variable to be analyzed. Note that the input data set does not need to be sorted in any order.

For example, with variables Y_1 , Y_2 , and Y_3 (in that order) in a data set, up to eight groups of observations can be formed from the data set. The following figure displays the eight groups of observations and a unique missing pattern for each group:

Missing Data Patterns				
Group	Y1	Y2	Y3	
1	X	X	X	
2	X	X	.	
3	X	.	X	
4	X	.	.	
5	.	X	X	
6	.	X	.	
7	.	.	X	
8	.	.	.	

Figure 44.6. Missing Data Patterns

Here, an “X” means that the variable is observed in the corresponding group and a “.” means that the variable is missing.

The variable order is used to derive the order of the groups from the data set, and thus, determines the order of missing values in the data to be imputed. If you specify a different order of variables in the VAR statement, then the results are different even if the other specifications remain the same.

A data set with variables Y_1, Y_2, \dots, Y_p (in that order) is said to have a *monotone missing pattern* when the event that a variable Y_j is missing for a particular individual implies that all subsequent variables $Y_k, k > j$, are missing for that individual. Alternatively, when a variable Y_j is observed for a particular individual, it is assumed that all previous variables $Y_k, k < j$, are also observed for that individual.

For example, the following figure displays a data set of three variables with a monotone missing pattern.

Monotone Missing Data Patterns			
Group	Y1	Y2	Y3
1	X	X	X
2	X	X	.
3	X	.	.

Figure 44.7. Monotone Missing Patterns

The following figure displays a data set of three variables with a non-monotone missing pattern.

Non-monotone Missing Data Patterns			
Group	Y1	Y2	Y3
1	X	X	X
2	X	.	X
3	.	X	.
4	.	.	X

Figure 44.8. Non-monotone Missing Patterns

A data set with an *arbitrary missing pattern* is a data set with either a monotone missing pattern or a non-monotone missing pattern.

Imputation Methods

This section describes the methods for multiple imputation that are available in the MI procedure. The method of choice depends on the pattern of missingness in the data and the type of the imputed variable, as summarized in the following table:

Table 44.3. Imputation Methods in PROC MI

Pattern of Missingness	Type of Imputed Variable	Recommended Methods
Monotone	Continuous	<ul style="list-style-type: none"> • Regression • Predicted Mean Matching • Propensity Score
Monotone	Classification (Ordinal)	<ul style="list-style-type: none"> • Logistic Regression
Monotone	Classification (Nominal)	<ul style="list-style-type: none"> • Discriminant Function Method
Arbitrary	Continuous	<ul style="list-style-type: none"> • MCMC Full-Data Imputation • MCMC Monotone-Data Imputation

To impute missing values for a continuous variable in data sets with monotone missing patterns, you should use either a parametric method that assumes multivariate normality or a nonparametric method that uses propensity scores (Rubin 1987, p. 124, 158; Lavori, Dawson, and Shera 1995). Parametric methods available include the regression method (Rubin 1987, pp. 166–167) and the predictive mean matching method (Heitjan and Little 1991; Schenker and Taylor 1996).

To impute missing values for a CLASS variable in data sets with monotone missing patterns, you should use the logistic regression method or the discriminant function method. Use the logistic regression method when the CLASS variable has a binary or ordinal response, and the discriminant function method when the CLASS variable has a binary or nominal response.

For continuous variables in data sets with arbitrary missing patterns, you can use the Markov Chain Monte Carlo (MCMC) method (Schafer 1997) to impute either all the missing values or just enough missing values to make the imputed data sets have monotone missing patterns.

With a monotone missing data pattern, you have greater flexibility in your choice of imputation models. In addition to the MCMC method, you can implement other methods, such as the regression method, that do not use Markov chains. You can also specify a different set of covariates for each imputed variable.

With an arbitrary missing data pattern, you can often use the MCMC method, which creates multiple imputations by drawing simulations from a Bayesian predictive distribution for normal data. Another way to handle a data set with an arbitrary missing data pattern is to use the MCMC approach to impute just enough values to make the missing data pattern monotone. Then, you can use a more flexible imputation method. This approach is described in the [“Producing Monotone Missingness with the MCMC Method”](#) section on page 2552.

Although the regression and MCMC methods assume multivariate normality, inferences based on multiple imputation can be robust to departures from multivariate normality if the amount of missing information is not large, because the imputation model is effectively applied not to the entire data set but only to its missing part (Schafer 1997, pp. 147–148).

You can also use a TRANSFORM statement to transform variables to conform to the multivariate normality assumption. Variables are transformed before the imputation process and then are reverse-transformed to create the imputed data set.

Li (1988) presented a theoretical argument for convergence of the MCMC method in the continuous case and used it to create imputations for incomplete multivariate continuous data. In practice, however, it is not easy to check the convergence of a Markov chain, especially for a large number of parameters. PROC MI generates statistics and plots which you can use to check for convergence of the MCMC process. The details are described in the [“Checking Convergence in MCMC”](#) section on page 2555.

Regression Method for Monotone Missing Data

The regression method is the default imputation method for continuous variables in a data set with a monotone missing pattern.

In the regression method, a regression model is fitted for a continuous variable with the covariates constructed from a set of effects. Based on the fitted regression model, a new regression model is simulated from the posterior predictive distribution of the parameters and is used to impute the missing values for each variable (Rubin 1987, pp. 166–167). That is, for a continuous variable Y_j with missing values, a model

$$Y_j = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_k X_k$$

is fitted using observations with observed values for the variable Y_j and its covariates X_1, X_2, \dots, X_k .

The fitted model includes the regression parameter estimates $\hat{\beta} = (\hat{\beta}_0, \hat{\beta}_1, \dots, \hat{\beta}_k)$ and the associated covariance matrix $\hat{\sigma}_j^2 \mathbf{V}_j$, where \mathbf{V}_j is the usual $\mathbf{X}'\mathbf{X}$ inverse matrix derived from the intercept and covariates X_1, X_2, \dots, X_k .

The following steps are used to generate imputed values for each imputation:

1. New parameters $\beta_* = (\beta_{*0}, \beta_{*1}, \dots, \beta_{*(k)})$ and σ_{*j}^2 are drawn from the posterior predictive distribution of the parameters. That is, they are simulated from $(\hat{\beta}_0, \hat{\beta}_1, \dots, \hat{\beta}_k)$, σ_j^2 , and \mathbf{V}_j . The variance is drawn as

$$\sigma_{*j}^2 = \hat{\sigma}_j^2 (n_j - k - 1) / g$$

where g is a $\chi_{n_j - k - 1}^2$ random variate and n_j is the number of nonmissing observations for Y_j . The regression coefficients are drawn as

$$\beta_* = \hat{\beta} + \sigma_{*j} \mathbf{V}'_{hj} \mathbf{Z}$$

where \mathbf{V}'_{hj} is the upper triangular matrix in the Cholesky decomposition, $\mathbf{V}_j = \mathbf{V}'_{hj} \mathbf{V}_{hj}$, and \mathbf{Z} is a vector of $k + 1$ independent random normal variates.

2. The missing values are then replaced by

$$\beta_{*0} + \beta_{*1} x_1 + \beta_{*2} x_2 + \dots + \beta_{*(k)} x_k + z_i \sigma_{*j}$$

where x_1, x_2, \dots, x_k are the values of the covariates and z_i is a simulated normal deviate.

Predictive Mean Matching Method for Monotone Missing Data

The predictive mean matching method is also an imputation method available for continuous variables. It is similar to the regression method except that for each missing value, it imputes a value randomly from a set of observed values whose predicted values are closest to the predicted value for the missing value from the simulated regression model (Heitjan and Little 1991; Schenker and Taylor 1996).

Following the description of the model in the “[Regression Method for Monotone Missing Data](#)” section on page 2541, the following steps are used to generate imputed values:

1. New parameters $\beta_* = (\beta_{*0}, \beta_{*1}, \dots, \beta_{*(k)})$ and σ_{*j}^2 are drawn from the posterior predictive distribution of the parameters. That is, they are simulated from $(\hat{\beta}_0, \hat{\beta}_1, \dots, \hat{\beta}_k)$, σ_j^2 , and \mathbf{V}_j . The variance is drawn as

$$\sigma_{*j}^2 = \hat{\sigma}_j^2(n_j - k - 1)/g$$

where g is a $\chi_{n_j - k - 1}^2$ random variate and n_j is the number of nonmissing observations for Y_j . The regression coefficients are drawn as

$$\beta_* = \hat{\beta} + \sigma_{*j} \mathbf{V}'_{hj} \mathbf{Z}$$

where \mathbf{V}'_{hj} is the upper triangular matrix in the Cholesky decomposition, $\mathbf{V}_j = \mathbf{V}'_{hj} \mathbf{V}_{hj}$, and \mathbf{Z} is a vector of $k + 1$ independent random normal variates.

2. For each missing value, a predicted value

$$y_{i*} = \beta_{*0} + \beta_{*1} x_1 + \beta_{*2} x_2 + \dots + \beta_{*(k)} x_k$$

is computed with the covariate values x_1, x_2, \dots, x_k .

3. A set of k_0 observations whose corresponding predicted values are closest to y_{i*} is generated. You can specify k_0 with the `K=` option.
4. The missing value is then replaced by a value drawn randomly from these k_0 observed values.

The predictive mean matching method requires the number of closest observations to be specified. A smaller k_0 tends to increase the correlation among the multiple imputations for the missing observation and results in a higher variability of point estimators in repeated sampling. On the other hand, a larger k_0 tends to lessen the effect from the imputation model and results in biased estimators (Schenker and Taylor 1996, p. 430). An optimal k_0 is currently not available in the literature on multiple imputation. The default is `K=5`. This default value is experimental and may change in future releases.

The predictive mean matching method ensures that imputed values are plausible and may be more appropriate than the regression method if the normality assumption is violated (Horton and Lipsitz 2001, p. 246).

Note that in SAS 9.0, the predictive mean matching method replaces each missing value by the observed value closest to its predicted value. This may result in a higher variability of point estimators in repeated sampling (Schenker and Taylor 1996, p. 430).

Propensity Score Method for Monotone Missing Data

The propensity score method is another imputation method available for continuous variables when the data set has a monotone missing pattern.

A propensity score is generally defined as the conditional probability of assignment to a particular treatment given a vector of observed covariates (Rosenbaum and Rubin 1983). In the propensity score method, for a variable with missing values, a propensity score is generated for each observation to estimate the probability that the observation is missing. The observations are then grouped based on these propensity scores, and an approximate Bayesian bootstrap imputation (Rubin 1987, p. 124) is applied to each group (Lavori, Dawson, and Shera 1995).

The propensity score method uses the following steps to impute values for variable Y_j with missing values:

1. Create an indicator variable R_j with the value 0 for observations with missing Y_j and 1 otherwise.
2. Fit a logistic regression model

$$\text{logit}(p_j) = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_k X_k$$

where X_1, X_2, \dots, X_k are covariates for Y_j , $p_j = Pr(R_j = 0 | X_1, X_2, \dots, X_k)$, and $\text{logit}(p) = \log(p/(1-p))$.

3. Create a propensity score for each observation to estimate the probability that it is missing.
4. Divide the observations into a fixed number of groups (typically assumed to be five) based on these propensity scores.
5. Apply an approximate Bayesian bootstrap imputation to each group. In group k , suppose that Y_{obs} denotes the n_1 observations with nonmissing Y_j values and Y_{mis} denotes the n_0 observations with missing Y_j . The approximate Bayesian bootstrap imputation first draws n_1 observations randomly with replacement from Y_{obs} to create a new data set Y_{obs}^* . This is a nonparametric analogue of drawing parameters from the posterior predictive distribution of the parameters. The process then draws the n_0 values for Y_{mis} randomly with replacement from Y_{obs}^* .

Steps 1 through 5 are repeated sequentially for each variable with missing values.

Note that the propensity score method was originally designed for a randomized experiment with repeated measures on the response variables. The goal was to impute the missing values on the response variables. The method uses only the covariate information that is associated with whether the imputed variable values are missing. It does not use correlations among variables. It is effective for inferences about the

distributions of individual imputed variables, such as an univariate analysis, but it is not appropriate for analyses involving relationship among variables, such as a regression analysis (Schafer 1999, p. 11). It can also produce badly biased estimates of regression coefficients when data on predictor variables are missing (Allison 2000).

Discriminant Function Method for Monotone Missing Data

The discriminant function method is the default imputation method for CLASS variables in a data set with a monotone missing pattern.

For a nominal class variable Y_j with responses $1, \dots, g$, and a set of effects from its preceding variables, if the covariates X_1, X_2, \dots, X_k associated with these effects within each group is approximately multivariate normal and the within-group covariance matrices are approximately equal, the discriminant function method (Brand 1999, pp. 95–96) can be used to impute missing values for the variable Y_j .

Denote the group-specific means for covariates X_1, X_2, \dots, X_k by

$$\bar{\mathbf{X}}_t = (\bar{X}_{t1}, \bar{X}_{t2}, \dots, \bar{X}_{tk}), \quad t = 1, 2, \dots, g$$

then the pooled covariance matrix is computed as

$$\mathbf{S} = \frac{1}{n - g} \sum_{t=1}^g (n_t - 1) \mathbf{S}_t$$

where \mathbf{S}_t is the within-group covariance matrix, n_t is the group-specific sample size, and $n = \sum_{t=1}^g n_t$ is the total sample size.

In each imputation, new parameters of the group-specific means (\mathbf{m}_{*t}), pooled covariance matrix (\mathbf{S}_*), and prior probabilities of group membership (q_{*t}) can be drawn from their corresponding posterior distributions (Schafer 1997, p. 356).

Pooled Covariance Matrix and Group-specific Means

For each imputation, the MI procedure uses either the fixed observed pooled covariance matrix (PCOV=FIXED) or a drawn pooled covariance matrix (PCOV=POSTERIOR) from its posterior distribution with a noninformative prior. That is,

$$\Sigma | \mathbf{X} \sim W^{-1}(n - g, (n - g)\mathbf{S})$$

where W^{-1} is an inverted Wishart distribution.

The group-specific means are then drawn from their posterior distributions with a noninformative prior

$$\boldsymbol{\mu}_t | (\Sigma, \bar{\mathbf{X}}_t) \sim N\left(\bar{\mathbf{X}}_t, \frac{1}{n_t} \Sigma\right)$$

See the “Bayesian Estimation of the Mean Vector and Covariance Matrix” section on page 2549 for a complete description of the inverted Wishart distribution and posterior distributions using a noninformative prior.

Prior Probabilities of Group Membership

The prior probabilities are computed through the drawing of new group sample sizes. When the total sample size n is considered fixed, the group sample sizes (n_1, n_2, \dots, n_g) has a multinomial distribution. A new multinomial parameters (group sample sizes) can be drawn from its posterior distribution using a Dirichlet prior with parameters $(\alpha_1, \alpha_2, \dots, \alpha_g)$.

After the new sample sizes are drawn from the posterior distribution of (n_1, n_2, \dots, n_g) , the prior probabilities q_{*t} are computed proportionally to the drawn sample sizes.

Refer to Schafer (1997, pp. 247–255) for a complete description of the Dirichlet prior.

Imputation Steps

The discriminant function method uses the following steps in each imputation to impute values for a nominal class variable Y_j with g responses:

1. Draw a pooled covariance matrix \mathbf{S}_* from its posterior distribution if the PCOV=POSTERIOR option is used.
2. For each group, draw group means \mathbf{m}_{*t} from the observed group mean $\bar{\mathbf{X}}_t$ and either the observed pooled covariance matrix (PCOV=FIXED) or the drawn pooled covariance matrix \mathbf{S}_* (PCOV=POSTERIOR).
3. For each group, compute or draw q_{*t} , prior probabilities of group membership, based on the PRIOR= option:
 - PRIOR=EQUAL, $q_{*t} = 1/g$, prior probabilities of group membership are all equal.
 - PRIOR=PROPORTIONAL, $q_{*t} = n_t/n$, prior probabilities are proportional to their group sample sizes.
 - PRIOR=JEFFREYS= c , a noninformative Dirichlet prior with $\alpha_t = c$ is used.
 - PRIOR=RIDGE= d , a ridge prior is used with $\alpha_t = d * n_t/n$ for $d \geq 1$ and $\alpha_t = d * n_t$ for $d < 1$.
4. With the group means \mathbf{m}_{*t} , the pooled covariance matrix \mathbf{S}_* , and the prior probabilities of group membership q_{*t} , the discriminant function method derives linear discriminant function and computes the posterior probabilities of an observation belonging to each group

$$p_t(\mathbf{x}) = \frac{\exp(-0.5D_t^2(\mathbf{x}))}{\sum_{u=1}^g \exp(-0.5D_u^2(\mathbf{x}))}$$

where $D_t^2(\mathbf{x}) = (\mathbf{x} - \mathbf{m}_{*t})' \mathbf{S}_*^{-1} (\mathbf{x} - \mathbf{m}_{*t}) - 2 \log(q_{*t})$ is the generalized squared distance from \mathbf{x} to group t .

5. Draw a random uniform variate u , between 0 and 1, for each observation with missing group value. With the posterior probabilities, $p_1(\mathbf{x}) + p_2(\mathbf{x}) + \dots + p_g(\mathbf{x}) = 1$, the discriminant function method imputes $Y_j = 1$ if the value of u is less than $p_1(\mathbf{x})$, $Y_j = 2$ if the value is greater than or equal to $p_1(\mathbf{x})$ but less than $p_1(\mathbf{x}) + p_2(\mathbf{x})$, and so on.

Logistic Regression Method for Monotone Missing Data

The logistic regression method is another imputation method available for CLASS variables in a data set with a monotone missing pattern.

In the logistic regression method, a logistic regression model is fitted for a class variable with a set of covariates constructed from the effects. For a binary class variable, based on the fitted regression model, a new logistic regression model is simulated from the posterior predictive distribution of the parameters and is used to impute the missing values for each variable (Rubin 1987, pp. 169–170).

For a binary variable Y_j with responses 1 and 2, a logistic regression model is fitted using observations with observed values for the imputed variable Y_j and its covariates X_1, X_2, \dots, X_k .

$$\text{logit}(p_j) = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_k X_k$$

where X_1, X_2, \dots, X_k are covariates for Y_j , $p_j = \Pr(R_j = 1 | X_1, X_2, \dots, X_k)$, and $\text{logit}(p) = \log(p/(1-p))$.

The fitted model includes the regression parameter estimates $\hat{\beta} = (\hat{\beta}_0, \hat{\beta}_1, \dots, \hat{\beta}_k)$ and the associated covariance matrix \mathbf{V}_j .

The following steps are used to generate imputed values for a binary variable Y_j with responses 1 and 2:

1. New parameters $\beta_* = (\beta_{*0}, \beta_{*1}, \dots, \beta_{*(k)})$ are drawn from the posterior predictive distribution of the parameters.

$$\beta_* = \hat{\beta} + \mathbf{V}'_{hj} \mathbf{Z}$$

where \mathbf{V}'_{hj} is the upper triangular matrix in the Cholesky decomposition, $\mathbf{V}_j = \mathbf{V}'_{hj} \mathbf{V}_{hj}$, and \mathbf{Z} is a vector of $k+1$ independent random normal variates.

2. For an observation with missing Y_j and covariates x_1, x_2, \dots, x_k , compute the expected probability that $Y_j = 1$.

$$p_j = \frac{\exp(\mu_j)}{1 + \exp(\mu_j)}$$

where $\mu_j = \beta_{*0} + \beta_{*1} x_1 + \beta_{*2} x_2 + \dots + \beta_{*(k)} x_k$.

3. Draw a random uniform variate, u , between 0 and 1. If the value of u is less than p_j , impute $Y_j = 1$, otherwise impute $Y_j = 2$.

The preceding logistic regression method can be extended to include the ordinal class variables with more than two levels of responses. The options ORDER= and DESCENDING can be used to specify the sorting order for the levels of the imputed variables.

MCMC Method for Arbitrary Missing Data

The Markov Chain Monte Carlo (MCMC) method originated in physics as a tool for exploring equilibrium distributions of interacting molecules. In statistical applications, it is used to generate pseudo-random draws from multidimensional and otherwise intractable probability distributions via Markov chains. A Markov chain is a sequence of random variables in which the distribution of each element depends only on the value of the previous one.

In MCMC simulation, one constructs a Markov chain long enough for the distribution of the elements to stabilize to a stationary distribution, which is the distribution of interest. By repeatedly simulating steps of the chain, the method simulates draws from the distribution of interest. Refer to Schafer (1997) for a detailed discussion of this method.

In Bayesian inference, information about unknown parameters is expressed in the form of a posterior probability distribution. This posterior distribution is computed using Bayes' theorem

$$p(\boldsymbol{\theta}|y) = \frac{p(y|\boldsymbol{\theta})p(\boldsymbol{\theta})}{\int p(y|\boldsymbol{\theta})p(\boldsymbol{\theta})d\boldsymbol{\theta}}$$

MCMC has been applied as a method for exploring posterior distributions in Bayesian inference. That is, through MCMC, one can simulate the entire joint posterior distribution of the unknown quantities and obtain simulation-based estimates of posterior parameters that are of interest.

In many incomplete data problems, the observed-data posterior $p(\boldsymbol{\theta}|Y_{obs})$ is intractable and cannot easily be simulated. However, when Y_{obs} is augmented by an estimated/simulated value of the missing data Y_{mis} , the complete-data posterior $p(\boldsymbol{\theta}|Y_{obs}, Y_{mis})$ is much easier to simulate. Assuming that the data are from a multivariate normal distribution, data augmentation can be applied to Bayesian inference with missing data by repeating the following steps:

1. The imputation I-step:

Given an estimated mean vector and covariance matrix, the I-step simulates the missing values for each observation independently. That is, if you denote the variables with missing values for observation i by $Y_{i(mis)}$ and the variables with observed values by $Y_{i(obs)}$, then the I-step draws values for $Y_{i(mis)}$ from a conditional distribution for $Y_{i(mis)}$ given $Y_{i(obs)}$.

2. The posterior P-step:

Given a complete sample, the P-step simulates the posterior population mean vector and covariance matrix. These new estimates are then used in the next I-step. Without prior information about the parameters, a noninformative prior is used. You can also use other informative priors. For example, a prior information about the covariance matrix can be helpful to stabilize the inference about the mean vector for a near singular covariance matrix.

The two steps are iterated long enough for the results to be reliable for a multiply imputed data set (Schafer 1997, p. 72). That is, with a current parameter estimate $\theta^{(t)}$ at the t th iteration, the I-step draws $Y_{mis}^{(t+1)}$ from $p(Y_{mis}|Y_{obs}, \theta^{(t)})$ and the P-step draws $\theta^{(t+1)}$ from $p(\theta|Y_{obs}, Y_{mis}^{(t+1)})$.

This creates a Markov chain

$$(Y_{mis}^{(1)}, \theta^{(1)}), (Y_{mis}^{(2)}, \theta^{(2)}), \dots,$$

which converges in distribution to $p(Y_{mis}, \theta|Y_{obs})$. Assuming the iterates converge to a stationary distribution, the goal is to simulate an approximately independent draw of the missing values from this distribution.

To validate the imputation results, you should repeat the process with different random number generators and starting values based on different initial parameter estimates.

The next three sections provide details for the imputation step, Bayesian estimation of the mean vector and covariance matrix, and the posterior step.

Imputation Step

In each iteration, starting with a given mean vector μ and covariance matrix Σ , the imputation step draws values for the missing data from the conditional distribution Y_{mis} given Y_{obs} .

Suppose $\mu = [\mu_1', \mu_2']'$ is the partitioned mean vector of two sets of variables, Y_{obs} and Y_{mis} , where μ_1 is the mean vector for variables Y_{obs} and μ_2 is the mean vector for variables Y_{mis} .

Also suppose

$$\Sigma = \begin{bmatrix} \Sigma_{11} & \Sigma_{12} \\ \Sigma_{12}' & \Sigma_{22} \end{bmatrix}$$

is the partitioned covariance matrix for these variables, where Σ_{11} is the covariance matrix for variables Y_{obs} , Σ_{22} is the covariance matrix for variables Y_{mis} , and Σ_{12} is the covariance matrix between variables Y_{obs} and variables Y_{mis} .

By using the sweep operator (Goodnight 1979) on the pivots of the Σ_{11} submatrix, the matrix becomes

$$\begin{bmatrix} \Sigma_{11}^{-1} & \Sigma_{11}^{-1}\Sigma_{12} \\ -\Sigma'_{12}\Sigma_{11}^{-1} & \Sigma_{22.1} \end{bmatrix}$$

where $\Sigma_{22.1} = \Sigma_{22} - \Sigma'_{12}\Sigma_{11}^{-1}\Sigma_{12}$ can be used to compute the conditional covariance matrix of \mathbf{Y}_{mis} after controlling for \mathbf{Y}_{obs} .

For an observation with the preceding missing pattern, the conditional distribution of \mathbf{Y}_{mis} given $\mathbf{Y}_{obs} = \mathbf{y}_1$ is a multivariate normal distribution with the mean vector

$$\boldsymbol{\mu}_{2.1} = \boldsymbol{\mu}_2 + \Sigma'_{12}\Sigma_{11}^{-1}(\mathbf{y}_1 - \boldsymbol{\mu}_1)$$

and the conditional covariance matrix

$$\Sigma_{22.1} = \Sigma_{22} - \Sigma'_{12}\Sigma_{11}^{-1}\Sigma_{12}$$

Bayesian Estimation of the Mean Vector and Covariance Matrix

Suppose that $\mathbf{Y} = (\mathbf{y}'_1, \mathbf{y}'_2, \dots, \mathbf{y}'_n)'$ is an $(n \times p)$ matrix made up of n $(p \times 1)$ independent vectors \mathbf{y}_i , each of which has a multivariate normal distribution with mean zero and covariance matrix $\mathbf{\Lambda}$. Then the SSCP matrix

$$\mathbf{A} = \mathbf{Y}'\mathbf{Y} = \sum_i \mathbf{y}_i \mathbf{y}'_i$$

has a Wishart distribution $W(n, \mathbf{\Lambda})$.

When each observation \mathbf{y}_i is distributed with a multivariate normal distribution with an unknown mean $\boldsymbol{\mu}$, then the CSSCP matrix

$$\mathbf{A} = \sum_i (\mathbf{y}_i - \bar{\mathbf{y}})(\mathbf{y}_i - \bar{\mathbf{y}})'$$

has a Wishart distribution $W(n - 1, \mathbf{\Lambda})$.

If \mathbf{A} has a Wishart distribution $W(n, \mathbf{\Lambda})$, then $\mathbf{B} = \mathbf{A}^{-1}$ has an inverted Wishart distribution $W^{-1}(n, \boldsymbol{\Psi})$, where n is the degrees of freedom and $\boldsymbol{\Psi} = \mathbf{\Lambda}^{-1}$ is the precision matrix (Anderson 1984).

Note that, instead of using the parameter $\boldsymbol{\Psi} = \mathbf{\Lambda}^{-1}$ for the inverted Wishart distribution, Schafer (1997) uses the parameter $\mathbf{\Lambda}$.

Suppose that each observation in the data matrix \mathbf{Y} has a multivariate normal distribution with mean $\boldsymbol{\mu}$ and covariance matrix Σ . Then with a prior inverted Wishart distribution for Σ and a prior normal distribution for $\boldsymbol{\mu}$

$$\begin{aligned} \Sigma &\sim W^{-1}(m, \boldsymbol{\Psi}) \\ \boldsymbol{\mu} | \Sigma &\sim N\left(\boldsymbol{\mu}_0, \frac{1}{\tau}\Sigma\right) \end{aligned}$$

where $\tau > 0$ is a fixed number.

The posterior distribution (Anderson 1984, p. 270; Schafer 1997, p. 152) is

$$\begin{aligned}\Sigma|\mathbf{Y} &\sim W^{-1}\left(n+m, (n-1)\mathbf{S} + \Psi + \frac{n\tau}{n+\tau}(\bar{\mathbf{y}} - \boldsymbol{\mu}_0)(\bar{\mathbf{y}} - \boldsymbol{\mu}_0)'\right) \\ \boldsymbol{\mu} | (\Sigma, \mathbf{Y}) &\sim N\left(\frac{1}{n+\tau}(n\bar{\mathbf{y}} + \tau\boldsymbol{\mu}_0), \frac{1}{n+\tau}\Sigma\right)\end{aligned}$$

where $(n-1)\mathbf{S}$ is the CSSCP matrix.

Posterior Step

In each iteration, the posterior step simulates the posterior population mean vector $\boldsymbol{\mu}$ and covariance matrix Σ from prior information for $\boldsymbol{\mu}$ and Σ , and the complete sample estimates.

You can specify the prior parameter information using one of the following methods:

- PRIOR=JEFFREYS, which uses a noninformative prior.
- PRIOR=INPUT=, which provides a prior information for Σ in the data set. Optionally, it also provides a prior information for $\boldsymbol{\mu}$ in the data set.
- PRIOR=RIDGE=, which uses a ridge prior.

The next four subsections provide details of the posterior step for different prior distributions.

1. A Noninformative Prior

Without prior information about the mean and covariance estimates, a noninformative prior can be used by specifying the PRIOR=JEFFREYS option. The posterior distributions (Schafer 1997, p. 154) are

$$\begin{aligned}\Sigma^{(t+1)}|\mathbf{Y} &\sim W^{-1}(n-1, (n-1)\mathbf{S}) \\ \boldsymbol{\mu}^{(t+1)} | (\Sigma^{(t+1)}, \mathbf{Y}) &\sim N\left(\bar{\mathbf{y}}, \frac{1}{n}\Sigma^{(t+1)}\right)\end{aligned}$$

2. An Informative Prior for $\boldsymbol{\mu}$ and Σ

When prior information is available for the parameters $\boldsymbol{\mu}$ and Σ , you can provide it with a SAS data set that you specify with the PRIOR=INPUT= option.

$$\begin{aligned}\Sigma &\sim W^{-1}(d^*, d^*\mathbf{S}^*) \\ \boldsymbol{\mu}|\Sigma &\sim N\left(\boldsymbol{\mu}_0, \frac{1}{n_0}\Sigma\right)\end{aligned}$$

To obtain the prior distribution for Σ , PROC MI reads the matrix \mathbf{S}^* from observations in the data set with `_TYPE_='COV'`, and it reads $n^* = d^* + 1$ from observations with `_TYPE_='N'`.

To obtain the prior distribution for $\boldsymbol{\mu}$, PROC MI reads the mean vector $\boldsymbol{\mu}_0$ from observations with `_TYPE_='MEAN'`, and it reads n_0 from observations with `_TYPE_='N_MEAN'`. When there are no observations with `_TYPE_='N_MEAN'`, PROC MI reads n_0 from observations with `_TYPE_='N'`.

The resulting posterior distribution, as described in the “[Bayesian Estimation of the Mean Vector and Covariance Matrix](#)” section on page 2549, is given by

$$\begin{aligned}\boldsymbol{\Sigma}^{(t+1)}|\mathbf{Y} &\sim W^{-1}(n+d^*, (n-1)\mathbf{S}+d^*\mathbf{S}^*+\mathbf{S}_m) \\ \boldsymbol{\mu}^{(t+1)}|\left(\boldsymbol{\Sigma}^{(t+1)}, \mathbf{Y}\right) &\sim N\left(\frac{1}{n+n_0}(n\bar{\mathbf{y}}+n_0\boldsymbol{\mu}_0), \frac{1}{n+n_0}\boldsymbol{\Sigma}^{(t+1)}\right)\end{aligned}$$

where

$$\mathbf{S}_m = \frac{nn_0}{n+n_0}(\bar{\mathbf{y}}-\boldsymbol{\mu}_0)(\bar{\mathbf{y}}-\boldsymbol{\mu}_0)'$$

3. An Informative Prior for $\boldsymbol{\Sigma}$

When the sample covariance matrix \mathbf{S} is singular or near singular, prior information about $\boldsymbol{\Sigma}$ can also be used without prior information about $\boldsymbol{\mu}$ to stabilize the inference about $\boldsymbol{\mu}$. You can provide it with a SAS data set that you specify with the `PRIOR=INPUT=` option.

To obtain the prior distribution for $\boldsymbol{\Sigma}$, PROC MI reads the matrix \mathbf{S}^* from observations in the data set with `_TYPE_='COV'`, and it reads n^* from observations with `_TYPE_='N'`.

The resulting posterior distribution for $(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ (Schafer 1997, p. 156) is

$$\begin{aligned}\boldsymbol{\Sigma}^{(t+1)}|\mathbf{Y} &\sim W^{-1}(n+d^*, (n-1)\mathbf{S}+d^*\mathbf{S}^*) \\ \boldsymbol{\mu}^{(t+1)}|\left(\boldsymbol{\Sigma}^{(t+1)}, \mathbf{Y}\right) &\sim N\left(\bar{\mathbf{y}}, \frac{1}{n}\boldsymbol{\Sigma}^{(t+1)}\right)\end{aligned}$$

Note that if the `PRIOR=INPUT=` data set also contains observations with `_TYPE_='MEAN'`, then a complete informative prior for both $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ will be used.

4. A Ridge Prior

A special case of the preceding adjustment is a ridge prior with $\mathbf{S}^* = \text{Diag}(\mathbf{S})$ (Schafer 1997, p. 156). That is, \mathbf{S}^* is a diagonal matrix with diagonal elements equal to the corresponding elements in \mathbf{S} .

You can request a ridge prior by using the `PRIOR=RIDGE=` option. You can explicitly specify the number $d^* \geq 1$ in the `PRIOR=RIDGE= d^*` option. Or you can implicitly specify the number by specifying the proportion p in the `PRIOR=RIDGE= p` option to request $d^* = (n-1)p$.

The posterior is then given by

$$\begin{aligned}\Sigma^{(t+1)} | \mathbf{Y} &\sim W^{-1}(n + d^*, (n - 1)\mathbf{S} + d^*\text{Diag}(\mathbf{S})) \\ \boldsymbol{\mu}^{(t+1)} | (\Sigma^{(t+1)}, \mathbf{Y}) &\sim N\left(\bar{\mathbf{y}}, \frac{1}{n} \Sigma^{(t+1)}\right)\end{aligned}$$

Producing Monotone Missingness with the MCMC Method

The monotone data MCMC method was first proposed by Li (1988), and Liu (1993) described the algorithm. The method is useful especially when a data set is close to having a monotone missing pattern. In this case, the method only needs to impute a few missing values to the data set to have a monotone missing pattern in the imputed data set. Compared to a full data imputation that imputes all missing values, the monotone data MCMC method imputes fewer missing values in each iteration and achieves approximate stationarity in fewer iterations (Schafer 1997, p. 227).

You can request the monotone MCMC method by specifying the option `IMPUTE=MONOTONE` in the MCMC statement. The “Missing Data Patterns” table now denotes the variables with missing values by “.” or “O”. The value “.” means that the variable is missing and will be imputed and the value “O” means that the variable is missing and will not be imputed. The tables of “Multiple Imputation Variance Information” and “Multiple Imputation Parameter Estimates” are not created.

You must specify the variables in the VAR statement. The variable order in the list determines the monotone missing pattern in the imputed data set. With a different order in the VAR list, the results will be different because the monotone missing pattern to be constructed will be different.

Assuming that the data are from a multivariate normal distribution, then similar to the MCMC method, the monotone MCMC method repeats the following steps:

1. The imputation I-step:

Given an estimated mean vector and covariance matrix, the I-step simulates the missing values for each observation independently. Only a subset of missing values are simulated to achieve a monotone pattern of missingness.

2. The posterior P-step:

Given a new sample with a monotone pattern of missingness, the P-step simulates the posterior population mean vector and covariance matrix with a noninformative Jeffreys prior. These new estimates are then used in the next I-step.

Imputation Step

The I-step is almost identical to the I-step described in the “MCMC Method for Arbitrary Missing Data” section on page 2547 except that only a subset of missing values need to be simulated. To state this precisely, denote the variables with observed values for observation i by $Y_{i(obs)}$ and the variables with missing values by $Y_{i(mis)} = (Y_{i(m1)}, Y_{i(m2)})$, where $Y_{i(m1)}$ is a subset of the the missing variables that will result a monotone missingness when their values are imputed. Then the I-step draws values for $Y_{i(m1)}$ from a conditional distribution for $Y_{i(m1)}$ given $Y_{i(obs)}$.

Posterior Step

The P-step is different from the P-step described in the “MCMC Method for Arbitrary Missing Data” section on page 2547. Instead of simulating the $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ parameters from the full imputed data set, this P-step simulates the $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ parameters through simulated regression coefficients from regression models based on the imputed data set with a monotone pattern of missingness. The step is similar to the process described in the “Regression Method for Monotone Missing Data” section on page 2541.

That is, for the variable Y_j , a model

$$Y_j = \beta_0 + \beta_1 Y_1 + \beta_2 Y_2 + \dots + \beta_{j-1} Y_{j-1}$$

is fitted using n_j nonmissing observations for variable Y_j in the imputed data sets.

The fitted model consists of the regression parameter estimates $\hat{\boldsymbol{\beta}} = (\hat{\beta}_0, \hat{\beta}_1, \dots, \hat{\beta}_{j-1})$ and the associated covariance matrix $\hat{\sigma}_j^2 \mathbf{V}_j$, where \mathbf{V}_j is the usual $\mathbf{X}'\mathbf{X}$ inverse matrix from the intercept and variables Y_1, Y_2, \dots, Y_{j-1} .

For each imputation, new parameters $\boldsymbol{\beta}_* = (\beta_{*0}, \beta_{*1}, \dots, \beta_{*(j-1)})$ and σ_{*j}^2 are drawn from the posterior predictive distribution of the parameters. That is, they are simulated from $(\hat{\beta}_0, \hat{\beta}_1, \dots, \hat{\beta}_{j-1})$, $\hat{\sigma}_j^2$, and \mathbf{V}_j . The variance is drawn as

$$\sigma_{*j}^2 = \hat{\sigma}_j^2 (n_j - j) / g$$

where g is a $\chi_{n_j - p + j - 1}^2$ random variate and n_j is the number of nonmissing observations for Y_j . The regression coefficients are drawn as

$$\boldsymbol{\beta}_* = \hat{\boldsymbol{\beta}} + \sigma_{*j} \mathbf{V}'_{hj} \mathbf{Z}$$

where \mathbf{V}'_{hj} is the upper triangular matrix in the Cholesky decomposition $\mathbf{V}_j = \mathbf{V}'_{hj} \mathbf{V}_{hj}$ and \mathbf{Z} is a vector of j independent random normal variates.

These simulated values of $\boldsymbol{\beta}_*$ and σ_{*j}^2 are then used to re-create the parameters $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$. For a detailed description of how to produce monotone-missingness with the MCMC method for a multivariate normal data, refer to Schafer (1997, pp. 226–235).

MCMC Method Specifications

With MCMC, you can impute either all missing values (IMPUTE=FULL) or just enough missing values to make the imputed data set have a monotone missing pattern (IMPUTE=MONOTONE). In the process, either a single chain for all imputations (CHAIN=SINGLE) or a separate chain for each imputation (CHAIN=MULTIPLE) is used. The single chain may be somewhat more precise for estimating a single quantity such as posterior mean (Schafer 1997, p. 138). Refer to Schafer (1997, pp. 137–138) for a discussion of single versus multiple chains.

You can specify the number of initial burn-in iterations before the first imputation with the `NBITER=` option. This number is also used for subsequent chains for multiple chains. For a single chain, you can also specify the number of iterations between imputations with the `NITER=` option.

You can explicitly specify initial parameter values for the MCMC process with the `INITIAL=INPUT=` data set option. Alternatively, you can use the EM algorithm to derive a set of initial parameter values for MCMC with the option `INITIAL=EM`. These estimates are used as either the starting value (`START=VALUE`) or as the starting distribution (`START=DIST`) for the MCMC process. For multiple chains, these estimates are used again as either the starting value (`START=VALUE`) or as the starting distribution (`START=DIST`) for the subsequent chains.

You can specify the prior parameter information in the `PRIOR=` option. You can use a noninformative prior (`PRIOR=JEFFREYS`), a ridge prior (`PRIOR=RIDGE`), or an informative prior specified in a data set (`PRIOR=INPUT`).

The parameter estimates used to generate imputed values in each imputation can be saved in a data set with the `OUTEST=` option. Later, this data set can be read with the `INEST=` option to provide the reference distribution for imputing missing values for a new data set.

By default, the MCMC method uses a single chain to produce five imputations. It completes 200 burn-in iterations before the first imputation and 100 iterations between imputations. The posterior mode computed from the EM algorithm with a noninformative prior is used as the starting values for the MCMC process.

INITIAL=EM Specifications

The EM algorithm is used to find the maximum likelihood estimates for incomplete data in the EM statement. You can also use the EM algorithm to find a posterior mode, the parameter estimates that maximize the observed-data posterior density. The resulting posterior mode provides a good starting value for the MCMC process.

With `INITIAL=EM`, PROC MI uses the MLE of the parameter vector as the initial estimates in the EM algorithm for the posterior mode. You can use the `ITPRINT` option in `INITIAL=EM` to display the iteration history for the EM algorithm.

You can use the `CONVERGE=` option to specify the convergence criterion in deriving the EM posterior mode. The iterations are considered to have converged when the maximum change in the parameter estimates between iteration steps is less than the value specified. By default, `CONVERGE=1E-4`.

You can also use the `MAXITER=` option to specify the maximum number of iterations in the EM algorithm. By default, `MAXITER=200`.

With the `BOOTSTRAP` option, you can use overdispersed starting values for the MCMC process. In this case, PROC MI applies the EM algorithm to a bootstrap sample, a simple random sample with replacement from the input data set, to derive the initial estimates for each chain (Schafer 1997, p. 128).

Checking Convergence in MCMC

The theoretical convergence of the MCMC process has been explored under various conditions, as described in Schafer (1997, p. 70). However, in practice, verification of convergence is not a simple matter.

The parameters used in the imputation step for each iteration can be saved in an output data set with the `OUTITER=` option. These include the means, standard deviations, covariances, the worst linear function, and observed-data LR statistics. You can then monitor the convergence in a single chain by displaying time-series plots and autocorrelations for those parameter values (Schafer 1997, p. 120). The time-series and autocorrelation function plots for parameters such as variable means, covariances, and the worst linear function can be displayed by specifying the `TIMEPLOT` and `ACFPLOT` option.

You can apply EM to a bootstrap sample to obtain overdispersed starting values for multiple chains (Gelman and Rubin 1992). This provides a conservative estimate of the number of iterations needed before each imputation.

The next four subsections describe useful statistics and plots that can be used to check the convergence of the MCMC process.

LR Statistics

You can save the observed-data likelihood ratio (LR) statistic in each iteration with the `LR` option in the `OUTITER=` data set. The statistic is based on the observed-data likelihood with parameter values used in the iteration and the observed-data maximum likelihood derived from the EM algorithm.

In each iteration, the LR statistic is given by

$$-2 \log \left(\frac{f(\hat{\theta}_i)}{f(\hat{\theta})} \right)$$

where $f(\hat{\theta})$ is the observed-data maximum likelihood derived from the EM algorithm and $f(\hat{\theta}_i)$ is the observed-data likelihood for $\hat{\theta}_i$ used in the iteration.

Similarly, you can also save the observed-data LR posterior mode statistic for each iteration with the `LR_POST` option. This statistic is based on the observed-data posterior density with parameter values used in each iteration and the observed-data posterior mode derived from the EM algorithm for posterior mode.

For large samples, these LR statistics tends to be approximately χ^2 distributed with degrees of freedom equal to the dimension of θ (Schafer 1997, p. 131). For example, with a large number of iterations, if the values of the LR statistic do not behave like a random sample from the described χ^2 distribution, then there is evidence that the MCMC process has not converged.

Worst Linear Function of Parameters

The worst linear function (WLF) of parameters (Schafer 1997, pp. 129-131) is a scalar function of parameters $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ that is “worst” in the sense that its function values converge most slowly among parameters in the MCMC process. The convergence of this function is evidence that other parameters are likely to converge as well.

For linear functions of parameters $\boldsymbol{\theta} = (\boldsymbol{\mu}, \boldsymbol{\Sigma})$, a worst linear function of $\boldsymbol{\theta}$ has the highest asymptotic rate of missing information. The function can be derived from the iterative values of $\boldsymbol{\theta}$ near the posterior mode in the EM algorithm. That is, an estimated worst linear function of $\boldsymbol{\theta}$ is

$$w(\boldsymbol{\theta}) = \mathbf{v}'(\boldsymbol{\theta} - \hat{\boldsymbol{\theta}})$$

where $\hat{\boldsymbol{\theta}}$ is the posterior mode and the coefficients $\mathbf{v} = \hat{\boldsymbol{\theta}}_{(-1)} - \hat{\boldsymbol{\theta}}$ is the difference between the estimated value of $\boldsymbol{\theta}$ one step prior to convergence and the converged value $\hat{\boldsymbol{\theta}}$.

You can display the coefficients of the worst linear function, \mathbf{v} , by specifying the WLF option in the MCMC statement. You can save the function value from each iteration in an OUTITER= data set by specifying the WLF option in the OUTITER option. You can also display the worst linear function values from iterations in an autocorrelation plot or a time-series plot by specifying WLF as an ACFPLOT or TIMEPLOT option, respectively.

Note that when the observed-data posterior is nearly normal, the WLF is one of the slowest functions to approach stationarity. When the posterior is not close to normal, other functions may take much longer than the WLF to converge, as described in Schafer (1997, p.130).

Time-Series Plot

A time-series plot for a parameter ξ is a scatter plot of successive parameter estimates ξ_i against the iteration number i . The plot provides a simple way to examine the convergence behavior of the estimation algorithm for ξ . Long-term trends in the plot indicate that successive iterations are highly correlated and that the series of iterations has not converged.

You can display time-series plots for the worst linear function, the variable means, variable variances, and covariances of variables. You can also request logarithmic transformations for positive parameters in the plots with the LOG option. When a parameter value is less than or equal to zero, the value is not displayed in the corresponding plot.

By default, the MI procedure uses solid line segments to connect data points in a time-series plot. You can use the CCONNECT=, LCONNECT=, and WCONNECT= options to change the color, line type, and width of the line segments. When WCONNECT=0 is specified, the data points are not connected, and the procedure

uses the plus sign (+) as the plot symbol to display the points with a height of one (percentage screen unit) in a time-series plot. You can use the SYMBOL=, CSYMBOL=, and HSYMBOL= options to change the shape, color, and height of the plot symbol.

By default, the plot title “Time-Series Plot” is displayed in a time-series plot. You can request another title by using the TITLE= option in the TIMEPLOT option. When another title is also specified in a TITLE statement, this title is displayed as the main title and the plot title is displayed as a subtitle in the plot.

You can use options in the GOPTIONS statement to change the color and height of the title. Refer to the chapter “The SAS/GRAPH Statements” in *SAS/GRAPH Software: Reference* for an illustration of title options. See [Example 44.8](#) for a usage of the time-series plot.

Autocorrelation Function Plot

To examine relationships of successive parameter estimates ξ , the autocorrelation function (ACF) can be used. For a stationary series, $\xi_i, i \geq 1$, in time series data, the autocorrelation function at lag k is

$$\rho_k = \frac{\text{Cov}(\xi_i, \xi_{i+k})}{\text{Var}(\xi_i)}$$

The sample k^{th} order autocorrelation is computed as

$$r_k = \frac{\sum_{i=1}^{n-k} (\xi_i - \bar{\xi})(\xi_{i+k} - \bar{\xi})}{\sum_{i=1}^n (\xi_i - \bar{\xi})^2}$$

You can display autocorrelation function plots for the worst linear function, the variable means, variable variances, and covariances of variables. You can also request logarithmic transformations for parameters in the plots with the LOG option. When a parameter has values less than or equal to zero, the corresponding plot is not created.

You specify the maximum number of lags of the series with the NLAG= option. The autocorrelations at each lag less than or equal to the specified lag are displayed in the graph. In addition, the plot also displays approximate 95% confidence limits for the autocorrelations. At lag k , the confidence limits indicate a set of approximate 95% critical values for testing the hypothesis $\rho_j = 0, j \geq k$.

By default, the MI procedure uses the star sign (*) as the plot symbol to display the points with a height of one (percentage screen unit) in the plot, a solid line to display the reference line of zero autocorrelation, vertical line segments to connect autocorrelations to the reference line, and a pair of dashed lines to display approximately 95% confidence limits for the autocorrelations.

You can use the SYMBOL=, CSYMBOL=, and HSYMBOL= options to change the shape, color, and height of the plot symbol, and the CNEEDLES= and WNEEDLES= options to change the color and width of the needles. You can also use the LREF=,

CREF=, and WREF= options to change the line type, color, and width of the reference line. Similarly, you can use the LCONF=, CCONF=, and WCONF= options to change the line type, color, and width of the confidence limits.

By default, the plot title “Autocorrelation Plot” is displayed in an autocorrelation function plot. You can request another title by using the TITLE= option in ACFPLOT. When another title is also specified in a TITLE statement, this title is displayed as the main title and the plot title is displayed as a subtitle in the plot.

You can use options in the GOPTIONS statement to change the color and height of the title. Refer to the chapter “The SAS/GRAPH Statements” in *SAS/GRAPH Software: Reference* for a description of title options. See [Example 44.8](#) for an illustration of the autocorrelation function plot.

Input Data Sets

You can specify the input data set with missing values with the DATA= option in the PROC MI statement. When an MCMC method is used, you can specify the data set containing the reference distribution information for imputation with the INEST= option, the data set containing initial parameter estimates for the MCMC process with the INITIAL=INPUT= option, and the data set containing information for the prior distribution with the PRIOR=INPUT= option in the MCMC statement.

DATA=SAS-data-set

The input DATA= data set is an ordinary SAS data set containing multivariate data with missing values.

INEST=SAS-data-set

The input INEST= data set is a TYPE=EST data set and contains a variable `_Imputation_` to identify the imputation number. For each imputation, PROC MI reads the point estimate from the observations with `_TYPE_='PARM'` or `_TYPE_='PARMS'` and the associated covariances from the observations with `_TYPE_='COV'` or `_TYPE_='COVB'`. These estimates are used as the reference distribution to impute values for observations in the DATA= data set. When the input INEST= data set also contains observations with `_TYPE_='SEED'`, PROC MI reads the seed information for the random number generator from these observations. Otherwise, the SEED= option provides the seed information.

INITIAL=INPUT=SAS-data-set

The input INITIAL=INPUT= data set is a TYPE=COV or CORR data set and provides initial parameter estimates for the MCMC process. The covariances derived from the TYPE=COV/CORR data set are divided by the number of observations to get the correct covariance matrix for the point estimate (sample mean).

If TYPE=COV, PROC MI reads the number of observations from the observations with `_TYPE_='N'`, the point estimate from the observations with `_TYPE_='MEAN'`, and the covariances from the observations with `_TYPE_='COV'`.

If TYPE=CORR, PROC MI reads the number of observations from the observations with `_TYPE_='N'`, the point estimate from the observations with

`_TYPE_='MEAN'`, the correlations from the observations with `_TYPE_='CORR'`, and the standard deviations from the observations with `_TYPE_='STD'`.

PRIOR=INPUT=SAS-data-set

The input `PRIOR=INPUT=` data set is a `TYPE=COV` data set that provides information for the prior distribution. You can use the data set to specify a prior distribution for Σ of the form

$$\Sigma \sim W^{-1}(d^*, d^* \mathbf{S}^*)$$

where $d^* = n^* - 1$ is the degrees of freedom. PROC MI reads the matrix \mathbf{S}^* from observations with `_TYPE_='COV'` and n^* from observations with `_TYPE_='N'`.

You can also use this data set to specify a prior distribution for μ of the form

$$\mu \sim N\left(\mu_0, \frac{1}{n_0} \Sigma\right)$$

PROC MI reads the mean vector μ_0 from observations with `_TYPE_='MEAN'` and n_0 from observations with `_TYPE_='N_MEAN'`. When there are no observations with `_TYPE_='N_MEAN'`, PROC MI reads n_0 from observations with `_TYPE_='N'`.

Output Data Sets

You can specify the output data set of imputed values with the `OUT=` option in the PROC MI statement. When an EM statement is used, you can specify the data set containing the original data set with missing values being replaced by the expected values from the EM algorithm with the `OUT=` option in the EM statement. You can also specify the data set containing MLE computed with the EM algorithm with the `OUTEM=` option.

When an MCMC method is used, you can specify the data set containing parameter estimates used in each imputation with the `OUTEST=` option and the data set containing parameters used in the imputation step for each iteration with the `OUTITER` option in the MCMC statement.

OUT=SAS-data-set in the PROC MI statement

The `OUT=` data set contains all the variables in the original data set and a new variable named `_Imputation_` that identifies the imputation. For each imputation, the data set contains all variables in the input `DATA=` data set with missing values being replaced by imputed values. Note that when the `NIMPUTE=1` option is specified, the variable `_Imputation_` is not created.

OUT=SAS-data-set in an EM statement

The `OUT=` data set contains the original data set with missing values being replaced by expected values from the EM algorithm.

OUTEM=SAS-data-set

The OUTEM= data set is a TYPE=COV data set and contains the MLE computed with the EM algorithm. The observations with _TYPE_='MEAN' contain the estimated mean and the observations with _TYPE_='COV' contain the estimated covariances.

OUTEST=SAS-data-set

The OUTEST= data set is a TYPE=EST data set and contains parameter estimates used in each imputation in the MCMC method. It also includes an index variable named _Imputation_, which identifies the imputation.

The observations with _TYPE_='SEED' contain the seed information for the random number generator. The observations with _TYPE_='PARM' or _TYPE_='PARMS' contain the point estimate and the observations with _TYPE_='COV' or _TYPE_='COVB' contain the associated covariances. These estimates are used as the parameters of the reference distribution to impute values for observations in the DATA= dataset.

Note that these estimates are the values used in the I-step before each imputation. These are not the parameter values simulated from the P-step in the same iteration. See [Example 44.9](#) for a usage of this option.

OUTITER < (options) > =SAS-data-set in an EM statement

The OUTITER= data set in an EM statement is a TYPE=COV data set and contains parameters for each iteration. It also includes a variable _Iteration_ that provides the iteration number.

The parameters in the output data set depend on the options specified. You can specify the MEAN and COV options for OUTITER. With the MEAN option, the output data set contains the mean parameters in observations with the variable _TYPE_='MEAN'. Similarly, with the COV option, the output data set contains the covariance parameters in observations with the variable _TYPE_='COV'. When no options are specified, the output data set contains the mean parameters for each iteration.

OUTITER < (options) > =SAS-data-set in an MCMC statement

The OUTITER= data set in an MCMC statement is a TYPE=COV data set and contains parameters used in the imputation step for each iteration. It also includes variables named _Imputation_ and _Iteration_, which provide the imputation number and iteration number.

The parameters in the output data set depend on the options specified. The following table summarizes the options available for OUTITER and the corresponding values for the output variable _TYPE_.

Table 44.4. Summary of Options for OUTITER in an MCMC statement

Options	Output Parameters	_TYPE_
MEAN	mean parameters	MEAN
STD	standard deviations	STD
COV	covariances	COV
LR	-2 log LR statistic	LOG_LR

Table 44.4. (continued)

Options	Output Parameters	_TYPE_
LR_POST	-2 log LR statistic of the posterior mode	LOG_POST
WLF	worst linear function	WLF

When no options are specified, the output data set contains the mean parameters used in the imputation step for each iteration. For a detailed description of the worst linear function and LR statistics, see the “[Checking Convergence in MCMC](#)” section on page 2555.

Combining Inferences from Multiply Imputed Data Sets

With m imputations, m different sets of the point and variance estimates for a parameter Q can be computed. Suppose \hat{Q}_i and \hat{U}_i are the point and variance estimates from the i th imputed data set, $i=1, 2, \dots, m$. Then the combined point estimate for Q from multiple imputation is the average of the m complete-data estimates:

$$\bar{Q} = \frac{1}{m} \sum_{i=1}^m \hat{Q}_i$$

Suppose \bar{U} is the within-imputation variance, which is the average of the m complete-data estimates:

$$\bar{U} = \frac{1}{m} \sum_{i=1}^m \hat{U}_i$$

and B is the between-imputation variance

$$B = \frac{1}{m-1} \sum_{i=1}^m (\hat{Q}_i - \bar{Q})^2$$

Then the variance estimate associated with \bar{Q} is the total variance (Rubin 1987)

$$T = \bar{U} + \left(1 + \frac{1}{m}\right)B$$

The statistic $(Q - \bar{Q})T^{-1/2}$ is approximately distributed as t with v_m degrees of freedom (Rubin 1987), where

$$v_m = (m-1) \left[1 + \frac{\bar{W}}{(1+m^{-1})B} \right]^2$$

The degrees of freedom v_m depends on m and the ratio

$$r = \frac{(1+m^{-1})B}{\bar{U}}$$

The ratio r is called the relative increase in variance due to nonresponse (Rubin 1987). When there is no missing information about Q , the values of r and B are both zero. With a large value of m or a small value of r , the degrees of freedom v_m will be large and the distribution of $(Q - \bar{Q})T^{-(1/2)}$ will be approximately normal.

Another useful statistic is the fraction of missing information about Q :

$$\hat{\lambda} = \frac{r + 2/(v_m + 3)}{r + 1}$$

Both statistics r and λ are helpful diagnostics for assessing how the missing data contribute to the uncertainty about Q .

When the complete-data degrees of freedom v_0 is small, and there is only a modest proportion of missing data, the computed degrees of freedom, v_m , can be much larger than v_0 , which is inappropriate. For example, with $m = 5$ and $r = 10\%$, the computed degrees of freedom $v_m = 484$, which is inappropriate for data sets with complete-data degrees of freedom less than 484.

Barnard and Rubin (1999) recommend the use of an adjusted degrees of freedom

$$v_m^* = \left[\frac{1}{v_m} + \frac{1}{\hat{v}_{obs}} \right]^{-1}$$

where $\hat{v}_{obs} = (1 - \gamma)v_0(v_0 + 1)/(v_0 + 3)$ and $\gamma = (1 + m^{-1})B/T$.

Note that the MI procedure uses the adjusted degrees of freedom, v_m^* , for inference.

Multiple Imputation Efficiency

The relative efficiency (RE) of using the finite m imputation estimator, rather than using an infinite number for the fully efficient imputation, in units of variance, is approximately a function of m and λ (Rubin 1987, p. 114).

$$RE = \left(1 + \frac{\lambda}{m} \right)^{-1}$$

The following table shows relative efficiencies with different values of m and λ .

Table 44.5. Relative Efficiency

m	λ				
	10%	20%	30%	50%	70%
3	0.9677	0.9375	0.9091	0.8571	0.8108
5	0.9804	0.9615	0.9434	0.9091	0.8772
10	0.9901	0.9804	0.9709	0.9524	0.9346
20	0.9950	0.9901	0.9852	0.9756	0.9662

The table shows that for situations with little missing information, only a small number of imputations are necessary. In practice, the number of imputations needed can be informally verified by replicating sets of m imputations and checking whether the estimates are stable between sets (Horton and Lipsitz 2001, p. 246).

Imputer's Model Versus Analyst's Model

Multiple imputation inference assumes that the model you used to analyze the multiply imputed data (the analyst's model) is the same as the model used to impute missing values in multiple imputation (the imputer's model). But in practice, the two models may not be the same (Schafer 1997, p. 139).

Schafer (1997, pp. 139–143) provides comprehensive coverage of this topic, and the following example is based on his work.

Consider a trivariate data set with variables Y_1 and Y_2 fully observed, and a variable Y_3 with missing values. An imputer creates multiple imputations with the model $Y_3 = Y_1 Y_2$. However, the analyst can later use the simpler model $Y_3 = Y_1$. In this case, the analyst assumes more than the imputer. That is, the analyst assumes there is no relationship between variables Y_3 and Y_2 .

The effect of the discrepancy between the models depends on whether the analyst's additional assumption is true. If the assumption is true, the imputer's model still applies. The inferences derived from multiple imputations will still be valid, although they may be somewhat conservative because they reflect the additional uncertainty of estimating the relationship between Y_3 and Y_2 .

On the other hand, suppose that the analyst models $Y_3 = Y_1$, and there is a relationship between variables Y_3 and Y_2 . Then the model $Y_3 = Y_1$ will be biased and is inappropriate. Appropriate results can be generated only from appropriate analyst models.

Another type of discrepancy occurs when the imputer assumes more than the analyst. For example, suppose that an imputer creates multiple imputations with the model $Y_3 = Y_1$, but the analyst later fits a model $Y_3 = Y_1 Y_2$. When the assumption is true, the imputer's model is a correct model and the inferences still hold.

On the other hand, suppose there is a relationship between Y_3 and Y_2 . Imputations created under the incorrect assumption that there is no relationship between Y_3 and Y_2 will make the analyst's estimate of the relationship biased toward zero. Multiple imputations created under an incorrect model can lead to incorrect conclusions.

Thus, generally you should include as many variables as you can when doing multiple imputation. The precision you lose with included unimportant predictors is usually a relatively small price to pay for the general validity of analyses of the resultant multiply imputed data set (Rubin 1996). But at the same time, you need to keep the model building and fitting feasible (Barnard and Meng, 1999, pp. 19–20).

To produce high-quality imputations for a particular variable, the imputation model should also include variables that are potentially related to the imputed variable and variables that are potentially related to the missingness of the imputed variable (Schafer 1997, p. 143).

Similar suggestions were also given by van Buuren, Boshuizen, and Knook (1999, p. 687). They recommended the imputation model includes three sets of covariates: variables in the analyst's model, variables associated with the missingness of the imputed variable, and variables correlated with the imputed variable. They also recommended the removal of the covariates not in the analyst's model if they have too many missing values for observations with missing imputed variable.

Note that it is good practice to include a description of the imputer's model with the multiply imputed data set (Rubin 1996, p.479). That way, the analysts will have information about the variables involved in the imputation and which relationships among the variables have been implicitly set to zero.

Parameter Simulation Versus Multiple Imputation

As an alternative to multiple imputation, parameter simulation can also be used to analyze the data for many incomplete-data problems. Although the MI procedure does not offer parameter simulation, the trade-offs between the two methods (Schafer 1997, pp. 89–90, 135–136) are examined in this section.

The parameter simulation method simulates random values of parameters from the observed-data posterior distribution and makes simple inferences about these parameters (Schafer 1997, p. 89). When a set of well-defined population parameters θ are of interest, parameter simulation can be used to directly examine and summarize simulated values of θ . This usually requires a large number of iterations, and involves calculating appropriate summaries of the resulting dependent sample of the iterates of the θ . If only a small set of parameters are involved, parameter simulation is suitable (Schafer 1997).

Multiple imputation only requires a small number of imputations. Generating and storing a few imputations can be more efficient than generating and storing a large number of iterations for parameter simulation.

When fractions of missing information are low, methods that average over simulated values of the missing data, as in multiple imputation, can be much more efficient than methods that average over simulated values of θ as in parameter simulation (Schafer 1997).

Summary of Issues in Multiple Imputation

This section summarizes issues which are encountered in applications of the MI procedure.

The MAR Assumption

The missing at random (MAR) assumption is needed for the imputation methods in the MI Procedure. Although this assumption cannot be verified with the data, it becomes more plausible as more variables are included in the imputation model (Schafer 1997, pp. 27–28; van Buuren, Boshuizen, and Knook, 1999, p. 687).

Number of Imputations

Based on the theory of multiple imputation, only a small number of imputations are needed for a data set with little missing information (Rubin 1987, p. 114). The number of imputations can be informally verified by replicating sets of m imputations and checking whether the estimates are stable (Horton and Lipsitz 2001, p. 246).

Imputation Model

Generally you should include as many variables as you can in the imputation model (Rubin 1996). At the same time, however, it is important to keep the number of variables in control, as discussed by Barnard and Meng (1999, pp. 19–20). For the imputation of a particular variable, the model should include variables in the complete data model, variables that are correlated with the imputed variable, and variables that are associated with the missingness of the imputed variable (Schafer 1997, p. 143; van Buuren, Boshuizen, and Knook 1999, p. 687).

Multivariate Normality Assumption

Although the regression and MCMC methods assume multivariate normality, inferences based on multiple imputation can be robust to departures from the multivariate normality if the amount of missing information is not large (Schafer 1997, pp. 147–148).

You can use variable transformations to make the normality assumption more tenable. Variables are transformed before the imputation process and then back-transformed to create imputed values.

Monotone Regression Method

With the multivariate normality assumption, either the regression method or the predictive mean matching method can be used to impute continuous variables in data sets with monotone missing patterns.

The predictive mean matching method ensures that imputed values are plausible and may be more appropriate than the regression method if the normality assumption is violated (Horton and Lipsitz 2001, p. 246).

Monotone Propensity Score Method

The propensity score method can also be used to impute continuous variables in data sets with monotone missing patterns.

The propensity score method does not use correlations among variables and is not appropriate for analyses involving relationship among variables, such as a regression analysis (Schafer 1999, p.11). It can also produce badly biased estimates of regression coefficients when data on predictor variables are missing (Allison 2000).

MCMC Monotone-Data Imputation

The MCMC Method is used to impute continuous variables in data sets with arbitrary missing patterns, assuming a multivariate normal distribution for the data. It can also be used to impute just enough missing values to make the imputed data sets have a monotone missing pattern. Then, a more flexible monotone imputation method can be used for the remaining missing values.

Checking Convergence in MCMC

In an MCMC process, parameters are drawn after the MCMC is run long enough to converge to its stationary distribution. In practice, however, it is not simple to verify the convergence of the process, especially for a large number of parameters.

You can check for convergence by examining the observed-data likelihood ratio statistic and worst linear function of the parameters in each iteration. You can also check for convergence by examining a plot of autocorrelation function, as well as a time-series plot of parameters (Schafer 1997, p. 120).

EM Estimates

The EM algorithm can be used to compute the MLE of the mean vector and covariance matrix of the data with missing values, assuming a multivariate normal distribution for the data. However, the covariance matrix associated with the estimate of the mean vector cannot be derived from the EM algorithm.

In the MI procedure, you can use the EM algorithm to compute the posterior mode, which provides a good starting value for the MCMC process (Schafer 1997, p. 169).

ODS Table Names

PROC MI assigns a name to each table it creates. You must use these names to reference tables when using the Output Delivery System (ODS). These names are listed in the following table. For more information on ODS, see [Chapter 14, “Using the Output Delivery System.”](#)

Table 44.6. ODS Tables Produced in PROC MI

ODS Table Name	Description	Statement	Option
Corr	Pairwise correlations		SIMPLE
EMEstimates	EM (MLE) estimates	EM	
EMInitEstimates	EM initial estimates	EM	
EMIterHistory	EM (MLE) iteration history	EM	ITPRINT
EMPostEstimates	EM (Posterior mode) estimates	MCMC	INITIAL=EM
EMPostIterHistory	EM (Posterior mode) iteration history	MCMC	INITIAL=EM (ITPRINT)
EMWLF	Worst linear function	MCMC	WLF
MCMCInitEstimates	MCMC initial estimates	MCMC	DISPLAYINIT
MissPattern	Missing data patterns		
ModelInfo	Model information		
MonoDiscrim	Discriminant model group means	MONOTONE	DISCRIM (/DETAILS)
MonoLogistic	Logistic model	MONOTONE	LOGISTIC (/DETAILS)
MonoModel	Multiple monotone models	MONOTONE	
MonoPropensity	Propensity score model logistic function	MONOTONE	PROPENSITY (/DETAILS)

ODS Graphics (Experimental)

This section describes the use of ODS for creating graphics with the MI procedure. These graphics are experimental in this release, meaning that both the graphical results and the syntax for specifying them are subject to change in a future release.

To request these graphs, you must specify the ODS GRAPHICS statement in addition to the following options in the MCMC statement. For more information on the ODS GRAPHICS statement, see [Chapter 15, “Statistical Graphics Using ODS.”](#)

ACFPLOT < (options < / display-options >) >

displays plots of the autocorrelation function of parameters from iterations.

For a detailed description of the ACFPLOT option, see the [“Autocorrelation Function Plot”](#) section on page 2557. Note that for the display-options, only the LOG, NLAG=, and TITLE= options are applicable.

TIMEPLOT < (options < / display-options >) >

displays time-series plots of parameters from iterations.

For a detailed description of the TIMEPLOT option, see the [“Time-Series Plot”](#) section on page 2556. Note that for the display-options, only the LOG, WCONNECT=, and TITLE= options are applicable. If you specify the WCONNECT=0 option, a scatter plot is created. Otherwise, a line plot is created.

ODS Graph Names

PROC MI assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in [Table 44.7](#).

To request these graphs, you must specify the ODS GRAPHICS statement in addition to the options indicated in [Table 44.7](#). For more information on the ODS GRAPHICS statement, see [Chapter 15, “Statistical Graphics Using ODS.”](#)

Table 44.7. ODS Graphics Produced by PROC MI

ODS Graph Name	Plot Description	Statement	Option
ACFPlot	ACF plot	MCMC	ACFPLOT
TimeScatterPlot	Time-series scatter plot	MCMC	TIMEPLOT(WCONNECT=0)
TimeSeriesPlot	Time-series plot	MCMC	TIMEPLOT

Examples

The Fish data described in the STEPDISC procedure are measurements of 159 fish of seven species caught in Finland's lake Laengelmavesi. For each fish, the length, height, and width are measured. Three different length measurements are recorded: from the nose of the fish to the beginning of its tail (Length1), from the nose to the notch of its tail (Length2), and from the nose to the end of its tail (Length3). See Chapter 67, "The STEPDISC Procedure," for more information.

The Fish1 data set is constructed from the Fish data set and contains only one species of the fish and the three length measurements. Some values have been set to missing and the resulting data set has a monotone missing pattern in variables Length1, Length2, and Length3. The Fish1 data set is used in Example 44.2 with the propensity score method and in Example 44.3 with the regression method.

The Fish2 data set is also constructed from the Fish data set and contains two species of fish. Some values have been set to missing and the resulting data set has a monotone missing pattern in variables Length3, Height, Width, and Species. The Fish2 data set is used in Example 44.4 with the logistic regression method and in Example 44.5 with the discriminant function method. Note that some values of the variable Species have also been altered in the data set.

The FitMiss data set created in the "Getting Started" section is used in other examples. The following statements create the Fish1 data set.

```
/*----- Fishes of Species Bream -----*/
data Fish1;

```

The Fish2 data set contains two of the seven species in the Fish data set. For each of the two species (Bream and Parkki), the length from the nose of the fish to the end of its tail, the height, and the width of each fish are measured. The height and width are recorded as percentages of the length variable.

The following statements create the Fish2 data set.

```

/*----- Fishes of Species Bream and Parkki Pike -----*/
data Fish2 (drop=HtPct WidthPct);
title 'Fish Measurement Data';
input Species $ Length3 HtPct WidthPct @@;
Height= HtPct*Length3/100;

Example 44.1. EM Algorithm for MLE

This example uses the EM algorithm to compute the maximum likelihood estimates for parameters of a multivariate normal distribution using data with missing values. The following statements invoke the MI procedure and request the EM algorithm to compute the MLE for (μ, Σ) of a multivariate normal distribution from the input data set FitMiss.

```

proc mi data=FitMiss seed=1518971 simple nimpute=0;
  em itprint outem=outem;
  var Oxygen RunTime RunPulse;
run;

```

Note that when you specify the NIMPUTE=0 option, the missing values will not be imputed. The procedure generates the following output:

Output 44.1.1. Model Information

Fish Measurement Data	
The MI Procedure	
Model Information	
Data Set	WORK.FITMISS
Method	MCMC
Multiple Imputation Chain	Single Chain
Initial Estimates for MCMC	EM Posterior Mode
Start	Starting Value
Prior	Jeffreys
Number of Imputations	0
Number of Burn-in Iterations	200
Number of Iterations	100
Seed for random number generator	1518971

The “Model Information” table shown in [Output 44.1.1](#) describes the method and options used in the procedure if a positive number is specified in the NIMPUTE= option.

The “Missing Data Patterns” table shown in [Output 44.1.2](#) lists distinct missing data patterns with corresponding frequencies and percents. Here, a value of “X” means that the variable is observed in the corresponding group and a value of “.” means that the variable is missing. The table also displays group-specific variable means.

Output 44.1.2. Missing Data Patterns

The MI Procedure					
Missing Data Patterns					
Group	Oxygen	Run Time	Run Pulse	Freq	Percent
1	X	X	X	21	67.74
2	X	X	.	4	12.90
3	X	.	.	3	9.68
4	.	X	X	1	3.23
5	.	X	.	2	6.45

Missing Data Patterns			
-----Group Means-----			
Group	Oxygen	RunTime	RunPulse
1	46.353810	10.809524	171.666667
2	47.109500	10.137500	.
3	52.461667	.	.
4	.	11.950000	176.000000
5	.	9.885000	.

With the SIMPLE option, the procedure displays simple descriptive univariate statistics for available cases in the “Univariate Statistics” table shown in [Output 44.1.3](#) and

correlations from pairwise available cases in the “Pairwise Correlations” table shown in [Output 44.1.4](#).

Output 44.1.3. Univariate Statistics

The MI Procedure					
Univariate Statistics					
Variable	N	Mean	Std Dev	Minimum	Maximum
Oxygen	28	47.11618	5.41305	37.38800	60.05500
RunTime	28	10.68821	1.37988	8.63000	14.03000
RunPulse	22	171.86364	10.14324	148.00000	186.00000

Univariate Statistics			
Variable	---Missing Values--		
	Count	Percent	
Oxygen	3	9.68	
RunTime	3	9.68	
RunPulse	9	29.03	

Output 44.1.4. Pairwise Correlations

The MI Procedure			
Pairwise Correlations			
	Oxygen	RunTime	RunPulse
Oxygen	1.00000000	-0.849118562	-0.343961742
RunTime	-0.849118562	1.00000000	0.247258191
RunPulse	-0.343961742	0.247258191	1.00000000

With the EM statement, the procedure displays the initial parameter estimates for EM in the “Initial Parameter Estimates for EM” table shown in [Output 44.1.5](#).

Output 44.1.5. Initial Parameter Estimates for EM

The MI Procedure				
Initial Parameter Estimates for EM				
<u>_TYPE_</u>	<u>_NAME_</u>	Oxygen	RunTime	RunPulse
MEAN		47.116179	10.688214	171.863636
COV	Oxygen	29.301078	0	0
COV	RunTime	0	1.904067	0
COV	RunPulse	0	0	102.885281

With the ITPRINT option in the EM statement, the “EM (MLE) Iteration History” table shown in [Output 44.1.6](#) displays the iteration history for the EM algorithm.

Output 44.1.6. EM (MLE) Iteration History

The MI Procedure				
EM (MLE) Iteration History				
<u>_Iteration_</u>	-2 Log L	Oxygen	RunTime	RunPulse
0	289.544782	47.116179	10.688214	171.863636
1	263.549489	47.116179	10.688214	171.863636
2	255.851312	47.139089	10.603506	171.538203
3	254.616428	47.122353	10.571685	171.426790
4	254.494971	47.111080	10.560585	171.398296
5	254.483973	47.106523	10.556768	171.389208
6	254.482920	47.104899	10.555485	171.385257
7	254.482813	47.104348	10.555062	171.383345
8	254.482801	47.104165	10.554923	171.382424
9	254.482800	47.104105	10.554878	171.381992
10	254.482800	47.104086	10.554864	171.381796
11	254.482800	47.104079	10.554859	171.381708
12	254.482800	47.104077	10.554858	171.381669

The “EM (MLE) Parameter Estimates” table shown in [Output 44.1.7](#) displays the maximum likelihood estimates for μ and Σ of a multivariate normal distribution from the data set FitMiss.

Output 44.1.7. EM (MLE) Parameter Estimates

The MI Procedure				
EM (MLE) Parameter Estimates				
<u>_TYPE_</u>	<u>_NAME_</u>	Oxygen	RunTime	RunPulse
MEAN		47.104077	10.554858	171.381669
COV	Oxygen	27.797931	-6.457975	-18.031298
COV	RunTime	-6.457975	2.015514	3.516287
COV	RunPulse	-18.031298	3.516287	97.766857

You can also output the EM (MLE) parameter estimates into an output data set with the OUTEM= option. The following statements list the observations in the output data set outem.

```
proc print data=outem;
  title 'EM Estimates';
run;
```

Output 44.1.8. EM Estimates

EM Estimates					
Obs	<u>_TYPE_</u>	<u>_NAME_</u>	Oxygen	RunTime	RunPulse
1	MEAN		47.1041	10.5549	171.382
2	COV	Oxygen	27.7979	-6.4580	-18.031
3	COV	RunTime	-6.4580	2.0155	3.516
4	COV	RunPulse	-18.0313	3.5163	97.767

The output data set outem shown in [Output 44.1.8](#) is a TYPE=COV data set. The observation with _TYPE_='MEAN' contains the MLE for the parameter μ and the observations with _TYPE_='COV' contain the MLE for the parameter Σ of a multivariate normal distribution from the data set FitMiss.

Example 44.2. Propensity Score Method

This example uses the propensity score method to impute missing values for variables in a data set with a monotone missing pattern. The following statements invoke the MI procedure and request the propensity score method. The resulting data set is named outex2.

```
proc mi data=Fish1 seed=899603 out=outex2;
  monotone propensity;
  var Length1 Length2 Length3;
run;
```

Note that the VAR statement is required and the data set must have a monotone missing pattern with variables as ordered in the VAR statement. The procedure generates the following output:

Output 44.2.1. Model Information

The MI Procedure	
Model Information	
Data Set	WORK.FISH1
Method	Monotone
Number of Imputations	5
Seed for random number generator	899603

The “Model Information” table shown in [Output 44.2.1](#) describes the method and options used in the multiple imputation process. By default, five imputations are created for the missing data.

When monotone methods are used in the imputation, MONOTONE is displayed as the method. The “Monotone Model Specification” table shown in [Output 44.2.2](#) displays the detailed model specification. By default, the observations are sorted into five groups based on their propensity scores.

Output 44.2.2. Monotone Model Specification

The MI Procedure	
Monotone Model Specification	
Method	Imputed Variables
Propensity(Groups= 5)	Length2 Length3

Without covariates specified for imputed variables Length2 and Length3, the variable Length1 is used as the covariate for Length2, and variables Length1 and Length2 are used as covariates for Length3.

Output 44.2.3. Missing Data Patterns

The MI Procedure					
Missing Data Patterns					
Group	Length1	Length2	Length3	Freq	Percent
1	X	X	X	30	85.71
2	X	X	.	3	8.57
3	X	.	.	2	5.71
Missing Data Patterns					
-----Group Means-----					
Group	Length1	Length2	Length3		
1	30.603333	33.436667	38.720000		
2	29.033333	31.666667	.		
3	27.750000	.	.		

The “Missing Data Patterns” table shown in [Output 44.2.3](#) lists distinct missing data patterns with corresponding frequencies and percents. Here, values of “X” and “.” indicate that the variable is observed or missing in the corresponding group. The table confirms a monotone missing pattern for these three variables.

For the imputation process, first, missing values of Length2 in Group 3 are imputed using observed values of Length1. Then the missing values of Length3 in Group 2 are imputed using observed values of Length1 and Length2. And finally, the missing values of Length3 in Group 3 are imputed using observed values of Length1 and imputed values of Length2.

After the completion of m imputations, the “Multiple Imputation Variance Information” table shown in [Output 44.2.4](#) displays the between-imputation variance, within-imputation variance, and total variance for combining complete-data inferences. It also displays the degrees of freedom for the total variance. The relative increase in variance due to missingness, the fraction of missing information, and the relative efficiency for each variable are also displayed. A detailed description of these statistics is provided in the “[Combining Inferences from Multiply Imputed Data Sets](#)” section on page 2561.

Output 44.2.4. Variance Information

The MI Procedure				
Multiple Imputation Variance Information				
Variable	-----Variance-----			DF
	Between	Within	Total	
Length2	0.001500	0.465422	0.467223	32.034
Length3	0.049725	0.547434	0.607104	27.103
Multiple Imputation Variance Information				
Variable	Relative Increase in Variance	Fraction Missing Information	Relative Efficiency	
Length2	0.003869	0.003861	0.999228	
Length3	0.108999	0.102610	0.979891	

The “Multiple Imputation Parameter Estimates” table shown in [Output 44.2.5](#) displays the estimated mean and standard error of the mean for each variable. The inferences are based on the t -distributions. For each variable, the table also displays a 95% mean confidence interval and a t -statistic with the associated p -value for the hypothesis that the population mean is equal to the value specified in the MU0= option, which is zero by default.

Output 44.2.5. Parameter Estimates

The MI Procedure					
Multiple Imputation Parameter Estimates					
Variable	Mean	Std Error	95% Confidence Limits		DF
Length2	33.006857	0.683537	31.61460	34.39912	32.034
Length3	38.361714	0.779169	36.76328	39.96015	27.103
Multiple Imputation Parameter Estimates					
Variable	Minimum	Maximum	Mu0	t for H0: Mean=Mu0	Pr > t
Length2	32.957143	33.060000	0	48.29	<.0001
Length3	38.080000	38.545714	0	49.23	<.0001

The following statements list the first ten observations of the data set `outex2`, as shown in [Output 44.2.6](#). The missing values are imputed from observed values with similar propensity scores.

```
proc print data=outex2(obs=10);
  title 'First 10 Observations of the Imputed Data Set';
run;
```

Output 44.2.6. Imputed Data Set

First 10 Observations of the Imputed Data Set				
Obs	_Imputation_	Length1	Length2	Length3
1	1	23.2	25.4	30.0
2	1	24.0	26.3	31.2
3	1	23.9	26.5	31.1
4	1	26.3	29.0	33.5
5	1	26.5	29.0	38.6
6	1	26.8	29.7	34.7
7	1	26.8	29.0	35.0
8	1	27.6	30.0	35.0
9	1	27.6	30.0	35.1
10	1	28.5	30.7	36.2

Example 44.3. Regression Method

This example uses the regression method to impute missing values for all variables in a data set with a monotone missing pattern. The following statements invoke the MI procedure and request the regression method for variable `Length2` and the predictive mean matching method for variable `Length3`. The resulting data set is named `outex3`.

```
proc mi data=Fish1 round=.1 mu0= 0 35 45
  seed=13951639 out=outex3;
  monotone reg(Length2/ details)
    regpmm(Length3= Length1 Length2 Length1*Length2/ details);
  var Length1 Length2 Length3;
run;
```

The `ROUND=` option is used to round the imputed values to the same precision as observed values. The values specified with the `ROUND=` option are matched with the variables `Length1`, `Length2`, and `Length3` in the order listed in the `VAR` statement. The `MU0=` option requests t tests for the hypotheses that the population means corresponding to the variables in the `VAR` statement are `Length2=35` and `Length3=45`.

Note that an optimal `K=` value is currently not available for the `REGPMM` option in the literature on multiple imputation. The default `K=5` is experimental and may change in future releases.

The “Missing Data Patterns” table lists distinct missing data patterns with corresponding frequencies and percents. It is identical to the table displayed in [Output 44.2.3](#) in the previous example.

The “Monotone Model Specification” table shown in [Output 44.3.1](#) displays the model specification.

Output 44.3.1. Monotone Model Specification

Fish Measurement Data	
The MI Procedure	
Monotone Model Specification	
Method	Imputed Variables
Regression	Length2
Regression-PMM(K= 5)	Length3

With the DETAILS option, the parameters estimated from the observed data and the parameters used in each imputation are displayed in [Output 44.3.2](#) and [Output 44.3.3](#).

Output 44.3.2. Regression Model

The MI Procedure					
Regression Models for Monotone Method

9	1	27.6	30.0	35.1
10	1	28.5	30.7	36.2

Example 44.4. Logistic Regression Method for CLASS Variables

This example uses logistic regression method to impute values for a binary variable in a data set with a monotone missing pattern.

The logistic regression method is used for the binary and ordinal CLASS variables. Since the variable `Species` is not an ordinal variable, only the first two species are used.

```
proc mi data=Fish2 seed=1305417 out=outex4;
  class Species;
  monotone logistic( Species= Height Width Height*Width/ details);
  var Height Width Species;
run;
```

The “Model Information” table shown in [Output 44.4.1](#) describes the method and options used in the multiple imputation process.

Output 44.4.1. Model Information

The MI Procedure	
Model Information	
Data Set	WORK.FISH2
Method	Monotone
Number of Imputations	5
Seed for random number generator	1305417

The “Monotone Model Specification” table shown in [Output 44.4.2](#) describes methods and imputed variables in the imputation model. The procedure uses the logistic regression method to impute variable `Species` in the model. Missing values in other variables are not imputed.

Output 44.4.2. Monotone Model Specification

The MI Procedure	
Monotone Model Specification	
Method	Imputed Variables
Logistic Regression	Species

The “Missing Data Patterns” table shown in [Output 44.4.3](#) lists distinct missing data patterns with corresponding frequencies and percents. The table confirms a monotone missing pattern for these variables.

Output 44.4.3. Missing Data Patterns

The MI Procedure							
Missing Data Patterns							
Group	Height	Width	Species	Freq	Percent	-----Group Means-----	
						Height	Width
1	X	X	X	47	85.45	12.097645	4.808204
2	X	X	.	6	10.91	11.411050	4.567050
3	X	.	.	2	3.64	14.126350	.

With the DETAILS option, parameters estimated from the observed data and the parameters used in each imputation are displayed in the “Logistic Models for Monotone Method” table in [Output 44.4.4](#).

Output 44.4.4. Logistic Regression Model

The MI Procedure					
Logistic Models for Monotone Method					
Imputed Variable	Effect	Obs-Data	-----Imputation-----		
			1	2	3
Species	Intercept	2.65234	1.794014	5.392323	5.859932
Species	Height	7.73757	3.727095	11.790557	12.200408
Species	Width	-5.25709	-1.209209	-8.492849	-8.696497
Species	Height*Width	-1.12990	-1.593964	-1.989302	-3.087310

Logistic Models for Monotone Method			
Imputed Variable	Effect	-----Imputation-----	
		4	5
Species	Intercept	-0.649860	6.393629
Species	Height	2.449332	13.644077
Species	Width	0.629963	-10.767135
Species	Height*Width	0.979165	-2.389491

The following statements list the first ten observations of the data set outex4 in [Output 44.4.5](#).

```
proc print data=outex4(obs=10);
  title 'First 10 Observations of the Imputed Data Set';
run;
```

Output 44.4.5. Imputed Data Set

First 10 Observations of the Imputed Data Set					
Obs	_Imputation_	Species	Length3	Height	Width
1	1	Gp1	30.0	11.5200	4.0200
2	1	Gp1	31.2	12.4800	4.3056
3	1	Gp1	31.1	12.3778	4.6961
4	1	.	33.5	12.7300	.
5	1	Gp1	34.0	12.4440	5.1340
6	1	Gp1	34.7	13.6024	4.9274
7	1	Gp1	34.5	14.1795	5.2785
8	1	Gp1	35.0	12.6700	4.6900
9	1	Gp1	35.1	14.0049	4.8438
10	1	Gp1	36.2	14.2266	4.9594

Note that a missing value of the variable **Species** is not imputed if the corresponding covariates are missing and not imputed, as shown by observation 4 in the table.

Example 44.5. Discriminant Function Method for CLASS Variables

This example uses discriminant monotone methods to impute values of a CLASS variable from the observed observation values in a data set with a monotone missing pattern.

The following statements impute the continuous variables **Height** and **Width** with the regression method and the CLASS variable **Species** with the discriminant function method.

```
proc mi data=Fish2 seed=7545417 nimpute=3 out=outex5;
  class Species;
  monotone reg( Height Width)
    discrim( Species= Length3 Height Width/ details);
  var Length3 Height Width Species;
run;
```

The “Model Information” table shown in [Output 44.5.1](#) describes the method and options used in the multiple imputation process.

Output 44.5.1. Model Information

The MI Procedure	
Model Information	
Data Set	WORK.FISH2
Method	Monotone
Number of Imputations	3
Seed for random number generator	7545417

The “Monotone Model Specification” table shown in [Output 44.5.2](#) describes methods and imputed variables in the imputation model. The procedure uses the regression method to impute variables **Height** and **Width**, and uses the logistic regression method to impute variable **Species** in the model.

Output 44.5.2. Monotone Model Specification

The MI Procedure	
Monotone Model Specification	
Method	Imputed Variables
Regression	Height Width
Discriminant Function	Species

The “Missing Data Patterns” table shown in [Output 44.5.3](#) lists distinct missing data patterns with corresponding frequencies and percents. The table confirms a monotone missing pattern for these variables.

Output 44.5.3. Missing Data Patterns

The MI Procedure						
Missing Data Patterns						
Group	Length3	Height	Width	Species	Freq	Percent
1	X	X	X	X	47	85.45
2	X	X	X	.	6	10.91
3	X	X	.	.	2	3.64
Missing Data Patterns

10	1	Gp1	36.2	14.2266	4.95940

Example 44.6. MCMC Method

This example uses the MCMC method to impute missing values for a data set with an arbitrary missing pattern. The following statements invoke the MI procedure and specify the MCMC method with six imputations.

```
proc mi data=FitMiss seed=21355417 nimpute=6 mu0=50 10 180 ;
  mcmc chain=multiple displayinit initial=em(itprint);
  var Oxygen RunTime RunPulse;
run;
```

Output 44.6.1. Model Information

The MI Procedure	
Model Information	
Data Set	WORK.FITMISS
Method	MCMC
Multiple Imputation Chain	Multiple Chains
Initial Estimates for MCMC	EM Posterior Mode
Start	Starting Value
Prior	Jeffreys
Number of Imputations	6
Number of Burn-in Iterations	200
Seed for random number generator	21355417

The “Model Information” table shown in [Output 44.6.1](#) describes the method used in the multiple imputation process. With CHAIN=MULTIPLE, the procedure uses multiple chains and completes the default 200 burn-in iterations before each imputation. The 200 burn-in iterations are used to make the iterations converge to the stationary distribution before the imputation.

By default, the procedure uses a noninformative Jeffreys prior to derive the posterior mode from the EM algorithm as the starting values for the MCMC process.

The “Missing Data Patterns” table shown in [Output 44.6.2](#) lists distinct missing data patterns with corresponding statistics.

Output 44.6.2. Missing Data Patterns

The MI Procedure					
Missing Data Patterns					
Group	Oxygen	Run Time	Run Pulse	Freq	Percent
1	X	X	X	21	67.74
2	X	X	.	4	12.90
3	X	.	.	3	9.68
4	.	X	X	1	3.23
5	.	X	.	2	6.45

Missing Data Patterns			
-----Group Means-----			
Group	Oxygen	RunTime	RunPulse
1	46.353810	10.809524	171.666667
2	47.109500	10.137500	.
3	52.461667	.	.
4	.	11.950000	176.000000
5	.	9.885000	.

With the ITPRINT option in INITIAL=EM, the procedure displays the “EM (Posterior Mode) Iteration History” table in [Output 44.6.3](#).

Output 44.6.3. EM (Posterior Mode) Iteration History

The MI Procedure				
EM (Posterior Mode) Iteration History				
<u>_Iteration_</u>	<u>-2 Log L</u>	<u>-2 Log Posterior</u>	<u>Oxygen</u>	<u>RunTime</u>

With the DISPLAYINIT option in the MCMC statement, the “Initial Parameter Estimates for MCMC” table shown in [Output 44.6.4](#) displays the starting mean and covariance estimates used in MCMC. The same starting estimates are used for the MCMC process for multiple chains because the EM algorithm is applied to the same data set in each chain. You can explicitly specify different initial estimates for different imputations, or you can use the bootstrap to generate different parameter estimates from the EM algorithm for the MCMC process.

Output 44.6.4. Initial Parameter Estimates

The MI Procedure				
Initial Parameter Estimates for MCMC				
<u>_TYPE_</u>	<u>_NAME_</u>	<u>Oxygen</u>	<u>RunTime</u>	<u>RunPulse</u>
MEAN		47.103766	10.554320	171.382196
COV	Oxygen	24.549967	-5.726112	-15.926036
COV	RunTime	-5.726112	1.781407	3.124798
COV	RunPulse	-15.926036	3.124798	83.164045

Output 44.6.5 and Output 44.6.6 display variance information and parameter estimates from the multiple imputation.

Output 44.6.5. Variance Information

The MI Procedure				
Multiple Imputation Variance Information				
Variable	-----Variance-----			DF
	Between	Within	Total	
Oxygen	0.051560	0.928170	0.988323	25.958
RunTime	0.003979	0.070057	0.074699	25.902
RunPulse	4.118578	4.260631	9.065638	7.5938

Multiple Imputation Variance Information			
Variable	Relative	Fraction	Relative
	Increase	Missing	
	in Variance	Information	
Oxygen	0.064809	0.062253	0.989731
RunTime	0.066262	0.063589	0.989513
RunPulse	1.127769	0.575218	0.912517

Output 44.6.6. Parameter Estimates

The MI Procedure					
Multiple Imputation Parameter Estimates					
Variable	Mean	Std Error	95% Confidence Limits		DF
Oxygen	47.164819	0.994145	45.1212	49.2085	25.958
RunTime	10.549936	0.273312	9.9880	11.1118	25.902
RunPulse	170.969836	3.010920	163.9615	177.9782	7.5938

Multiple Imputation Parameter Estimates					
Variable	Minimum	Maximum	Mu0	t for H0:	
				Mean=Mu0	Pr > t
Oxygen	46.858020	47.363540	50.000000	-2.85	0.0084
RunTime	10.476886	10.659412	10.000000	2.01	0.0547
RunPulse	168.252615	172.894991	180.000000	-3.00	0.0182

Example 44.7. Producing Monotone Missingness with MCMC

This example uses the MCMC method to impute just enough missing values for a data set with an arbitrary missing pattern so that each imputed data set has a monotone missing pattern based on the order of variables in the VAR statement.

The following statements invoke the MI procedure and specify the IMPUTE=MONOTONE option to create the imputed data set with a monotone missing pattern. You must specify a VAR statement to provide the order of variables for the imputed data to achieve a monotone missing pattern.

```
proc mi data=FitMiss seed=17655417 out=outex7;
  mcmc impute=monotone;
  var Oxygen RunTime RunPulse;
run;
```

Output 44.7.1. Model Information

The MI Procedure	
Model Information	
Data Set	WORK.FITMISS
Method	Monotone-data MCMC
Multiple Imputation Chain	Single Chain
Initial Estimates for MCMC	EM Posterior Mode
Start	Starting Value
Prior	Jeffreys
Number of Imputations	5
Number of Burn-in Iterations	200
Number of Iterations	100
Seed for random number generator	17655417

The “Model Information” table shown in [Output 44.7.1](#) describes the method used in the multiple imputation process.

The “Missing Data Patterns” table shown in [Output 44.7.2](#) lists distinct missing data patterns with corresponding statistics. Here, an “X” means that the variable is observed in the corresponding group, a “.” means that the variable is missing and will be imputed to achieve the monotone missingness for the imputed data set, and an “O” means that the variable is missing and will not be imputed. The table also displays group-specific variable means.

Output 44.7.2. Missing Data Pattern

The MI Procedure					
Missing Data Patterns					
Group	Oxygen	Run Time	Run Pulse	Freq	Percent
1	X	X	X	21	67.74
2	X	X	O	4	12.90
3	X	O	O	3	9.68
4	.	X	X	1	3.23
5	.	X	O	2	6.45

Missing Data Patterns			
-----Group Means-----			
Group	Oxygen	RunTime	RunPulse
1	46.353810	10.809524	171.666667
2	47.109500	10.137500	.
3	52.461667	.	.
4	.	11.950000	176.000000
5	.	9.885000	.

As shown in the table, the MI procedure only needs to impute three missing values from Group 4 and Group 5 to achieve a monotone missing pattern for the imputed data set.

When using the MCMC method to produce an imputed data set with a monotone missing pattern, tables of variance information and parameter estimates are not created.

The following statements are used just to show the monotone missingness of the output data set `outex7`.

```
proc mi data=outex7 nimpute=0;
  var Oxygen RunTime RunPulse;
run;
```

Output 44.7.3. Monotone Missing Data Pattern

The MI Procedure					
Missing Data Patterns					
Group	Oxygen	Run Time	Run Pulse	Freq	Percent
1	X	X	X	110	70.97
2	X	X	.	30	19.35
3	X	.	.	15	9.68

Missing Data Patterns			
Group	-----Group Means-----		
	Oxygen	RunTime	RunPulse
1	46.152428	10.861364	171.863636
2	47.796038	10.053333	.
3	52.461667	.	.

The “Missing Data Patterns” table shown in [Output 44.7.3](#) displays a monotone missing data pattern.

The following statements impute one value for each missing value in the monotone missingness data set `outex7`.

```
proc mi data=outex7 nimpute=1 seed=51343672 out=outds;
  monotone method=reg;
  var Oxygen RunTime RunPulse;
  by _Imputation_;
run;
```

You can then analyze these data sets by using other SAS procedures and combine these results by using the `MIANALYZE` procedure. Note that the `VAR` statement is required with a `MONOTONE` statement to provide the variable order for the monotone missing pattern.

Example 44.8. Checking Convergence in MCMC

This example uses the MCMC method with a single chain. It also displays time-series and autocorrelation plots to check convergence for the single chain.

The following statements use the MCMC method to create an iteration plot for the successive estimates of the mean of `Oxygen`. Note that iterations during the burn-in period are indicated with negative iteration numbers. These statements also create an autocorrelation function plot for the variable `Oxygen`.

```
proc mi data=FitMiss seed=42037921 noprint nimpute=2;
  mcmc timeplot(mean(Oxygen)) acfplot(mean(Oxygen));
  var Oxygen RunTime RunPulse;
run;
```

Output 44.8.1. Time-Series Plot for Oxygen

With the `TIMEPLOT(MEAN(Oxygen))` option, the procedure displays a time-series plot for the mean of `Oxygen` in [Output 44.8.1](#).

By default, the MI procedure displays solid line segments that connect data points in the time-series plot. The plot shows no apparent trends for the variable `Oxygen`.

Output 44.8.2. Autocorrelation Function Plot for Oxygen

With the ACFPLOT(MEAN(oxygen)) option, the procedure displays an autocorrelation plot for the mean of Oxygen in [Output 44.8.2](#).

By default, the MI procedure uses the star sign (*) as the plot symbol to display the points in the plot, a solid line to display the reference line of zero autocorrelation, and a pair of dashed lines to display approximately 95% confidence limits for the autocorrelations. The autocorrelation function plot shows no significant positive or negative autocorrelation.

The following statements use display options to modify the autocorrelation function plot for Oxygen in [Output 44.8.3](#).

```
proc mi data=FitMiss seed=42037921 noprint nimpute=2;
  mcmc acfplot(mean(Oxygen) / symbol=dot lref=2);
  var Oxygen RunTime RunPulse;
run;
```

Output 44.8.3. Autocorrelation Function Plot for Oxygen

You can also create plots for the worst linear function, the means of other variables, the variances of variables, and covariances between variables. Alternatively, you can use the OUTITER option to save statistics such as the means, standard deviations, covariances, $-2 \log LR$ statistic, $-2 \log LR$ statistic of the posterior mode, and worst linear function from each iteration in an output data set. Then you can do a more in-depth time-series analysis of the iterations with other procedures, such as PROC AUTOREG and PROC ARIMA in the *SAS/ETS User's Guide*.

With the experimental ODS GRAPHICS statement specified in the following statements

```
ods html;  
ods graphics on;  
  
proc mi data=FitMiss seed=42037921 noprint nimpute=2;  
  mcmc timeplot(mean(Oxygen)) acfplot(mean(Oxygen));  
  var Oxygen RunTime RunPulse;  
run;  
  
ods graphics off;  
ods html close;
```

the MI procedure produces the experimental graphs, as shown in [Output 44.8.4](#) and [Output 44.8.5](#).

Output 44.8.4. Time-Series Plot for Oxygen (Experimental)

Output 44.8.5. Autocorrelation Function Plot for Oxygen (Experimental)

For general information about ODS graphics see [Chapter 15, “Statistical Graphics Using ODS.”](#) For specific information about the graphics available in the MI procedure, see the “[ODS Graphics](#)” section on page 2567.

Example 44.9. Saving and Using Parameters for MCMC

This example uses the MCMC method with multiple chains as specified in [Example 44.6](#). It saves the parameter values used for each imputation in an output data set of type EST called `miest`. This output data set can then be used to impute missing values in other similar input data sets. The following statements invoke the MI procedure and specify the MCMC method with multiple chains to create three imputations.

```
proc mi data=FitMiss seed=21355417 nimpute=6 mu0=50 10 180 ;
  mcmc chain=multiple initial=em outest=miest;
  var Oxygen RunTime RunPulse;
run;
```

The following statements list the parameters used for the imputations in [Output 44.9.1](#). Note that the data set includes observations with `_TYPE_='SEED'` containing the seed to start the next random number generator.

```
proc print data=miest(obs=15);
  title 'Parameters for the Imputations';
run;
```

Output 44.9.1. OUTEST Data Set

Parameters for the Imputations						
Obs	_Imputation_	_TYPE_	_NAME_	Oxygen	RunTime	RunPulse
1	1	SEED		825240167.00	825240167.00	825240167.00
2	1	PARM		46.77	10.47	169.41
3	1	COV	Oxygen	30.59	-8.32	-50.99
4	1	COV	RunTime	-8.32	2.90	17.03
5	1	COV	RunPulse	-50.99	17.03	200.09
6	2	SEED		1895925872.00	1895925872.00	1895925872.00
7	2	PARM		47.41	10.37	173.34
8	2	COV	Oxygen	22.35	-4.44	-21.18
9	2	COV	RunTime	-4.44	1.76	1.25
10	2	COV	RunPulse	-21.18	1.25	125.67
11	3	SEED		137653011.00	137653011.00	137653011.00
12	3	PARM		48.21	10.36	170.52
13	3	COV	Oxygen	23.59	-5.25	-19.76
14	3	COV	RunTime	-5.25	1.66	5.00
15	3	COV	RunPulse	-19.76	5.00	110.99

The following statements invoke the MI procedure and use the INEST= option in the MCMC statement.

```
proc mi data=FitMiss;
  mcmc inest=miest;
  var Oxygen RunTime RunPulse;
run;
```

Output 44.9.2. Model Information

The MI Procedure	
Model Information	
Data Set	WORK.FITMISS
Method	MCMC
INEST Data Set	WORK.MIEST
Number of Imputations	6

The “Model Information” table shown in [Output 44.9.2](#) describes the method used in the multiple imputation process. The remaining tables for the example are identical to the tables in [Output 44.6.2](#), [Output 44.6.4](#), [Output 44.6.5](#), and [Output 44.6.6](#) in [Example 44.6](#).

Example 44.10. Transforming to Normality

This example applies the MCMC method to the `FitMiss` data set in which the variable `Oxygen` is transformed. Assume that `Oxygen` is skewed and can be transformed to normality with a logarithmic transformation. The following statements invoke the MI procedure and specify the transformation. The `TRANSFORM` statement specifies the log transformation for `Oxygen`. Note that the values displayed for `Oxygen` in all of the results correspond to transformed values.

```
proc mi data=FitMiss seed=32937921 mu0=50 10 180 out=outex10;
  transform log(Oxygen);
  mcmc chain=multiple displayinit;
  var Oxygen RunTime RunPulse;
run;
```

The “Missing Data Patterns” table shown in [Output 44.10.1](#) lists distinct missing data patterns with corresponding statistics for the `FitMiss` data. Note that the values of `Oxygen` shown in the tables are transformed values.

Output 44.10.1. Missing Data Pattern

The MI Procedure					
Missing Data Patterns					
Group	Oxygen	Run Time	Run Pulse	Freq	Percent
1	X	X	X	21	67.74
2	X	X	.	4	12.90
3	X	.	.	3	9.68
4	.	X	X	1	3.23
5	.	X	.	2	6.45

Transformed Variables: Oxygen			
Missing Data Patterns			
Group	-----Group Means-----		
	Oxygen	RunTime	RunPulse
1	3.829760	10.809524	171.666667
2	3.851813	10.137500	.
3	3.955298	.	.
4	.	11.950000	176.000000
5	.	9.885000	.

Transformed Variables: Oxygen

The “Variable Transformations” table shown in [Output 44.10.2](#) lists the variables that have been transformed.

Output 44.10.2. Variable Transformations

The MI Procedure	
Variable Transformations	
Variable	_Transform_
Oxygen	LOG

The “Initial Parameter Estimates for MCMC” table shown in [Output 44.10.3](#) displays the starting mean and covariance estimates used in the MCMC process.

Output 44.10.3. Initial Parameter Estimates

The MI Procedure				
Initial Parameter Estimates for MCMC				
TYPE	_NAME_	Oxygen	RunTime	RunPulse
MEAN		3.846122	10.557605	171.382949

* Transformed Variables
    
```

The following statements list the first ten observations of the data set `outmi` in [Output 44.10.6](#). Note that the values for Oxygen are in the original scale.

```
proc print data=outex10(obs=10);
  title 'First 10 Observations of the Imputed Data Set';
run;
```

Output 44.10.6. Imputed Data Set in Original Scale

First 10 Observations of the Imputed Data Set				
Obs	_Imputation_	Oxygen	RunTime	Run Pulse
1	1	44.6090	11.3700	178.000
2	1	45.3130	10.0700	185.000
3	1	54.2970	8.6500	156.000
4	1	59.5710	7.1440	167.012
5	1	49.8740	9.2200	170.092
6	1	44.8110	11.6300	176.000
7	1	38.5834	11.9500	176.000
8	1	43.7376	10.8500	158.851
9	1	39.4420	13.0800	174.000
10	1	60.0550	8.6300	170.000

Note that the preceding results can also be produced from the following statements without using a TRANSFORM statement. A transformed value of $\log(50)=3.91202$ is used in the MU0= option.

```
data temp;
  set FitMiss;
  LogOxygen= log(Oxygen);
run;

proc mi data=temp seed=14337921 mu0=3.91202 10 180 out=outtemp;
  mcmc chain=multiple displayinit;
  var LogOxygen RunTime RunPulse;
run;

data outex10;
  set outtemp;
  Oxygen= exp(LogOxygen);
run;
```

Example 44.11. Multistage Imputation

This example uses two separate imputation procedures to complete the imputation process. The first MI procedure uses the MCMC method to impute just enough missing values for a data set with an arbitrary missing pattern so that each imputed data set has a monotone missing pattern. The second MI procedure uses a MONOTONE statement to impute missing values for data sets with monotone missing patterns.

The following statements are identical to [Example 44.7](#). The statements invoke the MI procedure and specify the the IMPUTE=MONOTONE option to create the imputed data set with a monotone missing pattern.

```
proc mi data=FitMiss seed=17655417 out=outex11;
  mcmc impute=monotone;
  var Oxygen RunTime RunPulse;
run;
```

The “Missing Data Patterns” table shown in [Output 44.11.1](#) lists distinct missing data patterns with corresponding statistics. Here, an “X” means that the variable is observed in the corresponding group, a “.” means that the variable is missing and will be imputed to achieve the monotone missingness for the imputed data set, and an “O” means that the variable is missing and will not be imputed. The table also displays group-specific variable means.

Output 44.11.1. Missing Data Pattern

The MI Procedure					
Missing Data Patterns					
Group	Oxygen	Run Time	Run Pulse	Freq	Percent
1	X	X	X	21	67.74
2	X	X	O	4	12.90
3	X	O	O	3	9.68
4	.	X	X	1	3.23
5	.	X	O	2	6.45

Missing Data Patterns			
-----Group Means-----			
Group	Oxygen	RunTime	RunPulse
1	46.353810	10.809524	171.666667
2	47.109500	10.137500	.
3	52.461667	.	.
4	.	11.950000	176.000000
5	.	9.885000	.

As shown in the table, the MI procedure only needs to impute three missing values from Group 4 and Group 5 to achieve a monotone missing pattern for the imputed data set. When the MCMC method is used to produce an imputed data set with a monotone missing pattern, tables of variance information and parameter estimates are not created.

The following statements impute one value for each missing value in the monotone missingness data set `Outex11`.

```
proc mi data=outex11
      nimpute=1 seed=51343672
      out=outex11a;
  monotone reg;
  var Oxygen RunTime RunPulse;
  by _Imputation_;
run;
```

You can then analyze these data sets by using other SAS procedures and combine these results by using the procedure `MIANALYZE`. Note that the `VAR` statement is required with a `MONOTONE` statement to provide the variable order for the monotone missing pattern.

The “Model Information” table displayed in [Output 44.11.2](#) shows that a monotone method is used to generate imputed values in the first `BY` group.

Output 44.11.2. Model Information

----- Imputation Number=1 -----	
The MI Procedure

7	1	39.8345	11.9500	176.000
8	1	45.3196	10.8500	151.252
9	1	39.4420	13.0800	174.000
10	1	60.0550	8.6300	170.000

This example presents an alternative to the full-data MCMC imputation. When imputation of only a few missing values are needed to achieve a monotone missing pattern for the imputed data set. The example uses a monotone MCMC method that impute fewer missing values in each iteration and achieves approximate stationarity in fewer iterations (Schafer 1997, p. 227). The example also demonstrates how to combine the monotone MCMC method with a method for monotone missing data, which does not rely on iterations of steps.

Chapter 45

The MIANALYZE Procedure

Overview

The MIANALYZE procedure combines the results of the analyses of imputations and generates valid statistical inferences. Multiple imputation provides a useful strategy for analyzing data sets with missing values. Instead of filling in a single value for each missing value, Rubin's (1976; 1987) multiple imputation strategy replaces each missing value with a set of plausible values that represent the uncertainty about the right value to impute. You can implement the strategy with two SAS procedures: PROC MI, which generates imputed data sets, and PROC MIANALYZE, which combines the results of analyses carried out on the data sets.

The analyses of imputations are obtained by using standard SAS procedures (such as PROC REG) for complete data. No matter which complete-data analysis is used, the process of combining results from different imputed data sets is essentially the same and results in valid statistical inferences that properly reflect the uncertainty due to missing values.

The MIANALYZE procedure reads parameter estimates and associated standard errors or covariance matrix that are computed by the standard statistical procedure for each imputed data set. The MIANALYZE procedure then derives valid univariate inference for these parameters. With an additional assumption about the population between and within imputation covariance matrices, multivariate inference based on Wald tests can also be derived.

For some parameters of interest, you can use TEST statements to test linear hypotheses about the parameters. For others, it is not straightforward to compute estimates and associated covariance matrices with standard statistical SAS procedures. Examples include correlation coefficients between two variables and ratios of variable means. These special cases are described in the [“Examples of the Complete-Data Inferences”](#) section on page 2628.

In SAS 9, the VAR statement has been replaced by the MODELEFFECTS statement to accommodate various effects to be analyzed. A STDERR statement has been added to specify the standard errors when both parameter estimates and associated standard errors are stored as variables in the same data set.

Also, an experimental CLASS statement has been added to specify classification variables in the MODELEFFECTS statement. The CLASS statement must be used in conjunction with the MODELEFFECTS statement.

Getting Started

The Fitness data set has been altered to contain an arbitrary missing pattern:

```

*----- Data on Physical Fitness -----*
| These measurements were made on men involved in a physical |
| fitness course at N.C. State University.                   |
| Only selected variables of                                 |
| Oxygen (oxygen intake, ml per kg body weight per minute), |
| Runtime (time to run 1.5 miles in minutes), and           |
| RunPulse (heart rate while running) are used.             |
| Certain values were changed to missing for the analysis.  |

48.673  9.40 186      47.920 11.50 170
47.467 10.50 170
;

```

Suppose that the data are multivariate normally distributed and that the missing data are missing at random (see the “Statistical Assumptions for Multiple Imputation” section in “The MI Procedure” chapter for a description of these assumptions). The following statements use the MI procedure to impute missing values for the `FitMiss` data set.

```

proc mi data=FitMiss noprint out=outmi seed=3237851;
  var Oxygen RunTime RunPulse;
run;

```

The MI procedure creates imputed data sets, which are stored in the `outmi` data set. A variable named `_Imputation_` indicates the imputation numbers. Based on m imputations, m different sets of the point and variance estimates for a parameter can be computed. In this example, $m = 5$ is the default.

The following statements generate regression coefficients for each of the five imputed data sets:

```
proc reg data=outmi outest=outreg covout noprint;
  model Oxygen= RunTime RunPulse;
  by _Imputation_;
run;
```

The following statements display parameter estimates and covariance matrices from the first two imputed data sets in [Figure 45.1](#).

```
proc print data=outreg(obs=8);
  var _Imputation_ _Type_ _Name_
      Intercept RunTime RunPulse;
  title 'Parameter Estimates from Imputed Data Sets';
run;
```

Parameter Estimates from Imputed Data Sets						
Obs	_Imputation_	_TYPE_	_NAME_	Intercept	RunTime	RunPulse

RunPulse	0	-1.12	0.2695

Figure 45.4. Multiple Imputation Parameter Estimates

The “Multiple Imputation Parameter Estimates” table shown in [Figure 45.4](#) displays a combined estimate and standard error for each regression coefficient (parameter). Inferences are based on t distributions. The table displays a 95% confidence interval and a t -test with the associated p -value for the hypothesis that the parameter is equal to the value specified with the THETA0= option (in this case, zero by default). The minimum and maximum parameter estimates from the imputed data sets are also displayed.

Syntax

The following statements are available in PROC MIANALYZE.

```
PROC MIANALYZE < options > ;
  BY variables ;
  CLASS variables ;
  MODELEFFECTS effects ;
  < label: > TEST equation1 < , ... , < equationk > > < /options > ;
  STDERR variables ;
```

The BY statement specifies groups in which separate analyses are performed.

The CLASS statement lists the classification variables in the EFFECT statement. Classification variables can be either character or numeric.

The required MODELEFFECTS statement lists the effects to be analyzed. The variables in the statement that are not specified in a CLASS statement are assumed to be continuous.

The STDERR statement lists the standard errors associated with the effects in the MODELEFFECTS statement when both parameter estimates and standard errors are saved as variable in the same DATA= data set. The STDERR statement can be used only when each effect in the MODELEFFECTS statement is a continuous variable by itself.

The TEST statement tests linear hypotheses about the parameters. An F statistic is used to test jointly the null hypothesis ($H_0: \mathbf{L}\beta = \mathbf{c}$) specified in a single TEST statement. Several TEST statements can be used.

The PROC MIANALYZE and MODELEFFECTS statements are required for the MI procedure. The rest of this section provides detailed syntax information for each of these statements, beginning with the PROC MIANALYZE statement. The remaining statements are in alphabetical order.

PROC MIANALYZE Statement

PROC MIANALYZE < options > ;

The following table summarizes the options in the PROC MIANALYZE statement.

Table 45.1. Summary of PROC MIANALYZE Options

Tasks	Options
Specify input data sets	
COV, CORR, or EST type data set	DATA=
parameter estimates and standard errors	DATA=
parameter estimates	PARMS=
parameter information	PARMINFO=
covariance matrices	COVB=
$(X'X)^{-1}$ matrices	XPXI=
Specify statistical analysis	
parameters under the null hypothesis	THETA0=
level for the confidence interval	ALPHA=
complete-data degrees of freedom	EDF=
Display Printed Output	
within-imputation covariance matrix	WCOV
between-imputation covariance matrix	BCOV
total covariance matrix	TCOV
multivariate inferences	MULT

The following are explanations of the options that can be used in the PROC MIANALYZE statement (in alphabetical order):

ALPHA=*p*

specifies that confidence limits are to be constructed for the parameter estimates with confidence level $100(1 - p)\%$, where $0 < p < 1$. The default is $p=0.05$.

BCOV

displays the between-imputation covariance matrix.

COVB <(EFFECTVAR=STACKING | ROWCOL)> =SAS-data-set

names an input SAS data set that contains covariance matrices of the parameter estimates from imputed data sets. If you provide a COVB= data set, you must also provide a PARMS= data set.

The EFFECTVAR= option identifies the variables for parameters displayed in the covariance matrix and is used only when the PARMINFO= option is not specified. The default is EFFECTVAR= STACKING.

See the “[Input Data Sets](#)” section on page 2620 for a detailed description of the COVB= option.

DATA=SAS-data-set

names an input SAS data set.

If the input DATA= data set is not a specially structured SAS data set, the data set contains both the parameter estimates and associated standard errors. The parameter estimates are specified in the MODELEFFECTS statement and the standard errors are specified in the STDERR statement.

If the data set is a specially structured input SAS data set, it must have a TYPE of EST, COV, or CORR that contains estimates from imputed data sets:

- TYPE=EST, the data set contains the parameter estimates and associated covariance matrices.
- TYPE=COV, the data set contains the sample means, sample sizes, and covariance matrices. Each covariance matrix for variables is divided by the sample size n to create the covariance matrix for parameter estimates.
- TYPE=CORR, the data set contains the sample means, sample sizes, standard errors, and correlation matrices. The covariance matrices are computed from the correlation matrices and associated standard errors. Each covariance matrix for variables is divided by the sample size n to create the covariance matrix for parameter estimates.

If you do not specify an input data set with the DATA= or PARMS= option, then the most recently created SAS data set is used as an input DATA= data set. See the “[Input Data Sets](#)” section on page 2620 for a detailed description of the input data sets.

EDF=number

specifies the complete-data degrees of freedom for the parameter estimates. This is used to compute an adjusted degrees of freedom for each parameter estimate. By default, EDF= ∞ and the degrees of freedom for each parameter estimate is not adjusted.

MULT**MULTIVARIATE**

requests multivariate inference for the parameters. It is based on Wald tests and is a generalization of the univariate inference. See the “[Multivariate Inferences](#)” section on page 2626 for a detailed description of the multivariate inference.

PARMINFO=SAS-data-set

names an input SAS data set that contains parameter information associated with variables PRM1, PRM2, ..., and so on. These variables are used as variables for parameters in a COVB= data set. See the “[Input Data Sets](#)” section on page 2620 for a detailed description of the PARMINFO= option.

PARMS <(CLASSVAR= ctype)> =SAS-data-set

names an input SAS data set that contains parameter estimates computed from imputed data sets. When a COVB= data set is not specified, the input PARMS= data set also contains standard errors associated with these parameter estimates. If multivariate inference is requested, you must also provide a COVB= or XPXI= data set.

When the effects contain CLASS variables, the option CLASSVAR= *ctype* can be used to identify the associated CLASS variables when reading the classification levels from observations. The available types are FULL, LEVEL, and CLASSVAL. The default is CLASSVAR= FULL. See the “[Input Data Sets](#)” section on page 2620 for a detailed description of the PARMS= option.

TCOV

displays the total covariance matrix derived by assuming that the population between-imputation and within-imputation covariance matrices are proportional to each other.

THETA0=numbers**MU0=numbers**

specifies the parameter values θ_0 under the null hypothesis $\theta = \theta_0$ in the t tests for location for the effects. If only one number θ_0 is specified, that number is used for all effects. If more than one number is specified, the specified numbers correspond to effects in the MODELEFFECTS statement in the order in which they appear in the statement. When an effect contains CLASS variables, the corresponding value is not used and the test is not performed.

WCOV

displays the within-imputation covariance matrices.

XPXI=SAS-data-set

names an input SAS data set that contains the $(X'X)^{-1}$ matrices associated with the parameter estimates computed from imputed data sets. If you provide an XPXI= data set, you must also provide a PARMS= data set. In this case, PROC MIANALYZE reads the standard errors of the estimates from the PARMS= data. The standard errors and $(X'X)^{-1}$ matrices are used to derive the covariance matrices.

BY Statement

BY variables ;

You can specify a BY statement with PROC MIANALYZE to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the MI procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure.

For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

CLASS Statement (Experimental)

CLASS *variables* ;

The CLASS statement specifies the classification variables in the MODELEFFECTS statement. Classification variables can be either character or numeric.

Classification levels are determined from the formatted values of the CLASS variables. Refer to the chapter titled “The FORMAT Procedure” in the *SAS Procedures Guide*.

MODELEFFECTS Statement

MODELEFFECTS *effects* ;

The MODELEFFECTS statement lists the effects in the data set to be analyzed. Each effect is a variable or a combination of variables, and is specified with a special notation using variable names and operators.

Each variable is either a classification (or CLASS) variable or a continuous variable. If a variable is not declared in the CLASS statement, it is assumed to be continuous. Crossing and nesting operators can be used in an effect to create crossed and nested effects.

One general form of an effect involving several variables is

$$X1 * X2 * A * B * C (D E)$$

where A, B, C, D, and E are CLASS variables and X1 and X2 are continuous variables.

When the input DATA= data set is not a specially structured SAS data set, you must also specify standard errors of the parameter estimates in a STDERR statement.

STDERR Statement

STDERR *variables* ;

The STDERR statement lists standard errors associated with effects in the MODELEFFECTS statement, when the input DATA= data set contains both parameter estimates and standard errors as variables in the data set.

With the STDERR statement, only continuous effects are allowed in the MODELEFFECTS statement. The specified standard errors are corresponding to parameter estimates in the order in which they appear in the MODELEFFECTS statement.

For example, you can use the following MODELEFFECTS and STDERR statements to identify both the parameter estimates and associated standard errors in a SAS data set.

```
proc mianalyze;
  var y1-y3;
  stderr sy1-sy3;
run;
```

TEST Statement

`< label: > TEST equation1 < , ... , < equationk >>< /options > ;`

The TEST statement tests linear hypotheses about the parameters β . An F test is used to test jointly the null hypotheses ($H_0: \mathbf{L}\beta = \mathbf{c}$) specified in a single TEST statement.

Each *equation* specifies a linear hypothesis (a row of the \mathbf{L} matrix and the corresponding element of the \mathbf{c} vector); multiple *equations* are separated by commas. The label, which must be a valid SAS name, is used to identify the resulting output. You can submit multiple TEST statements. When a label is not included in a TEST statement, a label of “Test j ” is used for the j th TEST statement.

The form of an *equation* is as follows:

`term < \pm term ... > < = \pm term < \pm term ... >>`

where *term* is a parameter of the model, or a constant, or a constant times a parameter. When no equal sign appears, the expression is set to 0. Only parameters for regressor effects (continuous variables by themselves) are allowed.

For each TEST statement, PROC MIANALYZE displays a “Test Specification” table of the \mathbf{L} matrix and the \mathbf{c} vector. The procedure also displays a “Multiple Imputation Variance Information” table of the between-imputation, within-imputation, and total variances for combining complete-data inferences, and a “Multiple Imputation Parameter Estimates” table of a combined estimate and standard error for each linear component. The linear components are labeled TestPrm1, TestPrm2, ... in the tables.

The following code illustrates possible uses of the TEST statement:

```
proc mianalyze;
  var intercept a1 a2 a3;
  test1: test intercept + a2 = 0;
  test2: test intercept + a2;
  test3: test a1=a2=a3;
  test4: test a1=a2, a2=a3;
run;
```

The first and second TEST statements are equivalent and correspond to the following specification

```

The MIANALYZE Procedure
Test: test1

Test Specification

-----L Matrix-----
Parameter    intercept      a1      a2      a3      C
TestPrm1     1.000000      0      1.000000      0      0

```

Figure 45.5. Test Specification for test1 and test2

The third and fourth TEST statements are also equivalent and correspond to the specification

```

The MIANALYZE Procedure
Test: test3

Test Specification

-----L Matrix-----
Parameter    intercept      a1      a2      a3      C
TestPrm1     0      1.000000     -1.000000      0      0
TestPrm2     0      0      1.000000     -1.000000      0

```

Figure 45.6. Test Specification for test3 and test4

The ALPHA= and EDF options specified in the PROC MIANALYZE statement are also applied to the TEST statement. You can specify the following options in the TEST statement after a slash(/).

BCOV

displays the between-imputation covariance matrix.

MULT

displays the multivariate inference for parameters.

TCOV

displays the total covariance matrix.

WCOV

displays the within-imputation covariance matrix.

For more information, see the [“Testing Linear Hypotheses about the Parameters”](#) section on page 2628.

Details

Input Data Sets

You specify input data sets based on the type of inference you requested. For univariate inference, you can use one of the following options:

- a `DATA=` data set, which provides both parameter estimates and the associated standard errors.
- a `DATA=` type `EST`, `COV`, or `CORR` data set, which provides both parameter estimates and the associated standard errors either explicitly (type `CORR`) or through the covariance matrix (type `EST`, `COV`).
- `PARMS=` data set, which provides both parameter estimates and the associated standard errors.

For multivariate inference, which includes the testing of linear hypotheses about parameters, you can use one of the following option combinations:

- a `DATA=` type `EST`, `COV`, or `CORR` data set, which provides parameter estimates and the associated covariance matrix either explicitly (type `EST`, `COV`) or through the correlation matrix and standard errors (type `CORR`) in a single data set.
- `PARMS=` and `COVB=` data sets, which provide parameter estimates in a `PARMS=` data set and the associated covariance matrix in a `COVB=` data set.
- `PARMS=`, `COVB=`, and `PARMINFO=` data sets, which provide parameter estimates in a `PARMS=` data set, the associated covariance matrix in a `COVB=` data set with variables named `PRM1`, `PRM2`, ..., and the effects associated with these variables in a `PARMINFO=` data set.
- `PARMS=` and `XPXI=` data sets, which provide parameter estimates and the associated standard errors in a `PARMS=` data set and the associated $(X'X)^{-1}$ matrix in an `XPXI=` data set.

The appropriate combination depends on the type of inference and the SAS procedure you used to create the data sets. For instance, if you used `PROC REG` to create an `OUTEST=` data set containing the parameter estimates and covariance matrix, you would use the `DATA=` option to read the `OUTEST=` data set.

When the input `DATA=` data set is not a specially structured SAS data set, each observation corresponds to an imputation and contains both parameter estimates and associated standard errors. For others, each input data set must contain the variable `_Imputation_` to identify the imputation by number.

If you do not specify an input data set with the `DATA=` or `PARMS=` option, then the most recently created SAS data set is used as an input `DATA=` data set. Note that with a `DATA=` data set, each effect represents a continuous variable, only regressor effects (continuous variables by themselves) are allowed in the `MODELEFFECTS` statement.

DATA= SAS data set

The DATA= data set provides both parameter estimates and the associated standard errors computed from imputed data sets. Such data sets are typically created with an OUTPUT statement using procedures such as PROC MEANS and PROC UNIVARIATE.

The MIANALYZE procedure reads parameter estimates from observations with variables in the MODELEFFECTS statement, and standard errors for parameter estimates from observations with variables in the STDERR statement. The order of the variables for standard errors must match the order of the variables for parameter estimates.

DATA= type EST, COV, or CORR SAS data set

The specially structured DATA= data set provides both parameter estimates and the associated covariance matrix computed from imputed data sets. Such data sets are created by procedures such as PROC CORR (type COV, CORR) and PROC REG (type EST).

With TYPE=EST, the MIANALYZE procedure reads parameter estimates from observations with `_TYPE_='PARM'`, `_TYPE_='PARMS'`, `_TYPE_='OLS'`, or `_TYPE_='FINAL'`, and covariance matrices for parameter estimates from observations with `_TYPE_='COV'` or `_TYPE_='COVB'`.

With TYPE=COV, the procedure reads sample means from observations with `_TYPE_='MEAN'`, sample size n from observations with `_TYPE_='N'`, and covariance matrices for variables from observations with `_TYPE_='COV'`.

With TYPE=CORR, the procedure reads sample means from observations with `_TYPE_='MEAN'`, sample size n from observations with `_TYPE_='N'`, correlation matrices for variables from observations with `_TYPE_='CORR'`, and standard errors for variables from observations with `_TYPE_='STD'`. The standard errors and correlation matrix are used to generate a covariance matrix for the variables.

Note that with TYPE=COV or CORR, each covariance matrix for the variables is divided by n to create the covariance matrix for the sample means.

PARMS <(CLASSVAR= ctype)> = data set

The PARMS= data set contains parameter estimates and associated standard errors computed from imputed data sets. Such data sets are typically created with an ODS OUTPUT statement using procedures such as PROC GENMOD, PROC GLM, PROC LOGISTIC, and PROC MIXED.

The MIANALYZE procedure reads effect names from observations with the variable `Parameter`, `Effect`, `Variable`, or `Parm`. It then reads parameter estimates from observations with the variable `Estimate` and standard errors for parameter estimates from observations with the variable `StdErr`.

When the effects contain CLASS variables, the option `CLASSVAR= ctype` can be used to identify associated CLASS variables when reading the CLASS levels from

observations. The available types are FULL, LEVEL, and CLASSVAL. The default is CLASSVAR= FULL.

With CLASSVAR=FULL, the data set contains the CLASS variables explicitly. PROC MIANALYZE reads the CLASS levels from observations with their corresponding CLASS variables. PROC MIXED generates this type of tables.

With CLASSVAR=LEVEL, PROC MIANALYZE reads the classification levels for the effect from observations with variables Level1, Level2, and so on, where the variable Level1 contains the classification level for the first CLASS variable in the effect, the variable Level2 contains the classification level for the second CLASS variable in the effect. For each effect, the variables in the crossed list are displayed before the variables in the nested list. The variable order in the CLASS statement is used for variables inside each list. PROC GENMOD generates this type of tables.

For example, with the following statements,

```
proc mianalyze parms(classvar=Level)= dataparm;
  class c1 c2 c3;
  modeleffects c2 c3(c2 c1);
run;
```

the variable Level1 has the classification level of the variable c2 for the effect c2. For the effect c3(c2 c1), the variable Level1 has the classification level of the variable c3, Level2 has the level of c1, and Level3 has the level of c2.

Similarly, with CLASSVAR=CLASSVAL, PROC MIANALYZE reads the classification levels for the effect from observations with variables ClassVal0, ClassVal1, and so on, where the variable ClassVal0 contains the classification level for the first CLASS variable in the effect, the variable ClassVal1 contains the classification level for the second CLASS variable in the effect. For each effect, the variables in the crossed list are displayed before the variables in the nested list. The variable order in the CLASS statement is used for variables inside each list. PROC LOGISTIC generates this type of tables.

PARMS <(CLASSVAR= *ctype*)>= and COVB= data sets

The PARMS= data set contains parameter estimates and the COVB= data set contains associated covariance matrices computed from imputed data sets. Such data sets are typically created with an ODS OUTPUT statement using procedures such as PROC LOGISTIC, PROC MIXED, and PROC REG.

With a PARMS= data set, the MIANALYZE procedure reads effect names from observations with the variable Parameter, Effect, Variable, or Parm. It then reads parameter estimates from observations with the variable Estimate.

When the effects contain CLASS variables, the option CLASSVAR= *ctype* can be used to identify the associated CLASS variables when reading the CLASS levels from observations. The available types are FULL, LEVEL, and CLASSVAL, and are described in the “PARMS <(CLASSVAR= *ctype*)> = data set” section on page 2621. The default is CLASSVAR= FULL.

The option `EFFECTVAR=etype` identifies the variables for parameters displayed in the covariance matrix. The available types are `STACKING` and `ROWCOL`. The default is `EFFECTVAR=STACKING`.

With `EFFECTVAR=STACKING`, each parameter is displayed by stacking variables in the effect. Begin with the variables in the crossed list, followed by the continuous list, then followed by the nested list. Each `CLASS` variable is displayed with its `CLASS` level attached. `PROC LOGISTIC` generates this type of tables.

When each effect is a continuous variable by itself, each stacked parameter name reduces to the effect name. `PROC REG` generates this type of tables.

With `EFFECTVAR=STACKING`, the `MIANALYZE` procedure reads parameter names from observations with the variable `Parameter`, `Effect`, `Variable`, `Parm`, or `RowName`. It then reads covariance matrices from observations with the stacked variables in a `COVB=` data set.

With `EFFECTVAR=ROWCOL`, parameters are displayed by the variables `Col1`, `Col2`, ... The parameter associated with the variable `Col1` is identified by the observation with value 1 for the variable `Row`. The parameter associated with the variable `Col2` is identified by the observation with value 2 for the variable `Row`. `PROC MIXED` generates this type of table.

With `EFFECTVAR=ROWCOL`, the `MIANALYZE` procedure reads the parameter indices from observations with the variable `Row`, the effect names from observations with the variable `Parameter`, `Effect`, `Variable`, `Parm`, or `RowName`, and covariance matrices from observations with the variables `Col1`, `Col2`, ... in a `COVB=` data set.

When the effects contain `CLASS` variables, the data set contains the `CLASS` variables explicitly and the `MIANALYZE` procedure also reads the `CLASS` levels from their corresponding `CLASS` variables.

`PARMS <(CLASSVAR= ctype)> =, PARMINFO=, and COVB= data sets`

The input `PARMS=` data set contains parameter estimates and the input `COVB=` data set contains associated covariance matrices computed from imputed data sets. Such data sets are typically created with an `ODS OUTPUT` statement using procedure such as `PROC GENMOD`.

With a `PARMS=` data set, the `MIANALYZE` procedure reads effect names from observations with the variable `Parameter`, `Effect`, `Variable`, or `Parm`. It then reads parameter estimates from observations with the variable `Estimate`.

When the effects contain `CLASS` variables, the option `CLASSVAR= ctype` can be used to identify the associated `CLASS` variables when reading the `CLASS` levels from observations. The available types are `FULL`, `LEVEL`, and `CLASSVAL`, and are described in the “`PARMS <(CLASSVAR= ctype)> = data set`” section on page 2621. The default is `CLASSVAR= FULL`.

With a `COVB=` data set, the `MIANALYZE` procedure reads parameter names from observations with the variable `Parameter`, `Effect`, `Variable`, `Parm`, or `RowName` and covariance matrices from observations with variables `Prm1`, `Prm2`, and so on.

The parameters associated with the variables Prm1, Prm2, ... are identified in the PARMINFO= data set. PROC MIANALYZE reads the parameter names from observations with the variable **Parameter** and the corresponding effect from observations with the variable **Effect**. When the effects contain CLASS variables, the data set contains the CLASS variables explicitly and the MIANALYZE procedure also reads the CLASS levels from observations with their corresponding CLASS variables.

PARMS= and XPXI= data sets

The input PARMS= data set contains parameter estimates and the input XPXI= data set contains associated $(X'X)^{-1}$ matrices computed from imputed data sets. Such data sets are typically created with an ODS OUTPUT statement using a procedure such as PROC GLM.

With a PARMS= data set, the MIANALYZE procedure reads parameter names from observations with the variable **Parameter**, **Effect**, **Variable**, or **Parm**. It then reads parameter estimates from observations with the variable **Estimate** and standard errors for parameter estimates from observations with the variable **StdErr**.

With a XPXI= data set, the MIANALYZE procedure reads parameter names from observations with the variable **Parameter** and $(X'X)^{-1}$ matrices from observations with the parameter variables in the data set.

Note that this combination can only be used when each effect is a continuous variable by itself.

Combining Inferences from Imputed Data Sets

With m imputations, m different sets of the point and variance estimates for a parameter Q can be computed. Suppose that \hat{Q}_i and \hat{U}_i are the point and variance estimates from the i th imputed data set, $i=1, 2, \dots, m$. Then the combined point estimate for Q from multiple imputation is the average of the m complete-data estimates:

$$\bar{Q} = \frac{1}{m} \sum_{i=1}^m \hat{Q}_i$$

Suppose that \bar{W} is the within-imputation variance, which is the average of the m complete-data estimates:

$$\bar{W} = \frac{1}{m} \sum_{i=1}^m \hat{W}_i$$

and B be the between-imputation variance

$$B = \frac{1}{m-1} \sum_{i=1}^m (\hat{Q}_i - \bar{Q})^2$$

Then the variance estimate associated with \bar{Q} is the total variance (Rubin 1987)

$$T = \bar{W} + \left(1 + \frac{1}{m}\right)B$$

The statistic $(Q - \bar{Q})T^{-(1/2)}$ is approximately distributed as t with v_m degrees of freedom (Rubin 1987), where

$$v_m = (m - 1) \left[1 + \frac{\bar{W}}{(1 + m^{-1})B} \right]^2$$

The degrees of freedom v_m depends on m and the ratio

$$r = \frac{(1 + m^{-1})B}{\bar{W}}$$

The ratio r is called the relative increase in variance due to nonresponse (Rubin 1987). When there is no missing information about Q , the values of r and B are both zero. With a large value of m or a small value of r , the degrees of freedom v_m will be large and the distribution of $(Q - \bar{Q})T^{-(1/2)}$ will be approximately normal.

Another useful statistic is the fraction of missing information about Q :

$$\hat{\lambda} = \frac{r + 2/(v_m + 3)}{r + 1}$$

Both statistics r and λ are helpful diagnostics for assessing how the missing data contribute to the uncertainty about Q .

When the complete-data degrees of freedom v_0 is small, and there is only a modest proportion of missing data, the computed degrees of freedom, v_m , can be much larger than v_0 , which is inappropriate. For example, with $m = 5$ and $r = 10\%$, the computed degrees of freedom $v_m = 484$, which is inappropriate for data sets with complete-data degrees of freedom less than 484.

Barnard and Rubin (1999) recommend the use of an adjusted degrees of freedom

$$v_m^* = \left[\frac{1}{v_m} + \frac{1}{\hat{v}_{obs}} \right]^{-1}$$

where $\hat{v}_{obs} = (1 - \gamma)v_0(v_0 + 1)/(v_0 + 3)$ and $\gamma = (1 + m^{-1})B/T$.

If you specify the complete-data degrees of freedom v_0 with the EDF= option, the MIANALYZE procedure uses the adjusted degrees of freedom, v_m^* , for inference. Otherwise, the degrees of freedom v_m is used.

Multiple Imputation Efficiency

The relative efficiency (RE) of using the finite m imputation estimator, rather than using an infinite number for the fully efficient imputation, in units of variance, is approximately a function of m and λ (Rubin 1987, p. 114).

$$RE = \left(1 + \frac{\lambda}{m}\right)^{-1}$$

The following table shows relative efficiencies with different values of m and λ .

Table 45.2. Relative Efficiency

m	λ				
	10%	20%	30%	50%	70%
3	0.9677	0.9375	0.9091	0.8571	0.8108
5	0.9804	0.9615	0.9434	0.9091	0.8772
10	0.9901	0.9804	0.9709	0.9524	0.9346
20	0.9950	0.9901	0.9852	0.9756	0.9662

The table shows that for situations with little missing information, only a small number of imputations are necessary. In practice, the number of imputations needed can be informally verified by replicating sets of m imputations and checking whether the estimates are stable between sets (Horton and Lipsitz 2001, p. 246).

Multivariate Inferences

Multivariate inference based on Wald tests can be done with m imputed data sets. The approach is a generalization of the approach taken in the univariate case (Rubin 1987, p. 137; Schafer 1997, p. 113). Suppose that $\hat{\mathbf{Q}}_i$ and $\hat{\mathbf{U}}_i$ are the point and covariance matrix estimates for a p -dimensional parameter \mathbf{Q} (such as a multivariate mean) from the i th imputed data set, $i=1, 2, \dots, m$. Then the combined point estimate for \mathbf{Q} from the multiple imputation is the average of the m complete-data estimates:

$$\bar{\mathbf{Q}} = \frac{1}{m} \sum_{i=1}^m \hat{\mathbf{Q}}_i$$

Suppose that $\bar{\mathbf{U}}$ is the within-imputation covariance matrix, which is the average of the m complete-data estimates

$$\bar{\mathbf{W}} = \frac{1}{m} \sum_{i=1}^m \hat{\mathbf{W}}_i$$

and suppose that \mathbf{B} is the between-imputation covariance matrix

$$\mathbf{B} = \frac{1}{m-1} \sum_{i=1}^m (\hat{\mathbf{Q}}_i - \bar{\mathbf{Q}})(\hat{\mathbf{Q}}_i - \bar{\mathbf{Q}})'$$

Then the covariance matrix associated with $\bar{\mathbf{Q}}$ is the total covariance matrix

$$\mathbf{T}_0 = \bar{\mathbf{W}} + \left(1 + \frac{1}{m}\right)\mathbf{B}$$

The natural multivariate extension of the t statistic used in the univariate case is the F statistic

$$F_0 = (\mathbf{Q} - \bar{\mathbf{Q}})' \mathbf{T}_0^{-1} (\mathbf{Q} - \bar{\mathbf{Q}})$$

with degrees of freedom p and

$$v = (m - 1)\left(1 + 1/r\right)^2$$

where

$$r = \left(1 + \frac{1}{m}\right) \text{trace}(\mathbf{B}\bar{\mathbf{W}}^{-1})/p$$

is an average relative increase in variance due to nonresponse (Rubin 1987, p. 137; Schafer 1997, p. 114).

However, the reference distribution of the statistic F_0 is not easily derived. Especially for small m , the between-imputation covariance matrix \mathbf{B} is unstable and does not have full rank for $m \leq p$ (Schafer 1997, p. 113).

One solution is to make an additional assumption that the population between-imputation and within-imputation covariance matrices are proportional to each other (Schafer 1997, p. 113). This assumption implies that the fractions of missing information for all components of \mathbf{Q} are equal. Under this assumption, a more stable estimate of the total covariance matrix is

$$\mathbf{T} = (1 + r)\bar{\mathbf{W}}$$

With the total covariance matrix \mathbf{T} , the F statistic (Rubin 1987, p. 137)

$$F = (\mathbf{Q} - \bar{\mathbf{Q}})' \mathbf{T}^{-1} (\mathbf{Q} - \bar{\mathbf{Q}})/p$$

has an F distribution with degrees of freedom p and v_1 , where

$$v_1 = \frac{1}{2}(p + 1)(m - 1)\left(1 + \frac{1}{r}\right)^2$$

For $t = p(m - 1) \leq 4$, PROC MIANALYZE uses the degrees of freedom v_1 in the analysis. For $t = p(m - 1) > 4$, PROC MIANALYZE uses v_2 , a better approximation of the degrees of freedom given by Li, Raghunathan, and Rubin (1991).

$$v_2 = 4 + (t - 4) \left[1 + \frac{1}{r} \left(1 - \frac{2}{t}\right)\right]^2$$

Testing Linear Hypotheses about the Parameters

Linear hypotheses for parameters β are expressed in matrix form as

$$H_0: \mathbf{L}\beta = \mathbf{c}$$

where \mathbf{L} is a matrix of coefficients for the linear hypotheses, and \mathbf{c} is a vector of constants.

Suppose that $\hat{\mathbf{Q}}_i$ and $\hat{\mathbf{U}}_i$ are the point and covariance matrix estimates for a p -dimensional parameter \mathbf{Q} from the i th imputed data set, $i=1, 2, \dots, m$. Then for a given matrix \mathbf{L} , the point and covariance matrix estimates for the linear functions $\mathbf{L}\mathbf{Q}$ in the i th imputed data set are

$$\mathbf{L}\hat{\mathbf{Q}}_i$$

$$\mathbf{L}\hat{\mathbf{U}}_i\mathbf{L}'$$

The inferences described in the “[Combining Inferences from Imputed Data Sets](#)” section on page 2624 and the “[Multivariate Inferences](#)” section on page 2626 are applied to these linear estimates for testing the null hypothesis $H_0: \mathbf{L}\beta = \mathbf{c}$.

For each TEST statement, the “Test Specification” table displays the \mathbf{L} matrix and the \mathbf{c} vector, the “Multiple Imputation Variance Information” table displays the between-imputation, within-imputation, and total variances for combining complete-data inferences, the “Multiple Imputation Parameter Estimates” table displays a combined estimate and standard error for each linear component.

With the WCOV and BCOV options in the TEST statement, the procedure displays the within-imputation and between-imputation covariance matrices, respectively.

With the TCOV option, the procedure displays the total covariance matrix derived under the assumption that the population between-imputation and within-imputation covariance matrices are proportional to each other.

With the MULT option in the TEST statement, the “Multiple Imputation Multivariate Inference” table displays an F test for the null hypothesis $\mathbf{L}\beta = \mathbf{c}$ of the linear components.

Examples of the Complete-Data Inferences

For a given parameter of interest, it is not always possible to compute the estimate and associated covariance matrix directly from a SAS procedure. This section describes examples of parameters with their estimates and associated covariance matrices, which provide the input to the MIANALYZE procedure. Some are straightforward, and others require special techniques.

Means

For a population mean vector $\boldsymbol{\mu}$, the usual estimate is the sample mean vector

$$\bar{\mathbf{y}} = \frac{1}{n} \sum \mathbf{y}_i$$

A variance estimate for $\bar{\mathbf{y}}$ is $\frac{1}{n} \mathbf{S}$, where \mathbf{S} is the sample covariance matrix

$$\mathbf{S} = \frac{1}{n-1} \sum (\mathbf{y}_i - \bar{\mathbf{y}})(\mathbf{y}_i - \bar{\mathbf{y}})'$$

These statistics can be computed from a procedure such as CORR. This approach is illustrated in [Example 45.2](#).

Regression Coefficients

Many SAS procedures are available for regression analysis. Among them, PROC REG provides the most general analysis capabilities, and others like PROC LOGISTIC and PROC MIXED provide more specialized analyses.

Some regression procedures, such as REG and LOGISTIC, create an EST type data set that contains both the parameter estimates for the regression coefficients and their associated covariance matrix. You can read an EST type data set in the MIANALYZE procedure with the DATA= option. This approach is illustrated in [Example 45.3](#).

Other procedures, such as GLM, MIXED, and GENMOD, do not generate EST type data sets for regression coefficients. For PROC MIXED and PROC GENMOD, you can use ODS OUTPUT statement to save parameter estimates in a data set and the associated covariance matrix in a separate data set. These data sets are then read in the MIANALYZE procedure with the PARMS= and COVB= options, respectively. This approach is illustrated in [Example 45.4](#) for PROC MIXED and in [Example 45.5](#) for PROC GENMOD.

PROC GLM does not display tables for covariance matrices. However, you can use the ODS OUTPUT statement to save parameter estimates and associated standard errors in a data set and the associated $(X'X)^{-1}$ matrix in a separate data set. These data sets are then read in the MIANALYZE procedure with the PARMS= and XPXI= options, respectively. This approach is illustrated in [Example 45.6](#).

For univariate inference, only parameter estimates and associated standard errors are needed. You can use the ODS OUTPUT statement to save parameter estimates and associated standard errors in a data set. These data set is then read in the MIANALYZE procedure with the PARMS= option. This approach is illustrated in [Example 45.4](#).

Correlation Coefficients

For the population correlation coefficient ρ , a point estimate is the sample correlation coefficient r . However, for nonzero ρ , the distribution of r is skewed.

The distribution of r can be normalized through Fisher's z transformation

$$z(r) = \frac{1}{2} \log \left(\frac{1+r}{1-r} \right)$$

$z(r)$ is approximately normally distributed with mean $z(\rho)$ and variance $1/(n-3)$.

With a point estimate \hat{z} and an approximate 95% confidence interval (z_1, z_2) for $z(\rho)$, a point estimate \hat{r} and a 95% confidence interval (r_1, r_2) for ρ can be obtained by applying the inverse transformation

$$r = \tanh(z) = \frac{e^{2z} - 1}{e^{2z} + 1}$$

to $z = \hat{z}, z_1$, and z_2 .

This approach is illustrated in [Example 45.10](#).

Ratios of Variable Means

For the ratio μ_1/μ_2 of means for variables Y_1 and Y_2 , the point estimate is \bar{y}_1/\bar{y}_2 , the ratio of the sample means. The Taylor expansion and delta method can be applied to the function y_1/y_2 to obtain the variance estimate (Schafer 1997, p. 196)

$$\frac{1}{n} \left[\left(\frac{\bar{y}_1}{\bar{y}_2} \right)^2 s_{22} - 2 \left(\frac{\bar{y}_1}{\bar{y}_2} \right) \left(\frac{1}{\bar{y}_2} \right) s_{12} + \left(\frac{1}{\bar{y}_2} \right)^2 s_{11} \right]$$

where s_{11} and s_{22} are the sample variances of Y_1 and Y_2 , respectively, and s_{12} is the sample covariance between Y_1 and Y_2 .

A ratio of sample means will be approximately unbiased and normally distributed if the coefficient of variation of the denominator (the standard error for the mean divided by the estimated mean) is 10% or less (Cochran 1977, p. 166; Schafer 1997, p. 196).

ODS Table Names

PROC MIANALYZE assigns a name to each table it creates. You must use these names to reference tables when using the Output Delivery System (ODS). These names are listed in the following table. For more information on ODS, see [Chapter 14](#), “Using the Output Delivery System.”

Table 45.3. ODS Tables Produced in PROC MIANALYZE

ODS Table Name	Description	Statement	Option
BCov	Between-imputation covariance matrix		BCOV
ModelInfo	Model information		
MultStat	Multivariate inference		MULT
ParameterEstimates	Parameter estimates		
TCov	Total covariance matrix		TCOV
TestBCov	Between-imputation covariance matrix for $L\beta$	TEST	BCOV
TestMultStat	Multivariate inference for $L\beta$	TEST	MULT
TestParameterEstimates	Parameter estimates for $L\beta$	TEST	
TestSpec	Test specification, L and c	TEST	
TestTCov	Total covariance matrix for $L\beta$	TEST	TCOV
TestVarianceInfo	Variance information for $L\beta$	TEST	
TestWCov	Within-imputation covariance matrix for $L\beta$	TEST	WCOV
VarianceInfo	Variance information		
WCov	Within-imputation covariance matrix		WCOV

Examples

The following statements generate five imputed data sets to be used in this section. The data set `FitMiss` was created in the section “[Getting Started](#)” on page 2610. See “[The MI Procedure](#)” chapter for details concerning the MI procedure.

```
proc mi data=FitMiss seed=3237851 noprint out=outmi;
  var Oxygen RunTime RunPulse;
run;
```

The Fish data described in the STEPDISC procedure are measurements of 159 fish of seven species caught in Finland’s lake Laengelmavesi. For each fish, the length, height, and width are measured. Three different length measurements are recorded: from the nose of the fish to the beginning of its tail (`Length1`), from the nose to the notch of its tail (`Length2`), and from the nose to the end of its tail (`Length3`). See [Chapter 67](#), “[The STEPDISC Procedure](#),” for more information.

The Fish2 data set is constructed from the Fish data set and contains two species of fish. Some values have been set to missing and the resulting data set has a monotone missing pattern in variables `Length3`, `Height`, `Width`, and `Species`. Note that some values of the variable `Species` have also been altered in the data set.

The following statements create the Fish2 data set. It contains the first two species of fish in the Fish data set.

```

/*----- Fishes of Species Bream and Parkki Pike -----*/
data Fish2 (drop=HtPct WidthPct);
title 'Fish Measurement Data';
input Species $ Length3 HtPct WidthPct @@;
Height= HtPct*Length3/100;
Width= WidthPct*Length3/100;
datalines;

;

```

The following statements generate five imputed data sets to be used in this section. The regression method is used to impute missing values in the variable Width and the discriminant function method is used to impute the variable Species.

```

proc mi data=Fish2 seed=1305417 out=outfish;
  class Species;
  monotone reg (Width)
    discrim( Species= Length3 Height Width);
  var Length3 Height Width Species;
run;

```

Examples 1-6 use different input option combinations to combine parameter estimates computed from different procedures, Examples 7-8 combine parameter estimates with CLASS variables, Example 9 shows the use of a TEST statement, and Example 10 combines statistics that are not directly derived from procedures.

Example 45.1. Reading Means and Standard Errors from Variables in a DATA= Data Set

This example creates an ordinary SAS data set that contains sample means and standard errors computed from imputed data sets. These estimates are then combined to generate valid univariate inferences about the population means.

The following statements use the UNIVARIATE procedure to generate sample means and standard errors for the variables in each imputed data set.

```
proc univariate data=outmi noprint;
  var Oxygen RunTime RunPulse;
  output out=outuni mean=Oxygen RunTime RunPulse
           stderr=SOxygen SRunTime SRunPulse;
  by _Imputation_;
run;
```

The following statements display the output data set from PROC UNIVARIATE in [Output 45.1.1](#):

```
proc print data=outuni;
  title 'UNIVARIATE Means and Standard Errors';
run;
```

Output 45.1.1. UNIVARIATE Output Data Set

UNIVARIATE Means and Standard Errors							
Obs	_Imputation_	Oxygen	RunTime	Run Pulse	SOxygen	SRun Time	SRun Pulse
1	1	47.0120	10.4441	171.216	0.95984	0.28520	1.59910
2	2	47.2407	10.5040	171.244	0.93540	0.26661	1.75638
3	3	47.4995	10.5922	171.909	1.00766	0.26302	1.85795
4	4	47.1485	10.5279	171.146	0.95439	0.26405	1.75011
5	5	47.0042	10.4913	172.072	0.96528	0.27275	1.84807

The following statements combine the means and standard errors from imputed data sets. The EDF= option requests that the adjusted degrees of freedom be used in the analysis. For sample means based on 31 observations, the complete-data error degrees of freedom is 30.

```
proc mianalyze data=outuni edf=30;
  modeleffects Oxygen RunTime RunPulse;
  stderr SOxygen SRunTime SRunPulse;
run;
```

Output 45.1.2. Multiple Imputation Variance Information

The MIANALYZE Procedure				
Model Information				
	Data Set	WORK.OUTUNI		
	Number of Imputations	5		
Multiple Imputation Variance Information				
Parameter	-----Variance-----			DF
	Between	Within	Total

RunTime	0.048365	0.047147	0.990659	
RunPulse	0.073626	0.070759	0.986046	

The “Model Information” table shown in [Output 45.1.2](#) lists the input data set(s) and the number of imputations.

The “Multiple Imputation Variance Information” table shown in [Output 45.1.2](#) displays the between-imputation variance, within-imputation variance, and total variance for each univariate inference. It also displays the degrees of freedom for the total variance. The relative increase in variance due to missing values, the fraction of missing information, and the relative efficiency for each imputed variable are also displayed. A detailed description of these statistics is provided in the “[Combining Inferences from Imputed Data Sets](#)” section on page 2624 and the “[Multiple Imputation Efficiency](#)” section on page 2626.

Output 45.1.3. Multiple Imputation Parameter Estimates

The MIANALYZE Procedure					
Multiple Imputation Parameter Estimates					
Parameter	Estimate	Std Error	95% Confidence Limits		DF
Oxygen	47.180993	0.990266	45.1466	49.2154	26.298
RunTime	10.511906	0.276910	9.9432	11.0806	26.503
RunPulse	171.517500	1.828591	167.7549	175.2801	25.463
Multiple Imputation Parameter Estimates					
Parameter	Minimum	Maximum			
Oxygen	47.004201	47.499541			
RunTime	10.444149	10.592244			
RunPulse	171.146171	172.071730			
Multiple Imputation Parameter Estimates					
Parameter	Theta0	t for H0: Parameter=Theta0		Pr > t	
Oxygen	0	47.64	<.0001		
RunTime	0	37.96	<.0001		
RunPulse	0	93.80	<.0001		

The “Multiple Imputation Parameter Estimates” table shown in [Output 45.1.3](#) displays the estimated mean and corresponding standard error for each variable. The table also displays a 95% confidence interval for the mean and a t statistic with the associated p -value for testing the hypothesis that the mean is equal to the value specified. You can use the THETA0= option to specify the value for the null hypothesis, which is zero by default. The table also displays the minimum and maximum parameter estimates from the imputed data sets.

Note that the results in this example could also have been obtained with the MI procedure.

Example 45.2. Reading Means and Covariance Matrices from a DATA= COV Data Set

This example creates a COV type data set that contains sample means and covariance matrices computed from imputed data sets. These estimates are then combined to generate valid statistical inferences about the population means.

The following statements use the CORR procedure to generate sample means and a covariance matrix for the variables in each imputed data set.

```
proc corr data=outmi cov nocorr noprint out=outcov(type=cov);
  var Oxygen RunTime RunPulse;
  by _Imputation_;
run;
```

The following statements display sample means and covariance matrices from the first two imputed data sets in [Output 45.2.1](#).

```
proc print data=outcov(obs=12);
  title 'CORR Means and Covariance Matrices'
        '(First Two Imputations)';
run;
```

Output 45.2.1. COV Data Set

CORR Means and Covariance Matrices (First Two Imputations)						
Obs	_Imputation_	_TYPE_	_NAME_	Oxygen	RunTime	RunPulse
1	1	COV	Oxygen	28.5603	-7.2652	-11.812
2	1	COV	RunTime	-7.2652	2.5214	2.536
3	1	COV	RunPulse	-11.8121	2.5357	79.271
4	1	MEAN		47.0120	10.4441	171.216
5	1	STD		5.3442	1.5879	8.903
6	1	N		31.0000	31.0000	31.000
7	2	COV	Oxygen	27.1240	-6.6761	-10.217
8	2	COV	RunTime	-6.6761	2.2035	2.611
9	2	COV	RunPulse	-10.2170	2.6114	95.631
10	2	MEAN		47.2407	10.5040	171.244
11	2	STD		5.2081	1.4844	9.779
12	2	N		31.0000	31.0000	31.000

Note that the covariance matrices in the data set OUTCOV are estimated covariance matrices of variables, $V(\mathbf{y})$. The estimated covariance matrix of the sample means is $V(\bar{\mathbf{y}}) = V(\mathbf{y})/n$, where n is the sample size, and is not the same as an estimated covariance matrix for variables.

The following statements combine the results for the imputed data sets, and derive both univariate and multivariate inferences about the means. The EDF= option is specified to request that the adjusted degrees of freedom be used in the analysis. For sample means based on 31 observations, the complete-data error degrees of freedom is 30.

```
proc mianalyze data=outcov edf=30 wcov bcov tcov mult;
  modeleffects Oxygen RunTime RunPulse;
run;
```

The “Multiple Imputation Variance Information” and “Multiple Imputation Parameter Estimates” tables display the same results as in [Output 45.1.2](#) and [Output 45.1.3](#) in [Example 45.1](#).

With the WCOV, BCOV, and TCOV options, the procedure displays the between-imputation covariance matrix, within-imputation covariance matrix, and total covariance matrix assuming that the between-imputation covariance matrix is proportional to the within-imputation covariance matrix in [Output 45.2.2](#).

Output 45.2.2. Covariance Matrices

```

The MIANALYZE Procedure

      Within-Imputation Covariance Matrix

              Oxygen              RunTime              RunPulse

Oxygen          0.930852655          -0.226506411          -0.461022083
RunTime         -0.226506411           0.073141598           0.080316017
RunPulse        -0.461022083           0.080316017           3.114441784

      Between-Imputation Covariance Matrix

              Oxygen              RunTime              RunPulse

Oxygen          0.0414778123          0.0099248946          0.0183701754
RunTime         0.0099248946          0.0029478891          0.0091684769
RunPulse        0.0183701754          0.0091684769          0.1910855259

      Total Covariance Matrix

              Oxygen              RunTime              RunPulse

Oxygen          1.202882661          -0.292700068          -0.595750001
RunTime         -0.292700068           0.094516313           0.103787365
RunPulse        -0.595750001           0.103787365           4.024598310

```

With the MULT option, the procedure assumes that the between-imputation covariance matrix is proportional to the within-imputation covariance matrix and displays a multivariate inference for all the parameters taken jointly.

Output 45.2.3. Multiple Imputation Multivariate Inference

```

The MIANALYZE Procedure

      Multiple Imputation Multivariate Inference
      Assuming Proportionality of Between/Within Covariance Matrices

      Avg Relative
      Increase
      in Variance   Num DF   Den DF   F for H0:
                                     Parameter=Theta0   Pr > F

      0.292237          3   122.68   12519.7   <.0001

```

The “Multiple Imputation Multivariate Inference” table displayed in [Output 45.2.3](#) shows a significant p -value for the null hypothesis that the population means are all equal to zero.

Example 45.3. Reading Regression Results from a DATA= EST Data Set

This example creates an EST type data set that contains regression coefficients and their corresponding covariance matrices computed from imputed data sets. These estimates are then combined to generate valid statistical inferences about the regression model.

The following statements use the REG procedure to generate regression coefficients:

```
proc reg data=outmi outest=outreg covout noprint;
  model Oxygen= RunTime RunPulse;
  by _Imputation_;
run;
```

The following statements display regression coefficients and their covariance matrices from the first two imputed data sets in [Output 45.3.1](#).

```
proc print data=outreg(obs=8);
  var _Imputation_ _Type_ _Name_
      Intercept RunTime RunPulse;
  title 'REG Model Coefficients and Covariance matrices'
        '(First Two Imputations)';
run;
```

Output 45.3.1. EST Type Data Set

REG Model Coefficients and Covariance matrices (First Two Imputations)						
Obs	_Imputation_	_TYPE_	_NAME_	Intercept	RunTime	RunPulse
1	1	PARMS		86.544	-2.82231	-0.05873
2	1	COV	Intercept	100.145	-0.53519	-0.55077
3	1	COV	RunTime	-0.535	0.10774	-0.00345
4	1	COV	RunPulse	-0.551	-0.00345	0.00343
5	2	PARMS		83.021	-3.00023	-0.02491
6	2	COV	Intercept	79.032	-0.66765	-0.41918
7	2	COV	RunTime	-0.668	0.11456	-0.00313
8	2	COV	RunPulse	-0.419	-0.00313	0.00264

The following statements combine the results for the imputed data sets. The EDF= option is specified to request that the adjusted degrees of freedom be used in the analysis. For a regression model with three independent variables (including the Intercept) and 31 observations, the complete-data error degrees of freedom is 28.

```
proc mianalyze data=outreg edf=28;
  modeleffects Intercept RunTime RunPulse;
run;
```

Output 45.3.2. Multiple Imputation Variance Information

The MIANALYZE Procedure				
Multiple Imputation Variance Information				
Parameter	-----Variance-----			DF
	Between	Within	Total	
Intercept	45.529229	76.543614	131.178689	9.1917

Multiple Imputation Parameter Estimates		
Parameter	Minimum	Maximum
Intercept	83.020730	100.839807
RunTime	-3.204426	-2.822311
RunPulse	-0.112840	-0.024910

Multiple Imputation Parameter Estimates			
Parameter	Theta0	t for H0:	
		Parameter=Theta0	Pr > t
Intercept	0	7.93	<.0001
RunTime	0	-8.43	<.0001
RunPulse	0	-1.12	0.2842

The “Multiple Imputation Parameter Estimates” table shown in [Output 45.3.3](#) displays the estimated mean and standard error of the regression coefficients. The inferences are based on the t distribution. The table also displays a 95% mean confidence interval and a t test with the associated p -value for the hypothesis that the regression coefficient is equal to zero. Since the p -value for RunPulse is 0.1597, this variable can be removed from the regression model.

Example 45.4. Reading Mixed Model Results from PARMS= and COVB= Data Sets

This example creates data sets containing parameter estimates and covariance matrices computed by a mixed model analysis for a set of imputed data sets. These estimates are then combined to generate valid statistical inferences about the parameters.

The following PROC MIXED statements generate the fixed-effect parameter estimates and covariance matrix for each imputed data set:

```
proc mixed data=outmi;
  model Oxygen= RunTime RunPulse RunTime*RunPulse/solution covb;
  by _Imputation_;
  ods output SolutionF=mixparms CovB=mixcovb;
run;
```

The following statements display parameter estimates from the first two imputed data sets in [Output 45.4.1](#).

```
proc print data=mixparms (obs=8);
  var _Imputation_ Effect Estimate StdErr;
  title 'MIXED Model Coefficients (First Two Imputations)';
run;
```

Output 45.4.1. PROC MIXED Model Coefficients

MIXED Model Coefficients (First Two Imputations)				
Obs	_Imputation_	Effect	Estimate	StdErr
1	1	Intercept	148.09	81.5231
2	1	RunTime	-8.8115	7.8794
3	1	RunPulse	-0.4123	0.4684
4	1	RunTime*RunPulse	0.03437	0.04517
5	2	Intercept	64.3607	64.6034
6	2	RunTime	-1.1270	6.4307
7	2	RunPulse	0.08160	0.3688
8	2	RunTime*RunPulse	-0.01069	0.03664

The following statements display the covariance matrices associated with the parameter estimates from the first two imputed data sets in [Output 45.4.2](#). Note that the variables Col1, Col2, Col3, and Col4 are used to identify the effects Intercept, RunTime, RunPulse, and RunTime*RunPulse through the variable Row.

```
proc print data=mixcovb (obs=8);
  var _Imputation_ Row Effect Col1 Col2 Col3 Col4;
  title 'Covariance Matrices (First Two Imputations)';
run;
```

Output 45.4.2. PROC MIXED Covariance Matrices

Covariance Matrices (First Two Imputations)						
Obs	_Imputation_	Row Effect	Col1	Col2	Col3	Col4
1	1	1 Intercept	6646.01	-637.40	-38.1515	3.6542
2	1	2 RunTime	-637.40	62.0842	3.6548	-0.3556

The “Multiple Imputation Parameter Estimates” table shown in [Output 45.4.4](#) displays the estimated mean and standard error of the regression coefficients.

Since each covariance matrix contains variables Row, Col1, Col2, Col3, and Col4 for parameters, the EFFECTVAR=ROWCOL option is needed when specifying the COVB= option. The following statements illustrate the use of the MIANALYZE procedure with input PARMS= and COVB(EFFECTVAR=ROWCOL)= data sets:

```
proc mianalyze parms=mixparms edf=28
      covb(effectvar=rowcol)=mixcovb;
      modeleffects Intercept RunTime RunPulse RunTime*RunPulse;
run;
```

Example 45.5. Reading Generalized Linear Model Results from PARMS=, PARMINFO=, and COVB= Data Sets

This example creates data sets containing parameter estimates and corresponding covariance matrices computed by a generalized linear model analysis for a set of imputed data sets. These estimates are then combined to generate valid statistical inferences about the model parameters.

The following statements use PROC GENMOD to generate the parameter estimates and covariance matrix for each imputed data set:

```
proc genmod data=outmi;
  model Oxygen= RunTime RunPulse/covb;
  by _Imputation_;
  ods output ParameterEstimates=gmparms
             ParmInfo=gmpinfo
             CovB=gmcovb;
run;
```

The following statements print parameter estimates and covariance matrix from the first two imputed data sets in [Output 45.5.1](#).

```
proc print data=gmparms (obs=8);
  var _Imputation_ Parameter Estimate StdErr;
  title 'GENMOD Model Coefficients (First Two Imputations)';
run;
```

Output 45.5.1. PROC GENMOD Model Coefficients

GENMOD Model Coefficients (First Two Imputations)				
Obs	_Imputation_	Parameter	Estimate	StdErr
1	1	Intercept	86.5440	9.5107

7	2	Prm3	-0.378616	-0.002826	0.0023843
8	2	Scale	1.132E-14	2.181E-16	-7.62E-17

The following statements use the MIANALYZE procedure with input PARM=, PARMINFO=, and COVB= data sets:

```
proc mianalyze parms=gmparms covb=gmcovb parminfo=gmpinfo;
  modeleffects Intercept RunTime RunPulse;
run;
```

Since the GENMOD procedure computes maximum likelihood estimates for the covariance matrix, the EDF= option is not used. The resulting model coefficients are identical to the estimates in [Example 45.3](#) in [Output 45.3.3](#) but the standard errors are slightly different because in this example, maximum likelihood estimates for the standard errors are combined without the EDF= option, whereas in [Example 45.3](#), unbiased estimates for the standard errors are combined with the EDF= option.

Example 45.6. Reading GLM Results from PARMs= and XPXI= Data Sets

This example creates data sets containing parameter estimates and corresponding $(X'X)^{-1}$ matrices computed by a general linear model analysis for a set of imputed data sets. These estimates are then combined to generate valid statistical inferences about the model parameters.

The following statements use PROC GLM to generate the parameter estimates and $(X'X)^{-1}$ matrix for each imputed data set:

```
proc glm data=outmi;
  model Oxygen= RunTime RunPulse/inverse;
  by _Imputation_;
  ods output ParameterEstimates=glmparms
             InvXPX=glmxpxi;
quit;
```

The following statements display parameter estimates and standard errors from imputed data sets in [Output 45.6.1](#).

```
proc print data=glmparms (obs=6);
  var _Imputation_ Parameter Estimate StdErr;
  title 'GLM Model Coefficients (First Two Imputations)';
run;
```

Output 45.6.1. PROC GLM Model Coefficients

GLM Model Coefficients (First Two Imputations)				
Obs	_Imputation_	Parameter	Estimate	StdErr
1	1	Intercept	86.5440339	10.00726811

8	2	Oxygen	83.020730343	-3.000228818	-0.024910305

The standard errors for the estimates in the output `glmparms` data set are needed to create the covariance matrix from the $(X'X)^{-1}$ matrix. The following statements use the MIANALYZE procedure with input `PARMS=` and `XPXI=` data sets to produce the same results as displayed in Example 45.3 in Output 45.3.2 and Output 45.3.3:

```
proc mianalyze parms=glmparms xpxi=glmxpxi edf=28;
  modeleffects Intercept RunTime RunPulse;
run;
```

Example 45.7. Reading Logistic Model Results from `PARMS=` and `COVB=` Data Sets

This example creates data sets containing parameter estimates and corresponding covariance matrices computed by a logistic regression analysis for a set of imputed data sets. These estimates are then combined to generate valid statistical inferences about the model parameters.

The following statements use PROC LOGISTIC to generate the parameter estimates and covariance matrix for each imputed data set.

```
proc logistic data=outfish;
  class Species;
  model Species= Height Width Height*Width/ covb;
  by _Imputation_;
  ods output ParameterEstimates=lgsparms
             CovB=lgscovb;
run;
```

The following statements displays the logistic regression coefficients from the first two imputations in [Output 45.7.1](#).

```
proc print data=lgsparms (obs=8);
  title 'LOGISTIC Model Coefficients (First Two Imputations)';
run;
```

Output 45.7.1. PROC LOGISTIC Model Coefficients

LOGISTIC Model Coefficients (First Two Imputations)

Example 45.8. Reading Mixed Model Results with CLASS Variables

This example creates data sets containing parameter estimates and corresponding covariance matrices with CLASS variables computed by a mixed regression model analysis for a set of imputed data sets. These estimates are then combined to generate valid statistical inferences about the model parameters.

The following statements use PROC MIXED to generate the parameter estimates and covariance matrix for each imputed data set:

```
proc mixed data=outfish;
  class species;
  model length3= species height width/ solution covb;
  by _imputation_;
  ods output solutionF=mxparms covb=mxcovb;
run;
```

The following statements displays the mixed model coefficients from the first two imputations in [Output 45.8.1](#).

```
proc print data=mxparms (obs=10);
  var _Imputation_ Effect Species Estimate StdErr;
  title 'MIXED Model Coefficients (First Two Imputations)';
run;
```

Output 45.8.1. PROC MIXED Model Coefficients

The “Multiple Imputation Parameter Estimates” table shown in [Output 45.8.3](#) displays the combined parameter estimates with associated standard errors.

Example 45.9. Using a TEST statement

This example creates an EST type data set that contains regression coefficients and their corresponding covariance matrices computed from imputed data sets. These estimates are then combined to generate valid statistical inferences about the regression model. A TEST statement is used to test linear hypotheses about the parameters.

The following statements use the REG procedure to generate regression coefficients:

```
proc reg data=outmi outest=outreg covout noprint;
  model Oxygen= RunTime RunPulse;
  by _Imputation_;
run;
```

The following statements combine the results for the imputed data sets. A TEST statement is used to test linear hypotheses of Intercept=0 and RunTime=RunPulse.

```
proc mianalyze data=outreg edf=28;
  modeleffects Intercept RunTime RunPulse;
  test Intercept, RunTime=RunPulse / mult;
run;
```

Output 45.9.1. Test Specification

The MIANALYZE Procedure				
Test: Test 1				
Test Specification

Example 45.10. Combining Correlation Coefficients

This example combines sample correlation coefficients computed from a set of imputed data sets using Fisher’s z transformation.

Fisher’s z transformation of the sample correlation r is

$$z = \frac{1}{2} \log \left(\frac{1+r}{1-r} \right)$$

The statistic z is approximately normally distributed with mean

$$\log\left(\frac{1+\rho}{1-\rho}\right)$$

and variance $1/(n-3)$, where ρ is the population correlation coefficient and n is the number of observations.

The following statements use the CORR procedure to compute the correlation r and its associated Fisher's z statistic between variables **Oxygen** and **RunTime** for each imputed data set. The ODS statement is used to save Fisher's z statistic in an output data set.

```
proc corr data=outmi fisher(biasadj=no);
  var Oxygen RunTime;
  by _Imputation_;
  ods output FisherPearsonCorr= outz;
run;
```

The following statements display the number of observations and Fisher's z statistic for each imputed data set in [Output 45.10.1](#).

```
proc print data=outz;
  title 'Fisher''s Correlation Statistics';
  var _Imputation_ NObs ZVal;
run;
```

Output 45.10.1. Output z Statistics

Fisher's Correlation Statistics				
Obs	_Imputation_	NObs	ZVal	
1	1	31	-1.27869	
2	2	31	-1.30715	
3	3	31	-1.27922	
4	4	31	-1.39243	
5	5	31	-1.40146	

The following statements generate the standard error associated with the z statistic, $1/\sqrt{n-3}$:

```
data outz;
  set outz;
  StdZ= 1. / sqrt(NObs-3);
run;
```

The following statements use the MIANALYZE procedure to generate a combined parameter estimate \hat{z} and its variance, as shown in [Output 45.10.2](#). The ODS statement is used to save the parameter estimates in an output data set.

```
proc mianalyze data=outz;
  ods output ParameterEstimates=parms;
  modeffects ZVal;
  stderr StdZ;
run;
```

Output 45.10.2. Combining Fisher's z statistics

The MIANALYZE Procedure					
Multiple Imputation Parameter Estimates					
Parameter	Estimate	Std Error	95% Confidence Limits		DF
ZVal	-1.331787	0.200327	-1.72587	-0.93771	330.23
Multiple Imputation Parameter Estimates					
Parameter	Minimum	Maximum			
ZVal	-1.401459	-1.278686			
Multiple Imputation Parameter Estimates					
Parameter	Theta0	t for H0: Parameter=Theta0		Pr > t	
ZVal	0	-6.65		<.0001	

In addition to the estimate for z , PROC MIANALYZE also generates 95% confidence limits for z , $\hat{z}_{.025}$ and $\hat{z}_{.975}$. The following statements print the estimate and 95% confidence limits for z in [Output 45.10.3](#).

```
proc print data=parms;
  title 'Parameter Estimates with 95% Confidence Limits';
  var Estimate LCLMean UCLMean;
run;
```

Output 45.10.3. Parameter Estimates with 95% Confidence Limits

Parameter Estimates with 95% Confidence Limits			
Obs	Estimate	LCLMean	UCLMean
1	-1.331787	-1.72587	-0.93771

An estimate of the correlation coefficient and 95% confidence limits are then generated from the following inverse transformation as described in the “[Correlation Coefficients](#)” section on page 2630

$$r = \tanh(z) = \frac{e^{2z} - 1}{e^{2z} + 1}$$

for $z = \hat{z}$, $\hat{z}_{.025}$, and $\hat{z}_{.975}$.

The following statements generate and display an estimate of the correlation coefficient and its 95% confidence limits.

```
data corr_ci;
  set parms;
  r=      tanh( Estimate);
  r_lower= tanh( LCLMean);
  r_upper= tanh( UCLMean);
run;

proc print data=corr_ci;
  title 'Estimated Correlation Coefficient'
        ' with 95% Confidence Limits';
  var r r_lower r_upper;
run;
```

Output 45.10.4. Estimated Correlation Coefficient

Estimated Correlation Coefficient with 95% Confidence Limits			
Obs	r	r_lower	r_upper
1	-0.86969	-0.93857	-0.73417

Chapter 46

The MIXED Procedure

Overview

The MIXED procedure fits a variety of mixed linear models to data and enables you to use these fitted models to make statistical inferences about the data. A *mixed linear model* is a generalization of the standard linear model used in the GLM procedure, the generalization being that the data are permitted to exhibit correlation and nonconstant variability. The mixed linear model, therefore, provides you with the flexibility of modeling not only the means of your data (as in the standard linear model) but their variances and covariances as well.

The primary assumptions underlying the analyses performed by PROC MIXED are as follows:

- The data are normally distributed (Gaussian).
- The means (expected values) of the data are linear in terms of a certain set of parameters.
- The variances and covariances of the data are in terms of a different set of parameters, and they exhibit a structure matching one of those available in PROC MIXED.

Since Gaussian data can be modeled entirely in terms of their means and variances/covariances, the two sets of parameters in a mixed linear model actually specify the complete probability distribution of the data. The parameters of the mean model are referred to as *fixed-effects parameters*, and the parameters of the variance-covariance model are referred to as *covariance parameters*.

The fixed-effects parameters are associated with known explanatory variables, as in the standard linear model. These variables can be either qualitative (as in the traditional analysis of variance) or quantitative (as in standard linear regression). However, the covariance parameters are what distinguishes the mixed linear model from the standard linear model.

The need for covariance parameters arises quite frequently in applications, the following being the two most typical scenarios:

- The experimental units on which the data are measured can be grouped into clusters, and the data from a common cluster are correlated.
- Repeated measurements are taken on the same experimental unit, and these repeated measurements are correlated or exhibit variability that changes.

The first scenario can be generalized to include one set of clusters nested within another. For example, if students are the experimental unit, they can be clustered into

classes, which in turn can be clustered into schools. Each level of this hierarchy can introduce an additional source of variability and correlation. The second scenario occurs in longitudinal studies, where repeated measurements are taken over time. Alternatively, the repeated measures could be spatial or multivariate in nature.

PROC MIXED provides a variety of covariance structures to handle the previous two scenarios. The most common of these structures arises from the use of *random-effects parameters*, which are additional unknown random variables assumed to impact the variability of the data. The variances of the random-effects parameters, commonly known as *variance components*, become the covariance parameters for this particular structure. Traditional mixed linear models contain both fixed- and random-effects parameters, and, in fact, it is the combination of these two types of effects that led to the name *mixed model*. PROC MIXED fits not only these traditional variance component models but numerous other covariance structures as well.

PROC MIXED fits the structure you select to the data using the method of *restricted maximum likelihood (REML)*, also known as *residual maximum likelihood*. It is here that the Gaussian assumption for the data is exploited. Other estimation methods are also available, including *maximum likelihood* and *MIVQUEO*. The details behind these estimation methods are discussed in subsequent sections.

Once a model has been fit to your data, you can use it to draw statistical inferences via both the fixed-effects and covariance parameters. PROC MIXED computes several different statistics suitable for generating hypothesis tests and confidence intervals. The validity of these statistics depends upon the mean and variance-covariance model you select, so it is important to choose the model carefully. Some of the output from PROC MIXED helps you assess your model and compare it with others.

Basic Features

PROC MIXED provides easy accessibility to numerous mixed linear models that are useful in many common statistical analyses. In the style of the GLM procedure, PROC MIXED fits the specified mixed linear model and produces appropriate statistics.

Some basic features of PROC MIXED are

- covariance structures, including variance components, compound symmetry, unstructured, AR(1), Toeplitz, spatial, general linear, and factor analytic
- GLM-type grammar, using MODEL, RANDOM, and REPEATED statements for model specification and CONTRAST, ESTIMATE, and LSMEANS statements for inferences
- appropriate standard errors for all specified estimable linear combinations of fixed and random effects, and corresponding *t*- and *F*-tests
- subject and group effects that enable blocking and heterogeneity, respectively
- REML and ML estimation methods implemented with a Newton-Raphson algorithm

- capacity to handle unbalanced data
- ability to create a SAS data set corresponding to any table

PROC MIXED uses the Output Delivery System (ODS), a SAS subsystem that provides capabilities for displaying and controlling the output from SAS procedures. ODS enables you to convert any of the output from PROC MIXED into a SAS data set. See the “ODS Table Names” section on page 2752.

Experimental graphics are now available with the MIXED procedure. For more information, see the “ODS Graphics” section on page 2757.

Notation for the Mixed Model

This section introduces the mathematical notation used throughout this chapter to describe the mixed linear model. You should be familiar with basic matrix algebra (refer to Searle 1982). A more detailed description of the mixed model is contained in the “Mixed Models Theory” section on page 2731.

A statistical model is a mathematical description of how data are generated. The standard linear model, as used by the GLM procedure, is one of the most common statistical models:

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}$$

In this expression, \mathbf{y} represents a vector of observed data, $\boldsymbol{\beta}$ is an unknown vector of fixed-effects parameters with known design matrix \mathbf{X} , and $\boldsymbol{\epsilon}$ is an unknown random error vector modeling the statistical noise around $\mathbf{X}\boldsymbol{\beta}$. The focus of the standard linear model is to model the mean of \mathbf{y} by using the fixed-effects parameters $\boldsymbol{\beta}$. The residual errors $\boldsymbol{\epsilon}$ are assumed to be independent and identically distributed Gaussian random variables with mean 0 and variance σ^2 .

The mixed model generalizes the standard linear model as follows:

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\boldsymbol{\gamma} + \boldsymbol{\epsilon}$$

Here, $\boldsymbol{\gamma}$ is an unknown vector of random-effects parameters with known design matrix \mathbf{Z} , and $\boldsymbol{\epsilon}$ is an unknown random error vector whose elements are no longer required to be independent and homogeneous.

To further develop this notion of variance modeling, assume that $\boldsymbol{\gamma}$ and $\boldsymbol{\epsilon}$ are Gaussian random variables that are uncorrelated and have expectations $\mathbf{0}$ and variances \mathbf{G} and \mathbf{R} , respectively. The variance of \mathbf{y} is thus

$$\mathbf{V} = \mathbf{Z}\mathbf{G}\mathbf{Z}' + \mathbf{R}$$

Note that, when $\mathbf{R} = \sigma^2\mathbf{I}$ and $\mathbf{Z} = \mathbf{0}$, the mixed model reduces to the standard linear model.

You can model the variance of the data, y , by specifying the structure (or form) of Z , G , and R . The model matrix Z is set up in the same fashion as X , the model matrix for the fixed-effects parameters. For G and R , you must select some *covariance structure*. Possible covariance structures include

- variance components
- compound symmetry (common covariance plus diagonal)
- unstructured (general covariance)
- autoregressive
- spatial
- general linear
- factor analytic

By appropriately defining the model matrices X and Z , as well as the covariance structure matrices G and R , you can perform numerous mixed model analyses.

PROC MIXED Contrasted with Other SAS Procedures

PROC MIXED is a generalization of the GLM procedure in the sense that PROC GLM fits standard linear models, and PROC MIXED fits the wider class of mixed linear models. Both procedures have similar CLASS, MODEL, CONTRAST, ESTIMATE, and LSMEANS statements, but their RANDOM and REPEATED statements differ (see the following paragraphs). Both procedures use the non-full-rank model parameterization, although the sorting of classification levels can differ between the two. PROC MIXED computes only Type I–Type III tests of fixed effects, while PROC GLM offers Types I–IV.

The RANDOM statement in PROC MIXED incorporates random effects constituting the γ vector in the mixed model. However, in PROC GLM, effects specified in the RANDOM statement are still treated as fixed as far as the model fit is concerned, and they serve only to produce corresponding expected mean squares. These expected mean squares lead to the traditional ANOVA estimates of variance components. PROC MIXED computes REML and ML estimates of variance parameters, which are generally preferred to the ANOVA estimates (Searle 1988; Harville 1988; Searle, Casella, and McCulloch 1992). Optionally, PROC MIXED also computes MIVQUE0 estimates, which are similar to ANOVA estimates.

The REPEATED statement in PROC MIXED is used to specify covariance structures for repeated measurements on subjects, while the REPEATED statement in PROC GLM is used to specify various transformations with which to conduct the traditional univariate or multivariate tests. In repeated measures situations, the mixed model approach used in PROC MIXED is more flexible and more widely applicable than either the univariate or multivariate approaches. In particular, the mixed model approach provides a larger class of covariance structures and a better mechanism for handling missing values (Wolfinger and Chang 1995).

PROC MIXED subsumes the VARCOMP procedure. PROC MIXED provides a wide variety of covariance structures, while PROC VARCOMP estimates only simple random effects. PROC MIXED carries out several analyses that are absent in PROC VARCOMP, including the estimation and testing of linear combinations of fixed and random effects.

The ARIMA and AUTOREG procedures provide more time series structures than PROC MIXED, although they do not fit variance component models. The CALIS procedure fits general covariance matrices, but it does not allow fixed effects as does PROC MIXED. The LATTICE and NESTED procedures fit special types of mixed linear models that can also be handled in PROC MIXED, although PROC MIXED may run slower because of its more general algorithm. The TSCSREG procedure analyzes time-series cross-sectional data, and it fits some structures not available in PROC MIXED.

Getting Started

Clustered Data Example

Consider the following SAS data set as an introductory example:

```
data heights;
  input Family Gender$ Height @@;
  datalines;
1 F 67   1 F 66   1 F 64   1 M 71   1 M 72   2 F 63
2 F 63   2 F 67   2 M 69   2 M 68   2 M 70   3 F 63
3 M 64   4 F 67   4 F 66   4 M 67   4 M 67   4 M 69
run;
```

The response variable `Height` measures the heights (in inches) of 18 individuals. The individuals are classified according to `Family` and `Gender`. You can perform a traditional two-way analysis of variance of these data with the following PROC MIXED code:

```
proc mixed;
  class Family Gender;
  model Height = Gender Family Family*Gender;
run;
```

The PROC MIXED statement invokes the procedure. The CLASS statement instructs PROC MIXED to consider both `Family` and `Gender` as classification variables. Dummy (indicator) variables are, as a result, created corresponding to all of the distinct levels of `Family` and `Gender`. For these data, `Family` has four levels and `Gender` has two levels.

The MODEL statement first specifies the response (dependent) variable `Height`. The explanatory (independent) variables are then listed after the equal (=) sign. Here, the two explanatory variables are `Gender` and `Family`, and they comprise the main

effects of the design. The third explanatory term, `Family*Gender`, models an interaction between the two main effects.

PROC MIXED uses the dummy variables associated with `Gender`, `Family`, and `Family*Gender` to construct the **X** matrix for the linear model. A column of 1s is also included as the first column of **X** to model a global intercept. There are no **Z** or **G** matrices for this model, and **R** is assumed to equal $\sigma^2\mathbf{I}$, where **I** is an 18×18 identity matrix.

The RUN statement completes the specification. The coding is precisely the same as with the GLM procedure. However, much of the output from PROC MIXED is different from that produced by PROC GLM.

The following is the output from PROC MIXED.

The Mixed Procedure	
Model Information	
Data Set	WORK.HEIGHTS
Dependent Variable	Height
Covariance Structure	Diagonal
Estimation Method	REML
Residual Variance Method	Profile
Fixed Effects SE Method	Model-Based
Degrees of Freedom Method	Residual

Figure 46.1. Model Information

The “Model Information” table describes the model, some of the variables that it involves, and the method used in fitting it. This table also lists the method (profile, factor, or fit) for handling the residual variance.

The Mixed Procedure		
Class Level Information		
Class	Levels	Values
Family	4	1 2 3 4
Gender	2	F M

Figure 46.2. Class Level Information

The “Class Level Information” table lists the levels of all variables specified in the CLASS statement. You can check this table to make sure that the data are correct.

The Mixed Procedure	
Dimensions	
Covariance Parameters	1
Columns in X	15
Columns in Z	0
Subjects	1
Max Obs Per Subject	18

Figure 46.3. Dimensions

The “Number of Observations” table displays information about the sample size being processed.

The Mixed Procedure	
Covariance Parameter Estimates	
Cov Parm	Estimate
Residual	2.1000

Figure 46.5. Covariance Parameter Estimates

The “Covariance Parameter Estimates” table displays the estimate of σ^2 for the model.

The Mixed Procedure	
Fit Statistics	
-2 Res Log Likelihood	41.6
AIC (smaller is better)	43.6
AICC (smaller is better)	44.1
BIC (smaller is better)	43.9

Figure 46.6. Fit Statistics

The “Fit Statistics” table lists several pieces of information about the fitted mixed model, including values derived from the computed value of the restricted/residual likelihood.

The Mixed Procedure				
Type 3 Tests of Fixed Effects				
Effect	Num DF	Den DF	F Value	Pr > F
Gender	1	10	17.63	0.0018
Family	3	10	5.90	0.0139
Family*Gender	3	10	2.89	0.0889

Figure 46.7. Tests of Fixed Effects

The “Type 3 Tests of Fixed Effects” table displays significance tests for the three effects listed in the MODEL statement. The Type III F -statistics and p -values are the same as those produced by the GLM procedure. However, because PROC MIXED uses a likelihood-based estimation scheme, it does not directly compute or display sums of squares for this analysis.

The Type 3 test for Family*Gender effect is not significant at the 5% level, but the tests for both main effects are significant.

The important assumptions behind this analysis are that the data are normally distributed and that they are independent with constant variance. For these data, the normality assumption is probably realistic since the data are observed heights. However, since the data occur in clusters (families), it is very likely that observations from the same family are statistically correlated, that is, not independent.

The methods implemented in PROC MIXED are still based on the assumption of normally distributed data, but you can drop the assumption of independence by modeling statistical correlation in a variety of ways. You can also model variances that are heterogeneous, that is, nonconstant.

For the height data, one of the simplest ways of modeling correlation is through the use of *random effects*. Here the family effect is assumed to be normally distributed with zero mean and some unknown variance. This is in contrast to the previous model in which the family effects are just constants, or *fixed effects*. Declaring Family as a random effect sets up a common correlation among all observations having the same level of Family.

Declaring Family*Gender as a random effect models an additional correlation between all observations that have the same level of both Family and Gender. One interpretation of this effect is that a female in a certain family exhibits more correlation with the other females in that family than with the other males, and likewise for a male. With the height data, this model seems reasonable.

The code to fit this correlation model in PROC MIXED is as follows:

```

proc mixed;
  class Family Gender;
  model Height = Gender;
  random Family Family*Gender;
run;

```

Note that `Family` and `Family*Gender` are now listed in the `RANDOM` statement. The dummy variables associated with them are used to construct the \mathbf{Z} matrix in the mixed model. The \mathbf{X} matrix now consists of a column of 1s and the dummy variables for `Gender`.

The \mathbf{G} matrix for this model is diagonal, and it contains the variance components for both `Family` and `Family*Gender`. The \mathbf{R} matrix is still assumed to equal $\sigma^2 I$, where I is an identity matrix.

The output from this analysis is as follows.

The Mixed Procedure	
Model Information	
Data Set	WORK.HEIGHTS
Dependent Variable	Height
Covariance Structure	Variance Components
Estimation Method	REML
Residual Variance Method	Profile
Fixed Effects SE Method	Model-Based
Degrees of Freedom Method	Containment

Figure 46.8. Model Information

The “Model Information” table shows that the containment method is used to compute the degrees of freedom for this analysis. This is the default method when a `RANDOM` statement is used; see the description of the `DDFM=` option on page 2693 for more information.

The Mixed Procedure		
Class Level Information		
Class	Levels	Values
Family	4	1 2 3 4
Gender	2	F M

Figure 46.9. Class Levels Information

The “Class Levels Information” table is the same as before.

The Mixed Procedure

The Mixed Procedure	
Fit Statistics	
-2 Res Log Likelihood	71.0
AIC (smaller is better)	77.0
AICC (smaller is better)	79.0
BIC (smaller is better)	75.2

Figure 46.13. Fit Statistics

The “Fit Statistics” table contains basic information about the REML fit.

The Mixed Procedure				
Type 3 Tests of Fixed Effects				
Effect	Num DF	Den DF	F Value	Pr > F
Gender	1	3	7.95	0.0667

Figure 46.14. Type 3 Tests of Fixed Effects

The “Type 3 Tests of Fixed Effects” table contains a significance test for the lone fixed effect, Gender. Note that the associated p -value is not nearly as significant as in the previous analysis. This illustrates the importance of correctly modeling correlation in your data.

An additional benefit of the random effects analysis is that it enables you to make inferences about gender that apply to an entire population of families, whereas the inferences about gender from the analysis where Family and Family*Gender are fixed effects apply only to the particular families in the data set.

PROC MIXED thus offers you the ability to model correlation directly and to make inferences about fixed effects that apply to entire populations of random effects.

Syntax

The following statements are available in PROC MIXED.

```

PROC MIXED < options > ;
  BY variables ;
  CLASS variables ;
  ID variables ;
  MODEL dependent = < fixed-effects > < / options > ;
  RANDOM random-effects < / options > ;
  REPEATED < repeated-effect >< / options > ;
  PARMS (value-list) ... < / options > ;
  PRIOR < distribution >< / options > ;
  CONTRAST 'label' < fixed-effect values ... >
    < | random-effect values ... > , ... < / options > ;
  ESTIMATE 'label' < fixed-effect values ... >
    < | random-effect values ... >< / options > ;
  LSMEANS fixed-effects < / options > ;
  WEIGHT variable ;

```

Items within angle brackets (< >) are optional. The CONTRAST, ESTIMATE, LSMEANS, and RANDOM statements can appear multiple times; all other statements can appear only once.

The PROC MIXED and MODEL statements are required, and the MODEL statement must appear after the CLASS statement if a CLASS statement is included. The CONTRAST, ESTIMATE, LSMEANS, RANDOM, and REPEATED statements must follow the MODEL statement. The CONTRAST and ESTIMATE statements must also follow any RANDOM statements.

Table 46.1 summarizes the basic functions and important options of each PROC MIXED statement. The syntax of each statement in Table 46.1 is described in the following sections in alphabetical order after the description of the PROC MIXED statement.

Table 46.1. Summary of PROC MIXED Statements

Statement	Description	Important Options
PROC MIXED	invokes the procedure	DATA= specifies input data set, METHOD= specifies estimation method
BY	performs multiple PROC MIXED analyses in one invocation	none
CLASS	declares qualitative variables that create indicator variables in design matrices	none
ID	lists additional variables to be included in predicted values tables	none
MODEL	specifies dependent variable and fixed effects, setting up X	S requests solution for fixed-effects parameters, DDFM= specifies denominator degrees of freedom method, OUTP= outputs predicted values to a data set, INFLUENCE computes influence diagnostics
RANDOM	specifies random effects, setting up Z and G	SUBJECT= creates block-diagonality, TYPE= specifies covariance structure, S requests solution for random-effects parameters, G displays estimated G
REPEATED	sets up R	SUBJECT= creates block-diagonality, TYPE= specifies covariance structure, R displays estimated blocks of R , GROUP= enables between-subject heterogeneity, LOCAL adds a diagonal matrix to R
PARMS	specifies a grid of initial values for the covariance parameters	HOLD= and NOITER hold the covariance parameters or their ratios constant, PDATA= reads the initial values from a SAS data set
PRIOR	performs a sampling-based Bayesian analysis for variance component models	NSAMPLE= specifies the sample size, SEED= specifies the starting seed
CONTRAST	constructs custom hypothesis tests	E displays the L matrix coefficients
ESTIMATE	constructs custom scalar estimates	CL produces confidence limits
LSMEANS	computes least squares means for classification fixed effects	DIFF computes differences of the least squares means, ADJUST= performs multiple comparisons adjustments, AT changes covariates, OM changes weighting, CL produces confidence limits, SLICE= tests simple effects
WEIGHT	specifies a variable by which to weight R	none

PROC MIXED Statement

PROC MIXED < options >;

The PROC MIXED statement invokes the procedure. You can specify the following options.

ABSOLUTE

makes the convergence criterion absolute. By default, it is relative (divided by the current objective function value). See the [CONVF](#), [CONVG](#), and [CONVH](#) options in this section for a description of various convergence criteria.

ALPHA=*number*

requests that confidence limits be constructed for the covariance parameter estimates with confidence level $1 - \textit{number}$. The value of *number* must be between 0 and 1; the default is 0.05.

ASYCORR

produces the asymptotic correlation matrix of the covariance parameter estimates. It is computed from the corresponding asymptotic covariance matrix (see the description of the [ASYCOV](#) option, which follows). For ODS purposes, the label of the “Asymptotic Correlation” table is “AsyCorr.”

ASYCOV

requests that the asymptotic covariance matrix of the covariance parameters be displayed. By default, this matrix is the observed inverse Fisher information matrix, which equals $2\mathbf{H}^{-1}$, where \mathbf{H} is the Hessian (second derivative) matrix of the objective function. See the “Covariance Parameter Estimates” section on page 2750 for more information about this matrix. When you use the [SCORING=](#) option and PROC MIXED converges without stopping the scoring algorithm, PROC MIXED uses the expected Hessian matrix to compute the covariance matrix instead of the observed Hessian. For ODS purposes, the label of the “Asymptotic Covariance” table is “AsyCov.”

CL<=[WALD](#)>

requests confidence limits for the covariance parameter estimates. A Satterthwaite approximation is used to construct limits for all parameters that have a lower boundary constraint of zero. These limits take the form

$$\frac{\nu \hat{\sigma}^2}{\chi_{\nu, 1-\alpha/2}^2} \leq \sigma^2 \leq \frac{\nu \hat{\sigma}^2}{\chi_{\nu, \alpha/2}^2}$$

where $\nu = 2Z^2$, Z is the Wald statistic $\hat{\sigma}^2 / \text{se}(\hat{\sigma}^2)$, and the denominators are quantiles of the χ^2 -distribution with ν degrees of freedom. Refer to Milliken and Johnson (1992) and Burdick and Graybill (1992) for similar techniques.

For all other parameters, Wald Z -scores and normal quantiles are used to construct the limits. Wald limits are also provided for variance components if you specify the [NOBOUND](#) option. The optional [=WALD](#) specification requests Wald limits for all parameters.

The confidence limits are displayed as extra columns in the “Covariance Parameter Estimates” table. The confidence level is $1 - \alpha = 0.95$ by default; this can be changed with the [ALPHA=](#) option.

CONVF<=*number*>

requests the relative function convergence criterion with tolerance *number*. The relative function convergence criterion is

$$\frac{|f_k - f_{k-1}|}{|f_k|} \leq \textit{number}$$

where f_k is the value of the objective function at iteration k . To prevent the division by $|f_k|$, use the [ABSOLUTE](#) option. The default convergence criterion is [CONVH](#), and the default tolerance is $1\text{E}-8$.

CONVG <=*number*>

requests the relative gradient convergence criterion with tolerance *number*. The relative gradient convergence criterion is

$$\frac{\max_j |g_{jk}|}{|f_k|} \leq \textit{number}$$

where f_k is the value of the objective function, and g_{jk} is the j th element of the gradient (first derivative) of the objective function, both at iteration k . To prevent division by $|f_k|$, use the [ABSOLUTE](#) option. The default convergence criterion is [CONVH](#), and the default tolerance is $1\text{E}-8$.

CONVH<=*number*>

requests the relative Hessian convergence criterion with tolerance *number*. The relative Hessian convergence criterion is

$$\frac{\mathbf{g}_k' \mathbf{H}_k^{-1} \mathbf{g}_k}{|f_k|} \leq \textit{number}$$

where f_k is the value of the objective function, \mathbf{g}_k is the gradient (first derivative) of the objective function, and \mathbf{H}_k is the Hessian (second derivative) of the objective function, all at iteration k .

If \mathbf{H}_k is singular, then PROC MIXED uses the following relative criterion:

$$\frac{\mathbf{g}_k' \mathbf{g}_k}{|f_k|} \leq \textit{number}$$

To prevent the division by $|f_k|$, use the [ABSOLUTE](#) option. The default convergence criterion is [CONVH](#), and the default tolerance is $1\text{E}-8$.

COVTEST

produces asymptotic standard errors and Wald Z -tests for the covariance parameter estimates.

DATA=SAS-data-set

names the SAS data set to be used by PROC MIXED. The default is the most recently created data set.

DFBW

has the same effect as the **DDFM=BW** option in the MODEL statement.

EMPIRICAL

computes the estimated variance-covariance matrix of the fixed-effects parameters by using the asymptotically consistent estimator described in Huber (1967), White (1980), Liang and Zeger (1986), and Diggle, Liang, and Zeger (1994). This estimator is commonly referred to as the “sandwich” estimator, and it is computed as follows:

$$(\mathbf{X}'\widehat{\mathbf{V}}^{-1}\mathbf{X})^{-1} \left(\sum_{i=1}^S \mathbf{X}_i' \widehat{\mathbf{V}}_i^{-1} \widehat{\boldsymbol{\epsilon}}_i \widehat{\boldsymbol{\epsilon}}_i' \widehat{\mathbf{V}}_i^{-1} \mathbf{X}_i \right) (\mathbf{X}'\widehat{\mathbf{V}}^{-1}\mathbf{X})^{-1}$$

Here, $\widehat{\boldsymbol{\epsilon}}_i = y_i - \mathbf{X}_i\widehat{\boldsymbol{\beta}}$, S is the number of subjects, and matrices with an i subscript are those for the i th subject. You must include the SUBJECT= option in either a **RANDOM** or **REPEATED** statement for this option to take effect.

When you specify the EMPIRICAL option, PROC MIXED adjusts all standard errors and test statistics involving the fixed-effects parameters. This changes output in the following tables (listed in Table 46.8 on page 2752): Contrast, CorrB, CovB, DiffS, Estimates, InvCovB, LSMMeans, MMEq, MMEqSol, Slices, SolutionF, Tests1–Tests3. The OUTP= and OUTPM= data sets are also affected. Finally, the Satterthwaite and Kenward-Roger degrees of freedom methods are not available if you specify EMPIRICAL.

IC

displays a table of various information criteria. The criteria are all in smaller-is-better form, and are described in Table 46.2.

Table 46.2. Information Criteria

Criteria	Formula	Reference
AIC	$-2\ell + 2d$	Akaike (1974)
AICC	$-2\ell + 2dn^*/(n^* - d - 1)$	Hurvich and Tsai (1989) Burnham and Anderson (1998)
HQIC	$-2\ell + 2d \log \log n$	Hannan and Quinn (1979)
BIC	$-2\ell + d \log n$	Schwarz (1978)
CAIC	$-2\ell + d(\log n + 1)$	Bozdogan (1987)

Here ℓ denotes the maximum value of the (possibly restricted) log likelihood, d the dimension of the model, and n the number of observations. In Version 6 of SAS/STAT software, n equals the number of valid observations for maximum likelihood estimation and $n - p$ for restricted maximum likelihood estimation, where p equals the rank of \mathbf{X} . In later versions, n equals the number of effective subjects as displayed in the

“Dimensions” table, unless this value equals 1, in which case n equals the number of levels of the first RANDOM effect you specify. If the number of effective subjects equals 1 and you have no RANDOM statements, then n reverts to the Version 6 values. For AICC (a finite-sample corrected version of AIC), n^* equals the Version 6 values of n , unless this number is less than $d + 2$, in which case it equals $d + 2$.

For restricted likelihood estimation, d equals q the effective number of estimated covariance parameters. In Version 6, when a parameter estimate lies on a boundary constraint, then it is still included in the calculation of d , but in later versions it is not. The most common example of this behavior is when a variance component is estimated to equal zero. For maximum likelihood estimation, d equals $q + p$.

For ODS purposes, the name of the “Information Criteria” table is “InfoCrit.”

INFO

is a default option. The creation of the “Model Information”, “Dimensions”, and “Number of Observations” tables can be suppressed using the [NOINFO](#) option.

Note that, in Version 6, this option displays the “Model Information” and “Dimensions” tables.

ITDETAILS

displays the parameter values at each iteration and enables the writing of notes to the SAS log pertaining to “infinite likelihood” and “singularities” during Newton-Raphson iterations.

LOGNOTE

writes periodic notes to the log describing the current status of computations. It is designed for use with analyses requiring extensive CPU resources.

MAXFUNC=*number*

specifies the maximum number of likelihood evaluations in the optimization process. The default is 150.

MAXITER=*number*

specifies the maximum number of iterations. The default is 50.

METHOD=REML

METHOD=ML

METHOD=MIVQUE0

METHOD=TYPE1

METHOD=TYPE2

METHOD=TYPE3

specifies the estimation method for the covariance parameters. The REML specification performs residual (restricted) maximum likelihood, and it is the default method. The ML specification performs maximum likelihood, and the MIVQUE0 specification performs minimum variance quadratic unbiased estimation of the covariance parameters.

The METHOD=TYPE n specifications apply only to variance component models with no SUBJECT= effects and no REPEATED statement. An analysis of variance table is included in the output, and the expected mean squares are used to estimate

the variance components (see Chapter 32, “The GLM Procedure,” for further explanation). The resulting method-of-moment variance component estimates are used in subsequent calculations, including standard errors computed from ESTIMATE and LSMEANS statements. For ODS purposes, the new table names are “Type1,” “Type2,” and “Type3,” respectively.

MMEQ

requests that coefficients of the mixed model equations be displayed. These are

$$\begin{bmatrix} \mathbf{X}'\hat{\mathbf{R}}^{-1}\mathbf{X} & \mathbf{X}'\hat{\mathbf{R}}^{-1}\mathbf{Z} \\ \mathbf{Z}'\hat{\mathbf{R}}^{-1}\mathbf{X} & \mathbf{Z}'\hat{\mathbf{R}}^{-1}\mathbf{Z} + \hat{\mathbf{G}}^{-1} \end{bmatrix}, \begin{bmatrix} \mathbf{X}'\hat{\mathbf{R}}^{-1}\mathbf{y} \\ \mathbf{Z}'\hat{\mathbf{R}}^{-1}\mathbf{y} \end{bmatrix}$$

assuming that $\hat{\mathbf{G}}$ is nonsingular. If $\hat{\mathbf{G}}$ is singular, PROC MIXED produces the following coefficients

$$\begin{bmatrix} \mathbf{X}'\hat{\mathbf{R}}^{-1}\mathbf{X} & \mathbf{X}'\hat{\mathbf{R}}^{-1}\mathbf{Z}\hat{\mathbf{G}} \\ \hat{\mathbf{G}}\mathbf{Z}'\hat{\mathbf{R}}^{-1}\mathbf{X} & \hat{\mathbf{G}}\mathbf{Z}'\hat{\mathbf{R}}^{-1}\mathbf{Z}\hat{\mathbf{G}} + \hat{\mathbf{G}} \end{bmatrix}, \begin{bmatrix} \mathbf{X}'\hat{\mathbf{R}}^{-1}\mathbf{y} \\ \hat{\mathbf{G}}\mathbf{Z}'\hat{\mathbf{R}}^{-1}\mathbf{y} \end{bmatrix}$$

See the “Estimating β and γ in the Mixed Model” section on page 2739 for further information on these equations.

MMEQSOL

requests that a solution to the mixed model equations be produced, as well as the inverted coefficients matrix. Formulas for these equations are provided in the preceding description of the MMEQ option.

When $\hat{\mathbf{G}}$ is singular, $\hat{\boldsymbol{\tau}}$ and a generalized inverse of the left-hand-side coefficient matrix are transformed using $\hat{\mathbf{G}}$ to produce $\hat{\boldsymbol{\gamma}}$ and $\hat{\mathbf{C}}$, respectively, where $\hat{\mathbf{C}}$ is a generalized inverse of the left-hand-side coefficient matrix of the original equations.

NAMELEN<=*number*>

specifies the length to which long effect names are shortened. The default and minimum value is 20.

NOBOUND

has the same effect as the NOBOUND option in the PARMs statement (see page 2707).

NOCLPRINT<=*number*>

suppresses the display of the “Class Level Information” table if you do not specify *number*. If you do specify *number*, only levels with totals that are less than *number* are listed in the table.

NOINFO

suppresses the display of the “Model Information”, “Dimensions”, and “Number of Observations” tables.

NOITPRINT

suppresses the display of the “Iteration History” table.

NOPROFILE

includes the residual variance as part of the Newton-Raphson iterations. This option applies only to models that have a residual variance parameter. By default, this parameter is profiled out of the likelihood calculations, except when you have specified the **HOLD=** or **NOITER** option in the **PARMS** statement.

ORD

displays ordinates of the relevant distribution in addition to p -values. The ordinate can be viewed as an approximate odds ratio of hypothesis probabilities.

ORDER=DATA**ORDER=FORMATTED****ORDER=FREQ****ORDER=INTERNAL**

specifies the sorting order for the levels of all **CLASS** variables. This ordering determines which parameters in the model correspond to each level in the data, so the **ORDER=** option may be useful when you use **CONTRAST** or **ESTIMATE** statements.

The default is **ORDER=FORMATTED**, and its behavior has been modified for Version 8. When the default **ORDER=FORMATTED** is in effect for numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values. In releases previous to Version 8, numeric class levels with no explicit format were ordered by their BEST12. formatted values. In order to revert to the previous method you can specify this format explicitly for the **CLASS** variables. The change was implemented because the former default behavior for **ORDER=FORMATTED** often resulted in levels not being ordered numerically and required you to use an explicit format or **ORDER=INTERNAL** to get the more natural ordering.

The following table shows how PROC MIXED interprets values of the **ORDER=** option.

Value of ORDER=	Levels Sorted By
DATA	order of appearance in the input data set
FORMATTED	external formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ	descending frequency count; levels with the most observations come first in the order
INTERNAL	unformatted value

For **FORMATTED** and **INTERNAL**, the sort order is machine dependent. For more information on sorting order, see the chapter on the **SORT** procedure in the *SAS*

Procedures Guide and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

RATIO

produces the ratio of the covariance parameter estimates to the estimate of the residual variance when the latter exists in the model.

RIDGE=number

specifies the starting value for the minimum ridge value used in the Newton-Raphson algorithm. The default is 0.3125.

SCORING<=number>

requests that Fisher scoring be used in association with the estimation method up to iteration *number*, which is 0 by default. When you use the SCORING= option and PROC MIXED converges without stopping the scoring algorithm, PROC MIXED uses the expected Hessian matrix to compute approximate standard errors for the covariance parameters instead of the observed Hessian. The output from the ASYCOV and ASYCORR options is similarly adjusted.

SIGITER

is an alias for the [NOPROFILE](#) option.

UPDATE

is an alias for the [LOGNOTE](#) option.

BY Statement

BY variables ;

You can specify a BY statement with PROC MIXED to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. The *variables* are one or more variables in the input data set.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement options NOTSORTED or DESCENDING in the BY statement for the MIXED procedure. The NOTSORTED option does not mean that the data are unsorted but rather means that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure (in base SAS software).

Since sorting the data changes the order in which PROC MIXED reads observations, the sorting order for the levels of the CLASS variable may be affected if you have specified ORDER=DATA in the PROC MIXED statement. This, in turn, affects specifications in the CONTRAST statements.

For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

CLASS Statement

CLASS *variables* ;

The CLASS statement names the classification variables to be used in the analysis. If the CLASS statement is used, it must appear before the MODEL statement.

Classification variables can be either character or numeric. By default, class levels are determined from the entire formatted values of the CLASS variables. Note that this represents a slight change from previous releases in the way in which class levels are determined. In releases prior to Version 9, class levels were determined using no more than the first 16 characters of the formatted values. If you wish to revert to this previous behavior you can use the TRUNCATE option in the CLASS statement. In any case, you can use formats to group values into levels. Refer to the discussion of the FORMAT procedure in the *SAS Procedures Guide* and to the discussions of the FORMAT statement and SAS formats in *SAS Language Reference: Dictionary*. You can adjust the order of CLASS variable levels with the ORDER= option in the PROC MIXED statement.

You can specify the following option in the CLASS statement after a slash(/):

TRUNCATE MIXED specifies that class levels should be determined using only no more than the first 16 characters of the formatted values of CLASS variables. When formatted values are longer than 16 characters, you can use this option in order to revert to the levels as determined in releases previous to Version 9.

CONTRAST Statement

CONTRAST *'label'* < *fixed-effect values ...* >
< | *random-effect values ...* > , ... < / *options* > ;

The CONTRAST statement provides a mechanism for obtaining custom hypothesis tests. It is patterned after the CONTRAST statement in PROC GLM, although it has been extended to include random effects. This enables you to select an appropriate inference space (McLean, Sanders, and Stroup 1991).

You can test the hypothesis $\mathbf{L}'\phi = 0$, where $\mathbf{L}' = (\mathbf{K}' \mathbf{M}')$ and $\phi' = (\beta' \gamma')$, in several inference spaces. The inference space corresponds to the choice of \mathbf{M} . When $\mathbf{M} = \mathbf{0}$, your inferences apply to the entire population from which the random effects are sampled; this is known as the *broad* inference space. When all elements of \mathbf{M} are nonzero, your inferences apply only to the observed levels of the random effects. This is known as the *narrow* inference space, and you can also choose it by specifying all of the random effects as fixed. The GLM procedure uses the narrow inference space. Finally, by zeroing portions of \mathbf{M} corresponding to selected main effects and interactions, you can choose *intermediate* inference spaces. The broad

inference space is usually the most appropriate, and it is used when you do not specify any random effects in the CONTRAST statement.

In the CONTRAST statement,

<i>label</i>	identifies the contrast in the table. A label is required for every contrast specified. Labels can be up to 20 characters and must be enclosed in single quotes.
<i>fixed-effect</i>	identifies an effect that appears in the MODEL statement. The keyword INTERCEPT can be used as an effect when an intercept is fitted in the model. You do not need to include all effects that are in the MODEL statement.
<i>random-effect</i>	identifies an effect that appears in the RANDOM statement. The first random effect must follow a vertical bar (); however, random effects do not have to be specified.
<i>values</i>	are constants that are elements of the L matrix associated with the fixed and random effects.

The rows of **L'** are specified in order and are separated by commas. The rows of the **K'** component of **L'** are specified on the left side of the vertical bars (|). These rows test the fixed effects and are, therefore, checked for estimability. The rows of the **M'** component of **L'** are specified on the right side of the vertical bars. They test the random effects, and no estimability checking is necessary.

If PROC MIXED finds the fixed-effects portion of the specified contrast to be nonestimable (see the [SINGULAR= option](#) on page 2684), then it displays “Non-est” for the contrast entries.

The following CONTRAST statement reproduces the *F*-test for the effect *A* in the split-plot example (see [Example 46.1](#) on page 2777):

```
contrast 'A broad'
  A 1 -1 0      A*B .5 .5 -.5 -.5 0 0 ,
  A 1 0 -1      A*B .5 .5 0 0 -.5 -.5 / df=6;
```

Note that no random effects are specified in the preceding contrast; thus, the inference space is broad. The resulting *F*-test has two numerator degrees of freedom because **L'** has two rows. The denominator degrees of freedom is, by default, the residual degrees of freedom (9), but the **DF=** option changes the denominator degrees of freedom to 6.

The following CONTRAST statement reproduces the *F*-test for *A* when **Block** and **A*Block** are considered fixed effects (the narrow inference space):

```

contrast 'A narrow'
  A          1 -1 0
  A*B       .5 .5 -.5 -.5 0 0 |
  A*Block   .25 .25 .25 .25
            -.25 -.25 -.25 -.25
            0 0 0 0 ,
  A          1 0 -1
  A*B       .5 .5 0 0 -.5 -.5 |
  A*Block   .25 .25 .25 .25
            0 0 0 0
            -.25 -.25 -.25 -.25 ;

```

The preceding contrast does not contain coefficients for **B** and **Block** because they cancel out in estimated differences between levels of **A**. Coefficients for **B** and **Block** are necessary when estimating the mean of one of the levels of **A** in the narrow inference space (see [Example 46.1](#) on page 2777).

If the elements of **L** are not specified for an effect that contains a specified effect, then the elements of the specified effect are automatically “filled in” over the levels of the higher-order effect. This feature is designed to preserve estimability for cases when there are complex higher-order effects. The coefficients for the higher-order effect are determined by equitably distributing the coefficients of the lower-level effect as in the construction of least squares means. In addition, if the intercept is specified, it is distributed over all classification effects that are not contained by any other specified effect. If an effect is not specified and does not contain any specified effects, then all of its coefficients in **L** are set to 0. You can override this behavior by specifying coefficients for the higher-order effect.

If too many values are specified for an effect, the extra ones are ignored; if too few are specified, the remaining ones are set to 0. If no random effects are specified, the vertical bar can be omitted; otherwise, it must be present. If a **SUBJECT** effect is used in the **RANDOM** statement, then the coefficients specified for the effects in the **RANDOM** statement are equitably distributed across the levels of the **SUBJECT** effect. You can use the **E** option to see exactly what **L** matrix is used.

The **SUBJECT** and **GROUP** options in the **CONTRAST** statement are useful for the case when a **SUBJECT=** or **GROUP=** variable appears in the **RANDOM** statement, and you want to contrast different subjects or groups. By default, **CONTRAST** statement coefficients on random effects are distributed equally across subjects and groups.

PROC MIXED handles missing level combinations of classification variables similarly to the way **PROC GLM** does. Both procedures delete fixed-effects parameters corresponding to missing levels in order to preserve estimability. However, **PROC MIXED** does not delete missing level combinations for random-effects parameters because linear combinations of the random-effects parameters are always estimable. These conventions can affect the way you specify your **CONTRAST** coefficients.

The CONTRAST statement computes the statistic

$$F = \frac{\begin{bmatrix} \hat{\beta} \\ \hat{\gamma} \end{bmatrix}' \mathbf{L}(\mathbf{L}'\hat{\mathbf{C}}\mathbf{L})^{-1}\mathbf{L}' \begin{bmatrix} \hat{\beta} \\ \hat{\gamma} \end{bmatrix}}{\text{rank}(\mathbf{L})}$$

and approximates its distribution with an F -distribution. In this expression, $\hat{\mathbf{C}}$ is an estimate of the generalized inverse of the coefficient matrix in the mixed model equations. See the “[Inference and Test Statistics](#)” section on page 2741 for more information on this F -statistic.

The numerator degrees of freedom in the F -approximation is $\text{rank}(\mathbf{L})$, and the denominator degrees of freedom is taken from the “Tests of Fixed Effects” table and corresponds to the final effect you list in the CONTRAST statement. You can change the denominator degrees of freedom by using the [DF=](#) option.

You can specify the following options in the CONTRAST statement after a slash (/).

CHISQ

requests that χ^2 -tests be performed in addition to any F -tests. A χ^2 -statistic equals its corresponding F -statistic times the associate numerator degrees of freedom, and this same degrees of freedom is used to compute the p -value for the χ^2 -test. This p -value will always be less than that for the F -test, as it effectively corresponds to an F -test with infinite denominator degrees of freedom.

DF=*number*

specifies the denominator degrees of freedom for the F -test. The default is the denominator degrees of freedom taken from the “Tests of Fixed Effects” table and corresponds to the final effect you list in the CONTRAST statement.

E

requests that the \mathbf{L} matrix coefficients for the contrast be displayed. For ODS purposes, the label of this “L Matrix Coefficients” table is “Coef.”

GROUP *coeffs*

GRP *coeffs*

sets up random-effect contrasts between different groups when a [GROUP=](#) variable appears in the RANDOM statement. By default, CONTRAST statement coefficients on random effects are distributed equally across groups.

SINGULAR=*number*

tunes the estimability checking. If \mathbf{v} is a vector, define $\text{ABS}(\mathbf{v})$ to be the absolute value of the element of \mathbf{v} with the largest absolute value. If $\text{ABS}(\mathbf{K}' - \mathbf{K}'\mathbf{T})$ is greater than $C*\text{number}$ for any row of \mathbf{K}' in the contrast, then \mathbf{K} is declared nonestimable. Here \mathbf{T} is the Hermite form matrix $(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{X}$, and C is $\text{ABS}(\mathbf{K}')$ except when it equals 0, and then C is 1. The value for *number* must be between 0 and 1; the default is $1\text{E}-4$.

SUBJECT *coeffs*

SUB *coeffs*

sets up random-effect contrasts between different subjects when a **SUBJECT=** variable appears on the **RANDOM** statement. By default, **CONTRAST** statement coefficients on random effects are distributed equally across subjects.

ESTIMATE Statement

```
ESTIMATE 'label' < fixed-effect values ... >
          < | random-effect values ... > , ... < / options > ;
```

The **ESTIMATE** statement is exactly like a **CONTRAST** statement, except only one-row **L** matrices are permitted. The actual estimate, $L'\hat{p}$, is displayed along with its approximate standard error. An approximate *t*-test that $L'\hat{p} = 0$ is also produced.

PROC MIXED selects the degrees of freedom to match those displayed in the “Tests of Fixed Effects” table for the final effect you list in the **ESTIMATE** statement. You can modify the degrees of freedom using the **DF=** option.

If **PROC MIXED** finds the fixed-effects portion of the specified estimate to be non-estimable, then it displays “Non-est” for the estimate entries.

The following examples of **ESTIMATE** statements compute the mean of the first level of **A** in the split-plot example (see [Example 46.1](#) on page 2777) for various inference spaces.

```
estimate 'A1 mean narrow'  intercept 1
                          A 1 B .5 .5 A*B .5 .5 |
                          block .25 .25 .25 .25
                          A*Block .25 .25 .25 .25
                               0 0 0 0
                               0 0 0 0;

estimate 'A1 mean intermed' intercept 1
                          A 1 B .5 .5 A*B .5 .5 |
                          Block .25 .25 .25 .25;

estimate 'A1 mean broad'  intercept 1
                          A 1 B .5 .5 A*B .5 .5;
```

The construction of the **L** vector for an **ESTIMATE** statement follows the same rules as listed under the **CONTRAST** statement.

You can specify the following options in the **ESTIMATE** statement after a slash (/).

ALPHA=number

requests that a *t*-type confidence interval be constructed with confidence level $1 - \text{number}$. The value of *number* must be between 0 and 1; the default is 0.05.

CL

requests that *t*-type confidence limits be constructed. The confidence level is 0.95 by default; this can be changed with the **ALPHA=** option.

DF=number

specifies the degrees of freedom for the t -test and confidence limits. The default is the denominator degrees of freedom taken from the “Tests of Fixed Effects” table and corresponds to the final effect you list in the ESTIMATE statement.

DIVISOR=number

specifies a value by which to divide all coefficients so that fractional coefficients can be entered as integer numerators.

E

requests that the **L** matrix coefficients be displayed. For ODS purposes, the label of this “L Matrix Coefficients” table is “Coef.”

GROUP coeffs**GRP coeffs**

sets up random-effect contrasts between different groups when a **GROUP=** variable appears in the RANDOM statement. By default, ESTIMATE statement coefficients on random effects are distributed equally across groups.

LOWER**LOWERTAILED**

requests that the p -value for the t -test be based only on values less than the t -statistic. A two-tailed test is the default. A lower-tailed confidence limit is also produced if you specify the **CL** option.

SINGULAR=number

tunes the estimability checking as documented for the **CONTRAST** statement.

SUBJECT coeffs**SUB coeffs**

sets up random-effect contrasts between different subjects when a **SUBJECT=** variable appears in the RANDOM statement. By default, ESTIMATE statement coefficients on random effects are distributed equally across subjects.

For example, the ESTIMATE statement in the following code from [Example 46.5](#) constructs the difference between the random slopes of the first two batches.

```
proc mixed data=rc;
  class batch;
  model y = month / s;
  random int month / type=un sub=batch s;
  estimate 'slope b1 - slope b2' | month 1 / subject 1 -1;
run;
```

UPPER**UPPERTAILED**

requests that the p -value for the t -test be based only on values greater than the t -statistic. A two-tailed test is the default. An upper-tailed confidence limit is also produced if you specify the **CL** option.

ID Statement

ID *variables* ;

The ID statement specifies which variables from the input data set are to be included in the OUTP= and OUTPM= data sets from the MODEL statement. If you do not specify an ID statement, then all variables are included in these data sets. Otherwise, only the variables you list in the ID statement are included. Specifying an ID statement with no variables prevents any variables from being included in these data sets.

LSMEANS Statement

LSMEANS *fixed-effects* < / *options* > ;

The LSMEANS statement computes least-squares means (LS-means) of fixed effects. As in the GLM procedure, LS-means are *predicted population margins*—that is, they estimate the marginal means over a balanced population. In a sense, LS-means are to unbalanced designs as class and subclass arithmetic means are to balanced designs. The **L** matrix constructed to compute them is the same as the **L** matrix formed in PROC GLM; however, the standard errors are adjusted for the covariance parameters in the model.

Each LS-mean is computed as $\mathbf{L}\hat{\boldsymbol{\beta}}$ where **L** is the coefficient matrix associated with the least-squares mean and $\hat{\boldsymbol{\beta}}$ is the estimate of the fixed-effects parameter vector (see the “[Estimating \$\beta\$ and \$\gamma\$ in the Mixed Model](#)” section on page 2739). The approximate standard errors for the LS-mean is computed as the square root of $\mathbf{L}(\mathbf{X}'\hat{\mathbf{V}}^{-1}\mathbf{X})^{-1}\mathbf{L}'$.

LS-means can be computed for any effect in the MODEL statement that involves CLASS variables. You can specify multiple effects in one LSMEANS statement or in multiple LSMEANS statements, and all LSMEANS statements must appear after the MODEL statement. As in the ESTIMATE statement, the **L** matrix is tested for estimability, and if this test fails, PROC MIXED displays “Non-est” for the LS-means entries.

Assuming the LS-mean is estimable, PROC MIXED constructs an approximate *t*-test to test the null hypothesis that the associated population quantity equals zero. By default, the denominator degrees of freedom for this test are the same as those displayed for the effect in the “Tests of Fixed Effects” table (see the “[Default Output](#)” section on page 2748).

You can specify the following options in the LSMEANS statement after a slash (/).

ADJUST=BON
ADJUST=DUNNETT
ADJUST=SCHEFFE
ADJUST=SIDAK
ADJUST=SIMULATE< (*simoptions*)>
ADJUST=SMM | GT2
ADJUST=TUKEY

requests a multiple comparison adjustment for the *p*-values and confidence

limits for the differences of LS-means. By default, PROC MIXED adjusts all pairwise differences unless you specify ADJUST=DUNNETT, in which case PROC MIXED analyzes all differences with a control level. The ADJUST= option implies the [DIFF option](#) (see page 2690).

The BON (Bonferroni) and SIDAK adjustments involve correction factors described in [Chapter 32, “The GLM Procedure,”](#) and [Chapter 48, “The MULTTEST Procedure,”](#); also refer to Westfall and Young (1993) and Westfall *et al.* (1999). When you specify ADJUST=TUKEY and your data are unbalanced, PROC MIXED uses the approximation described in Kramer (1956). Similarly, when you specify ADJUST=DUNNETT and the LS-means are correlated, PROC MIXED uses the factor-analytic covariance approximation described in Hsu (1992). The preceding references also describe the SCHEFFE and SMM adjustments.

The SIMULATE adjustment computes adjusted p -values and confidence limits from the simulated distribution of the maximum or maximum absolute value of a multivariate t random vector. All covariance parameters except the residual variance are fixed at their estimated values throughout the simulation, potentially resulting in some underdispersion. The simulation estimates q , the true $(1 - \alpha)$ th quantile, where $1 - \alpha$ is the confidence coefficient. The default α is 0.05, and you can change this value with the [ALPHA=](#) option in the LSMEANS statement.

The number of samples is set so that the tail area for the simulated q is within γ of $1 - \alpha$ with $100(1 - \epsilon)\%$ confidence. In equation form,

$$P(|F(\hat{q}) - (1 - \alpha)| \leq \gamma) = 1 - \epsilon$$

where \hat{q} is the simulated q and F is the true distribution function of the maximum; refer to Edwards and Berry (1987) for details. By default, $\gamma = 0.005$ and $\epsilon = 0.01$, placing the tail area of \hat{q} within 0.005 of 0.95 with 99% confidence. The ACC= and EPS= *simoptions* reset γ and ϵ , respectively; the NSAMP= *simoption* sets the sample size directly; and the SEED= *simoption* specifies an integer used to start the pseudo-random number generator for the simulation. If you do not specify a seed, or specify a value less than or equal to zero, the seed is generated from reading the time of day from the computer clock. For additional descriptions of these and other simulation options, see the “[LSMEANS Statement](#)” section on page 1753 in [Chapter 32, “The GLM Procedure.”](#)

ALPHA=number

requests that a t -type confidence interval be constructed for each of the LS-means with confidence level $1 - \text{number}$. The value of *number* must be between 0 and 1; the default is 0.05.

AT variable = value

AT (*variable-list*) = (*value-list*)

AT MEANS

enables you to modify the values of the covariates used in computing LS-means. By default, all covariate effects are set equal to their mean values for computation of standard LS-means. The AT option enables you to assign arbitrary values to the covariates. Additional columns in the output table indicate the values of the covariates.

If there is an effect containing two or more covariates, the AT option sets the effect equal to the product of the individual means rather than the mean of the product (as with standard LS-means calculations). The AT MEANS option sets covariates equal to their mean values (as with standard LS-means) and incorporates this adjustment to cross products of covariates.

As an example, consider the following invocation of PROC MIXED:

```
proc mixed;
  class A;
  model Y = A X1 X2 X1*X2;
  lsmeans A;
  lsmeans A / at means;
  lsmeans A / at X1=1.2;
  lsmeans A / at (X1 X2)=(1.2 0.3);
run;
```

For the first two LSMEANS statements, the LS-means coefficient for X1 is \bar{x}_1 (the mean of X1) and for X2 is \bar{x}_2 (the mean of X2). However, for the first LSMEANS statement, the coefficient for X1*X2 is $\overline{x_1 x_2}$, but for the second LSMEANS statement, the coefficient is $\bar{x}_1 \cdot \bar{x}_2$. The third LSMEANS statement sets the coefficient for X1 equal to 1.2 and leaves it at \bar{x}_2 for X2, and the final LSMEANS statement sets these values to 1.2 and 0.3, respectively.

If a WEIGHT variable is present, it is used in processing AT variables. Also, observations with missing dependent variables are included in computing the covariate means, unless these observations form a missing cell and the FULLX option in the MODEL statement is not in effect. You can use the E option in conjunction with the AT option to check that the modified LS-means coefficients are the ones you desire.

The AT option is disabled if you specify the BYLEVEL option.

BYLEVEL

requests PROC MIXED to process the OM data set by each level of the LS-mean effect (LSMEANS effect) in question. For more details, see the OM option later in this section.

CL

requests that *t*-type confidence limits be constructed for each of the LS-means. The confidence level is 0.95 by default; this can be changed with the ALPHA= option.

CORR

displays the estimated correlation matrix of the least-squares means as part of the “Least Squares Means” table.

COV

displays the estimated covariance matrix of the least-squares means as part of the “Least Squares Means” table.

DF=number

specifies the degrees of freedom for the *t*-test and confidence limits. The default is the denominator degrees of freedom taken from the “Tests of Fixed Effects” table corresponding to the LS-means effect unless the DDFM=SATTERTH or DDFM=KENWARDROGER option is in effect on the MODEL statement. For these DDFM= methods degrees of freedom are determined separately for each test; see the [DDFM= option](#) on page 2693 for more information.

DIFF<=difftype>**PDIF<=difftype>**

requests that differences of the LS-means be displayed. The optional *difftype* specifies which differences to produce, with possible values being ALL, CONTROL, CONTROLL, and CONTROLU. The *difftype* ALL requests all pairwise differences, and it is the default. The *difftype* CONTROL requests the differences with a control, which, by default, is the first level of each of the specified LSMEANS effects.

To specify which levels of the effects are the controls, list the quoted formatted values in parentheses after the keyword CONTROL. For example, if the effects A, B, and C are class variables, each having two levels, 1 and 2, the following LSMEANS statement specifies the (1,2) level of A*B and the (2,1) level of B*C as controls:

```
lsmeans A*B B*C / diff=control('1' '2' '2' '1');
```

For multiple effects, the results depend upon the order of the list, and so you should check the output to make sure that the controls are correct.

Two-tailed tests and confidence limits are associated with the CONTROL *difftype*. For one-tailed results, use either the CONTROLL or CONTROLU *difftype*. The CONTROLL *difftype* tests whether the noncontrol levels are significantly smaller than the control; the upper confidence limits for the control minus the noncontrol levels are considered to be infinity and are displayed as missing. Conversely, the CONTROLU *difftype* tests whether the noncontrol levels are significantly larger than the control; the upper confidence limits for the noncontrol levels minus the control are considered to be infinity and are displayed as missing.

If you want to perform multiple comparison adjustments on the differences of LS-Means, you must specify the ADJUST= option.

The differences of the LS-means are displayed in a table titled “Differences of Least Squares Means.” For ODS purposes, the table name is “Diffs.”

E

requests that the **L** matrix coefficients for all LSMEANS effects be displayed. For ODS purposes, the label of this “L Matrix Coefficients” table is “Coef.”

OM<=OM-data-set>**OBSMARGINS<=OM-data-set>**

specifies a potentially different weighting scheme for the computation of LS-means coefficients. The standard LS-means have equal coefficients across classification effects; however, the OM option changes these coefficients to be proportional to those found in *OM-data-set*. This adjustment is reasonable when you want your inferences

to apply to a population that is not necessarily balanced but has the margins observed in *OM-data-set*.

By default, *OM-data-set* is the same as the analysis data set. You can optionally specify another data set that describes the population for which you want to make inferences. This data set must contain all model variables except for the dependent variable (which is ignored if it is present). In addition, the levels of all CLASS variables must be the same as those occurring in the analysis data set. Specifying an *OM-data-set* enables you to construct arbitrarily weighted LS-means.

In computing the observed margins, PROC MIXED uses all observations for which there are no missing or invalid independent variables, including those for which there are missing dependent variables. Also, if *OM-data-set* has a WEIGHT variable, PROC MIXED uses weighted margins to construct the LS-means coefficients. If *OM-data-set* is balanced, the LS-means are unchanged by the OM option.

The **BYLEVEL** option modifies the observed-margins LS-means. Instead of computing the margins across all of the *OM-data-set*, PROC MIXED computes separate margins for each level of the LSMEANS effect in question. In this case the resulting LS-means are actually equal to raw means for fixed effects models and certain balanced random effects models, but their estimated standard errors account for the covariance structure that you have specified. If the AT option is specified, the BYLEVEL option disables it.

You can use the **E** option in conjunction with either the OM or BYLEVEL option to check that the modified LS-means coefficients are the ones you desire. It is possible that the modified LS-means are not estimable when the standard ones are, or vice versa. Nonestimable LS-means are noted as “Non-est” in the output.

PDIFF

is the same as the **DIFF** option. See the description of the DIFF option on page 2690.

SINGULAR=number

tunes the estimability checking as documented on the “**CONTRAST Statement**” section on page 2681.

SLICE= fixed-effect

SLICE= (fixed-effects)

specifies effects by which to partition interaction LSMEANS effects. This can produce what are known as tests of simple effects (Winer 1971). For example, suppose that **A*B** is significant, and you want to test the effect of **A** for each level of **B**. The appropriate LSMEANS statement is

```
lsmeans A*B / slice=B;
```

This code tests for the simple main effects of **A** for **B**, which are calculated by extracting the appropriate rows from the coefficient matrix for the **A*B** LS-means and using them to form an *F*-test. See the “**Inference and Test Statistics**” section on page 2741 for more information on this *F*-test.

The SLICE option produces a table titled “Tests of Effect Slices.” For ODS purposes, the table name is “Slices.”

MODEL Statement

MODEL *dependent* = < *fixed-effects* >< / *options* >;

The MODEL statement names a single dependent variable and the fixed effects, which determine the \mathbf{X} matrix of the mixed model (see the “Parameterization of Mixed Models” section on page 2743 for details). The specification of effects is the same as in the GLM procedure; however, unlike PROC GLM, you do not specify random effects in the MODEL statement. The MODEL statement is required.

An intercept is included in the fixed-effects model by default. If no fixed effects are specified, only this intercept term is fit. The intercept can be removed by using the NOINT option.

You can specify the following options in the MODEL statement after a slash (/).

ALPHA=*number*

requests that a t -type confidence interval be constructed for each of the fixed-effects parameters with confidence level $1 - \textit{number}$. The value of *number* must be between 0 and 1; the default is 0.05.

ALPHAP=*number*

requests that a t -type confidence interval be constructed for the predicted values with confidence level $1 - \textit{number}$. The value of *number* must be between 0 and 1; the default is 0.05.

CHISQ

requests that χ^2 -tests be performed for all specified effects in addition to the F -tests. Type III tests are the default; you can produce the Type I and Type II tests using the HTYPE= option.

CL

requests that t -type confidence limits be constructed for each of the fixed-effects parameter estimates. The confidence level is 0.95 by default; this can be changed with the ALPHA= option.

CONTAIN

has the same effect as the DDFM=CONTAIN option.

CORRB

produces the approximate correlation matrix of the fixed-effects parameter estimates. For ODS purposes, the label for this table is “CorrB.”

COVB

produces the approximate variance-covariance matrix of the fixed-effects parameter estimates $\hat{\beta}$. By default, this matrix equals $(\mathbf{X}'\hat{\mathbf{V}}^{-1}\mathbf{X})^{-1}$ and results from sweeping $(\mathbf{X} \mathbf{y})'\hat{\mathbf{V}}^{-1}(\mathbf{X} \mathbf{y})$ on all but its last pivot and removing the y border. The EMPIRICAL option in the PROC MIXED statement changes this matrix into “empirical sandwich” form, as described on page 2676. For ODS purposes, the label for this table is “CovB.”

COVBI

produces the inverse of the approximate variance-covariance matrix of the fixed-effects parameter estimates. For ODS purposes, the label for this table is “InvCovB.”

DDF=*value-list*

enables you to specify your own denominator degrees of freedom for the fixed effects. The *value-list* specification is a list of numbers or missing values (.) separated by commas. The degrees of freedom should be listed in the order in which the effects appear in the “Tests of Fixed Effects” table. If you want to retain the default degrees of freedom for a particular effect, use a missing value for its location in the list. For example,

```
model Y = A B A*B / ddf=3,.,4.7;
```

assigns 3 denominator degrees of freedom to A and 4.7 to A*B, while those for B remain the same. If you specify DDFM=SATTERTH or DDFM=KENWARDROGER the DDF= option has no effect.

DDFM=CONTAIN**DDFM=BETWITHIN****DDFM=RESIDUAL****DDFM=SATTERTH****DDFM=KENWARDROGER**

specifies the method for computing the denominator degrees of freedom for the tests of fixed effects resulting from the MODEL, CONTRAST, ESTIMATE, and LSMEANS statements.

The DDFM=CONTAIN option invokes the *containment method* to compute denominator degrees of freedom, and it is the default when you specify a RANDOM statement. The containment method is carried out as follows: Denote the fixed effect in question A, and search the RANDOM effect list for the effects that *syntactically* contain A. For example, the RANDOM effect B(A) contains A, but the RANDOM effect C does not, even if it has the same levels as B(A).

Among the RANDOM effects that contain A, compute their rank contribution to the (X Z) matrix. The DDF assigned to A is the smallest of these rank contributions. If no effects are found, the DDF for A is set equal to the residual degrees of freedom, $N - \text{rank}(\mathbf{X Z})$. This choice of DDF matches the tests performed for balanced split-plot designs and should be adequate for moderately unbalanced designs.

Caution: If you have a Z matrix with a large number of columns, the overall memory requirements and the computing time after convergence can be substantial for the containment method. If it is too large, you may want to use the DDFM=BETWITHIN option.

The DDFM=BETWITHIN option is the default for REPEATED statement specifications (with no RANDOM statements). It is computed by dividing the residual degrees of freedom into between-subject and within-subject portions. PROC MIXED then checks whether a fixed effect changes within any subject. If so, it assigns within-subject degrees of freedom to the effect; otherwise, it assigns the between-subject

degrees of freedom to the effect (refer to Schluchter and Elashoff 1990). If there are multiple within-subject effects containing classification variables, the within-subject degrees of freedom is partitioned into components corresponding to the subject-by-effect interactions.

One exception to the preceding method is the case when you have specified no RANDOM statements and a REPEATED statement with the TYPE=UN option. In this case, all effects are assigned the between-subject degrees of freedom to provide for better small-sample approximations to the relevant sampling distributions. DDFM=KENWARDROGER may be a better option to try for this case.

The DDFM=RESIDUAL option performs all tests using the residual degrees of freedom, $n - \text{rank}(\mathbf{X})$, where n is the number of observations.

The DDFM=SATTERTH option performs a general Satterthwaite approximation for the denominator degrees of freedom, computed as follows. Suppose θ is the vector of unknown parameters in V and suppose $C = (X'V^{-1}X)^{-}$, where $^{-}$ denotes a generalized inverse. Let \hat{C} and $\hat{\theta}$ be the corresponding estimates.

Consider the one-dimensional case, and consider ℓ to be a vector defining an estimable linear combination of β . The Satterthwaite degrees of freedom for the t -statistic

$$t = \frac{\ell\hat{\beta}}{\sqrt{\ell\hat{C}\ell'}}$$

is computed as

$$\nu = \frac{2(\ell\hat{C}\ell')^2}{g'Ag}$$

where g is the gradient of $\ell C \ell'$ with respect to θ , evaluated at $\hat{\theta}$, and A is the asymptotic variance-covariance matrix of $\hat{\theta}$ obtained from the second derivative matrix of the likelihood equations.

For the multi-dimensional case, let L be an estimable contrast matrix of rank $q > 1$. The Satterthwaite denominator degrees of freedom for the F -statistic

$$F = \frac{\hat{\beta}'L'(L\hat{C}L')^{-1}L\hat{\beta}}{q}$$

is computed by first performing the spectral decomposition $L\hat{C}L' = P'DP$ where P is an orthogonal matrix of eigenvectors and D is a diagonal matrix of eigenvalues, both of dimension $q \times q$. Define ℓ_m to be the m th row of PL , and let

$$\nu_m = \frac{2(D_m)^2}{g_m'Ag_m}$$

where D_m is the m th diagonal element of D and g_m is the gradient of $\ell_m C \ell_m'$ with respect to θ , evaluated at $\hat{\theta}$. Then let

$$E = \sum_{m=1}^q \frac{\nu_m}{\nu_m - 2} I(\nu_m > 2)$$

where the indicator function eliminates terms for which $\nu_m \leq 2$. The degrees of freedom for F are then computed as

$$\nu = \frac{2E}{E - q}$$

provided $E > q$; otherwise ν is set to zero.

This method is a generalization of the techniques described in Giesbrecht and Burns (1985), McLean and Sanders (1988), and Fai and Cornelius (1996). The method can also include estimated random effects. In this case, append $\hat{\gamma}$ to $\hat{\beta}$ and change \hat{C} to be the inverse of the coefficient matrix in the mixed model equations. The calculations require extra memory to hold c matrices that are the size of the mixed model equations, where c is the number of covariance parameters. In the notation of Table 46.12 on page 2773, this is approximately $8q(p+g)(p+g)/2$ bytes. Extra computing time is also required to process these matrices. The Satterthwaite method implemented here is intended to produce an accurate F -approximation; however, the results may differ from those produced by PROC GLM. Also, the small sample properties of this approximation have not been extensively investigated for the various models available with PROC MIXED.

The DDFM=KENWARDROGER option performs the degrees-of-freedom calculations detailed by Kenward and Roger (1997). This approximation involves inflating the estimated variance-covariance matrix of the fixed and random effects by the method proposed by Prasad and Rao (1990) and Harville and Jeske (1992); refer also to Kackar and Harville (1984). Satterthwaite-type degrees of freedom are then computed based on this adjustment. By default, the observed information matrix of the covariance parameter estimates is used in the calculations.

When the asymptotic variance matrix of the covariance parameters is found to be singular, a generalized inverse is used. Covariance parameters with zero variance then do not contribute to the degrees-of-freedom adjustment for DDFM=SATTERTH and DDFM=KENWARDROGER, and a message is written to the LOG.

This method changes output in the following tables (listed in Table 46.8 on page 2752): Contrast, CorrB, CovB, Diffs, Estimates, InvCovB, LSMeans, MMEq, MMEqSol, Slices, SolutionF, SolutionR, Tests1–Tests3. The OUTP= and OUTPM= data sets are also affected.

E

requests that Type I, Type II, and Type III **L** matrix coefficients be displayed for all specified effects. For ODS purposes, the labels of the tables are “Coef.”

E1

requests that Type I **L** matrix coefficients be displayed for all specified effects. For ODS purposes, the label of this table is “Coef.”

E2

requests that Type II **L** matrix coefficients be displayed for all specified effects. For ODS purposes, the label of this table is “Coef.”

E3

requests that Type III L matrix coefficients be displayed for all specified effects. For ODS purposes, the label of this table is “Coef.”

FULLX

requests that columns of the **X** matrix that consist entirely of zeros not be eliminated from **X**; otherwise, they are eliminated by default. For a column corresponding to a missing cell to be added to **X**, its particular levels must be present in at least one observation in the analysis data set along with a missing dependent variable. The use of the FULLX option can impact coefficient specifications in the CONTRAST and ESTIMATE statements, as well as covariate coefficients from LSMEANS statements specified with the AT MEANS option.

HTYPE=value-list

indicates the type of hypothesis test to perform on the fixed effects. Valid entries for *value* are 1, 2, and 3; the default value is 3. You can specify several types by separating the values with a comma or a space. The ODS table names are “Tests1” for the Type 1 tests, “Tests2” for the Type 2 tests, and “Tests3” for Type 3 tests.

Experimental

INFLUENCE<(<EFFECT=effect>
 <ESTIMATES|EST>
 <ITER=number>
 <KEEP=number>
 <SELECT=value-list>
 <SIZE=number>)>

specifies that influence and case deletion diagnostics are to be computed.

The INFLUENCE option of the MODEL statement in the MIXED procedure computes influence diagnostics by noniterative or iterative methods. The noniterative diagnostics rely on recomputation formulas under the assumption that covariance parameters or their ratios remain fixed. With the possible exception of a profiled residual variance, no covariance parameters are updated. This is the default behavior because of its computational efficiency. However, the impact of an observation on the overall analysis can be underestimated if its effect on covariance parameters is not assessed. Toward this end, iterative methods can be applied to gauge the overall impact of observations and to obtain influence diagnostics for the covariance parameter estimates.

If you specify the INFLUENCE option without further suboptions, PROC MIXED computes single-case deletion diagnostics and influence statistics for each observation in the data set by updating estimates for the fixed effects parameter estimates, and also the residual variance, if it is profiled. The EFFECT=, SELECT=, ITER=, SIZE=, and KEEP= suboptions provide additional flexibility in the computation and reporting of influence statistics.

Description	Suboption
Compute influence diagnostics for individual observations	default
Measure influence of sets of observations chosen according to a classification variable or effect	EFFECT=
Remove pairs of observations and report the results sorted by degree of influence	SIZE=2
Remove triples, quadruples of observations,...	SIZE=
Allow selection of individual observations, observations sharing specific levels of effects, and construction of tuples from specified subsets of observations	SELECT=
Update fixed effects and covariance parameters by refitting the mixed model, adding up to n iterations	ITER= $n > 0$
Compute influence diagnostics for the covariance parameters	ITER= $n > 0$
Update only fixed effects and the residual variance, if it is profiled	ITER=0
Add the reduced-data estimates to the data set created with ODS OUTPUT	ESTIMATES

The modifiers and their default values are discussed in the following paragraphs. The set of computed influence diagnostics varies with the suboptions. The most extensive set of influence diagnostics is obtained when ITER= n with $n > 0$.

You can produce statistical graphics of influence diagnostics when the experimental ODS GRAPHICS statement is specified. For general information about ODS graphics, see [Chapter 15, “Statistical Graphics Using ODS.”](#) For specific information about the graphics available in the MIXED procedure, see the [“ODS Graphics”](#) section on page 2757.

EFFECT=effect specifies an effect according to which observations are grouped. Observations sharing the same level of the *effect* are removed from the analysis as a group. The *effect* must contain only class variables, but need not be contained in the model.

Removing observations can change the rank of the $(\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1}$ matrix. This is particularly likely to happen when multiple observations are eliminated from the analysis. If the rank of the estimated variance-covariance matrix of $\hat{\beta}$ changes or its singularity pattern is altered, no influence diagnostics are computed.

ESTIMATES|EST specifies that the updated parameter estimates should be written to the ODS output data set. The values are not displayed in the “Influence” table, but if you use ODS OUTPUT to create a data set from the listing, the estimates are added to the data set. If ITER=0, only the fixed effects estimates are saved. In iterative influence

analyses, fixed effects and covariance parameters are stored. The p fixed effects parameter estimates are named `Parm1–Parm p` , and the q covariance parameter estimates are named `CovP1–CovP q` . The order corresponds to that in the “Solution for Fixed Effects” and “Covariance Parameter Estimates” tables. If parameter updates fail, for example, because of a loss of rank or a nonpositive definite Hessian, missing values are reported.

`ITER= n`

controls the maximum number of additional iterations PROC MIXED performs to update the fixed effects and covariance parameter estimates following data point removal. If you specify $n > 0$, then statistics such as `DFFITS`, `MDFFITS`, and the likelihood distances measure the impact of observation(s) on all aspects of the analysis. Typically, the influence will grow compared to values at `ITER=0`. In models without `RANDOM` or `REPEATED` effects, the `ITER=` option has no effect.

This documentation refers to analyses when $n > 0$ simply as iterative influence analysis, even if final covariance parameter estimates can be updated in a single step (for example, when `METHOD=MIVQUE0` or `METHOD=TYPE3`). This nomenclature reflects the fact that only if $n > 0$ will all model parameters be updated, which may require additional iterations. If $n > 0$ and `METHOD=REML` (default) or `METHOD=ML`, the procedure updates fixed effects *and* variance-covariance parameters after removing the selected observations with additional Newton-Raphson iterations, starting from the converged estimates for the entire data. The process stops for each observation or set of observations if the convergence criterion is satisfied or the number of further iterations exceeds n . If $n > 0$ and `METHOD=TYPE1`, `TYPE2`, or `TYPE3`, ANOVA estimates of the covariance parameters are recomputed in a single step.

Compared to noniterative updates the computations are more involved. In particular for large data sets and/or a large number of random effects, iterative updates require considerably more resources. A one-step (`ITER=1`) or two-step update may be a good compromise. The output includes the number of iterations performed, which is less than n if the iteration converges. If the process does not converge in n iterations, you should be careful in interpreting the results, especially if n is fairly large.

Bounds and other restrictions on the covariance parameters carry over from the full-data model. Covariance parameters that are not iterated in the model fit to the full data (the `NOITER` or `HOLD` option of the `PARMS` statement) are likewise not updated in the refit. In certain models, for example, random effects models, the ratios between the covariance parameters and the residual variance are maintained rather than the actual value of the covariance parameter estimate (see the section “[Influence Diagnostics](#)” on page 2765

in the “Details” section).

KEEP=*n* determines how many observations are retained for display and in the output data set or how many tuples if you specify **SIZE=**. The output is sorted by an influence statistic as discussed for the **SIZE=** suboption.

SELECT = *value-list* specifies which observations or effect levels are chosen for influence calculations. If **SELECT=** is not specified, diagnostics are computed for all possible subsets, that is

- all observations, if **EFFECT=** or **SIZE=** are not given
- all levels of the specified effect, if **EFFECT=** is specified
- all tuples of size *k* formed from the observations in *value-list*, if **SIZE=*k*** is specified

When you specify an effect with the **EFFECT=** option, the values in *value-list* represent indices of the levels in the order in which PROC MIXED builds classification effects. Which observations in the data set correspond to this index depends on the order of the variables in the **CLASS** statement, not the order in which the variables appear in the interaction effect. See the section “Parameterization of Mixed Models” on page 2743 on precisely how the procedure indexes nested and crossed effects and how levels of classification variables are ordered. The actual values of the classification variables involved in the effect are shown on the output so you can determine which observations were removed.

If the **EFFECT=** suboption is not specified, the **SELECT=** value list refers to the sequence in which observations are read from the input data set or from the current **BY** group if there is a **BY** statement. This indexing is not necessarily the same as the observation numbers in the input data set, for example, if a **WHERE** clause is specified or during **BY** processing.

SIZE= *n* instructs PROC MIXED to remove groups of observations formed as tuples of size *n*. For example, **SIZE=2** specifies all $n \times (n - 1) / 2$ unique pairs of observations. The number of tuples for **SIZE=*k*** is $n! / (k!(n - k)!)$ and grows quickly with *n* and *k*. Using the **SIZE=** option can result in considerable computing time. The MIXED procedure displays by default only the 50 tuples with the greatest influence. Use the **KEEP=** option to override this default and to retain a different number of tuples in the listing or ODS output data set. Regardless of the **KEEP=** specification, all tuples are evaluated and the results are ordered according to an influence statistic. This statistic is the (restricted) likelihood distance as a measure of overall influence if **ITER = *n* > 0** or when a residual variance is profiled. When likelihood distances are unavailable, the results are ordered by the **PRESS** statistic.

To reduce computational burden, the **SIZE=** option can be combined with the **SELECT=*value-list*** modifier. For example,

```

proc mixed data=aerosol;
  class aerosol manufacturer filter;
  model penetration = aerosol manufacturer /
    influence(size=2 keep=5
              select=13,14,18,30,31,33);
  random filter(manuf);
run;

```

evaluates all $15 = 6 \times 5/2$ pairs formed from observations 13, 14, 18, 30, 31, and 33 and displays the five pairs with the greatest influence. If any observation in a tuple contains missing values or has otherwise not contributed to the analysis, the tuple is not evaluated. This guarantees that the displayed results refer to the same number of observations, so that meaningful statistics are available by which to order the results. If computations fail for a particular tuple, for example, because the $(\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1}$ matrix changes rank or the \mathbf{G} matrix is not positive definite, no results are produced. Results are retained when the maximum number of iterative updates is exceeded in iterative influence analyses.

The SIZE= suboption cannot be combined with the EFFECT= suboption.

As in the case of the EFFECT= suboption, the statistics being computed are those appropriate for removal of multiple data points, even if SIZE=1.

For ODS purposes the label of the “Influence Diagnostics” table is “Influence.” The variables in this table depend on whether you specify the EFFECT=, SIZE=, or KEEP= suboption and whether covariance parameters are iteratively updated. When ITER=0 (the default) certain influence diagnostics are only meaningful if the residual variance is profiled. Table 46.3 and Table 46.4 summarize the statistics obtained depending on the model and modifiers. The last column in these tables gives the variable name in the ODS OUTPUT INFLUENCE= data set. Restricted likelihood distances are reported instead of the likelihood distance unless METHOD=ML. See the “Influence Diagnostics” section beginning on page 2765 for details on the individual statistics.

INTERCEPT

adds a row to the tables for Type 1, 2, and 3 tests corresponding to the overall intercept.

LCOMPONENTS

requests an estimate for each row of the **L** matrix used to form tests of fixed effects. Components corresponding to Type 3 tests are the default; you can produce the Type 1 and Type 2 component estimates with the **HTYPE=** option.

Tests of fixed effects involve testing of linear hypotheses of the form $\mathbf{L}\beta = \mathbf{0}$. The matrix **L** is constructed from Type 1, 2, or 3 estimable functions. By default the MIXED procedure constructs Type 3 tests. In many situations, the individual rows of the matrix **L** represent contrasts of interest. For example, in a one-way classification model, the Type 3 estimable functions define differences of factor level means. In a balanced two-way layout, the rows of **L** correspond to differences of cell means.

For example, if factors **A** and **B** have *a* and *b* levels, respectively, the statements

```
class A B;
model y = A B x / htype=1,3 lcomponents;
```

produce $(a - 1)$ one degree of freedom tests for the rows of **L** associated with the Type 1 and Type 3 estimable functions for factor **A**, $(b - 1)$ tests for the rows of **L** associated with factor **B**, and a single test for the Type 1 and Type 3 coefficients associated with regressor **X**.

The denominator degrees of freedom associated with a row of **L** are the same as those in the corresponding “Tests of Fixed Effects” table, except for **DDFM=KENWARDROGER** and **DDFM=SATTERTH**. For these degree of freedom methods, the denominator degrees of freedom are computed separately for each row of **L**.

For ODS purposes, the name of the table containing all requested component tests is “LComponents.” See [Example 46.9](#) on page 2839 for examples incorporating the **LCOMPONENTS** option.

NOCONTAIN

has the same effect as the [DDFM=RESIDUAL](#) option.

NOINT

requests that no intercept be included in the model. An intercept is included by default.

NOTEST

specifies that no hypothesis tests be performed for the fixed effects.

OUTP=SAS-data-set**OUTPRED=SAS-data-set**

specifies an output data set containing predicted values and related quantities. This option replaces the P option from Version 6.

Predicted values are formed by using the rows from $(\mathbf{X} \ \mathbf{Z})$ as \mathbf{L} matrices. Thus, predicted values from the original data are $\mathbf{X}\hat{\boldsymbol{\beta}} + \mathbf{Z}\hat{\boldsymbol{\gamma}}$. Their approximate standard errors of prediction are formed from the quadratic form of \mathbf{L} with $\hat{\mathbf{C}}$ defined in the “[Statistical Properties](#)” section on page 2740. The L95 and U95 variables provide a t -type confidence interval for the predicted values, and they correspond to the L95M and U95M variables from the GLM and REG procedures for fixed-effect models. The residuals are the observed minus the predicted values. Predicted values for data points other than those observed can be obtained by using missing dependent variables in your input data set.

Specifications that have a REPEATED statement with the SUBJECT= option and missing dependent variables compute predicted values using empirical best linear unbiased prediction (EBLUP). Using hats ($\hat{}$) to denote estimates, the EBLUP formula is

$$\hat{\mathbf{m}} = \mathbf{X}_m \hat{\boldsymbol{\beta}} + \hat{\mathbf{C}}_m \hat{\mathbf{V}}^{-1} (\mathbf{y} - \mathbf{X} \hat{\boldsymbol{\beta}})$$

where \mathbf{m} represents a hypothetical realization of a missing data vector with associated design matrix \mathbf{X}_m . The matrix \mathbf{C}_m is the model-based covariance matrix between \mathbf{m} and the observed data \mathbf{y} , and other notation is as presented in the “[Mixed Models Theory](#)” section beginning on page 2731.

The estimated prediction variance is as follows:

$$\hat{\text{Var}}(\hat{\mathbf{m}} - \mathbf{m}) = \hat{\mathbf{V}}_m - \hat{\mathbf{C}}_m \hat{\mathbf{V}}^{-1} \hat{\mathbf{C}}_m^T + [\mathbf{X}_m - \hat{\mathbf{C}}_m \hat{\mathbf{V}}^{-1} \mathbf{X}] (\mathbf{X}^T \hat{\mathbf{V}}^{-1} \mathbf{X})^{-1} [\mathbf{X}_m - \hat{\mathbf{C}}_m \hat{\mathbf{V}}^{-1} \mathbf{X}]^T$$

where \mathbf{V}_m is the model-based variance matrix of \mathbf{m} . For further details, refer to Henderson (1984) and Harville (1990). This feature can be useful for forecasting time series or for computing spatial predictions.

By default, all variables from the input data set are included in the OUTP= data set. You can select a subset of these variables using the ID statement.

OUTPM=SAS-data-set

OUTPREDM=SAS-data-set

specifies an output data set containing predicted means and related quantities. This option replaces the PM option from Version 6.

The output data set is of the same form as that resulting from the OUTP= option, except that the predicted values do not incorporate the EBLUP values $Z\hat{\gamma}$. They also do not use the EBLUPs for specifications that have a REPEATED statement with the SUBJECT= option and missing dependent variables. The predicted values are formed as $X\hat{\beta}$ in the OUTPM= data set, and standard errors are quadratic forms in the approximate variance-covariance matrix of $\hat{\beta}$ as displayed by the COVB option.

By default, all variables from the input data set are included in the OUTPM= data set. You can select a subset of these variables using the ID statement.

Experimental

RESIDUAL

requests that Pearson-type and (internally) studentized residuals be added to the OUTP= and OUTPM= data sets. Studentized residuals are raw residuals standardized by their estimated standard error. When residuals are internally studentized, the data point in question has contributed to the estimation of the covariance parameter estimates on which the standard error of the residual is based. Externally studentized residuals can be computed with the INFLUENCE option. Pearson-type residuals scale the residual by the standard deviation of the response.

The RESIDUAL option adds the variables PearsonResid and StudentResid to the OUTP= and OUTPM= data sets. In the former case, the standardization draws on the variance of the conditional distribution (given the random effects). The standardization of residuals in the OUTPM= data set draws on the variance of the marginal distribution of the response.

The option has no effect unless the OUTP= or OUTPM= option are specified or you request statistical graphics with the experimental ODS GRAPHICS statement. For general information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the MIXED procedure, see the “ODS Graphics” section on page 2757. For computational details about studentized and Pearson residuals in MIXED, see the “Residual Diagnostics” section beginning on page 2763.

SINGULAR=number

tunes the sensitivity in sweeping. If a diagonal pivot element is less than $D*number$ as PROC MIXED sweeps a matrix, the associated column is declared to be linearly dependent upon previous columns, and the associated parameter is set to 0. The value D is the original diagonal element of the matrix. The default is 1E4 times the machine epsilon; this product is approximately 1E–12 on most computers.

SINGCHOL=number

tunes the sensitivity in computing Cholesky roots. If a diagonal pivot element is less than $D*number$ as PROC MIXED performs the Cholesky decomposition on a matrix, the associated column is declared to be linearly dependent upon previous columns and is set to 0. The value D is the original diagonal element of the matrix. The default

for *number* is 1E4 times the machine epsilon; this product is approximately 1E–12 on most computers.

SINGRES=number

sets the tolerance for which the residual variance is considered to be zero. The default is 1E4 times the machine epsilon; this product is approximately 1E–12 on most computers.

SOLUTION

S

requests that a solution for the fixed-effects parameters be produced. Using notation from the “[Mixed Models Theory](#)” section beginning on page 2731, the fixed-effects parameter estimates are $\hat{\mathbf{b}}$ and their approximate standard errors are the square roots of the diagonal elements of $(\mathbf{X}'\hat{\mathbf{V}}^{-1}\mathbf{X})^{-1}$. You can output this approximate variance matrix with the [COVB](#) option or modify it with the [EMPIRICAL](#) option in the PROC MIXED statement.

Along with the estimates and their approximate standard errors, a *t*-statistic is computed as the estimate divided by its standard error. The degrees of freedom for this *t*-statistic matches the one appearing in the “Tests of Fixed Effects” table under the effect containing the parameter. The “Pr > |t|” column contains the two-tailed *p*-value corresponding to the *t*-statistic and associated degrees of freedom. You can use the [CL](#) option to request confidence intervals for all of the parameters; they are constructed around the estimate by using a radius of the standard error times a percentage point from the *t*-distribution.

VCIRY

Experimental

requests that responses and marginal residuals be scaled by the inverse Cholesky root of the marginal variance-covariance matrix. The variables [ScaledDep](#) and [ScaledResid](#) are added to the OUTPM= data set. These quantities can be important in bootstrapping of data or residuals. Examination of the scaled residuals is also helpful in diagnosing departures from normality. Notice that the results of this scaling operation can depend on the order in which the MIXED procedure processes the data.

The VCIRY option has no effect unless you also use the OUTPM= option or you request statistical graphics with the experimental ODS GRAPHICS statement. For general information about ODS graphics, see [Chapter 15, “Statistical Graphics Using ODS.”](#) For specific information about the graphics available in the MIXED procedure, see the “[ODS Graphics](#)” section on page 2757.

XPVIX

is an alias for the [COVBI](#) option.

XPVIXI

is an alias for the [COVB](#) option.

ZETA=number

tunes the sensitivity in forming Type III functions. Any element in the estimable function basis with an absolute value less than *number* is set to 0. The default is 1E–8.

PARMS Statement

PARMS (*value-list*) ... < / *options* > ;

The PARMS statement specifies initial values for the covariance parameters, or it requests a grid search over several values of these parameters. You must specify the values in the order in which they appear in the “Covariance Parameter Estimates” table.

The *value-list* specification can take any of several forms:

m	a single value
m_1, m_2, \dots, m_n	several values
m to n	a sequence where m equals the starting value, n equals the ending value, and the increment equals 1
m to n by i	a sequence where m equals the starting value, n equals the ending value, and the increment equals i
m_1, m_2 to m_3	mixed values and sequences

You can use the PARMS statement to input known parameters. Referring to the split-plot example ([Example 46.1](#) on page 2777), suppose the three variance components are known to be 60, 20, and 6. The SAS statements to fix the variance components at these values is as follows:

```
proc mixed data=sp noprofile;
  class Block A B;
  model Y = A B A*B;
  random Block A*Block;
  parms (60) (20) (6) / noiter;
run;
```

The NOPROFILE option requests PROC MIXED to refrain from profiling the residual variance parameter during its calculations, thereby enabling its value to be held at 6 as specified in the PARMS statement. The NOITER option prevents any Newton-Raphson iterations so that the subsequent results are based on the given variance components. You can also specify known parameters of \mathbf{G} using the [GDATA=](#) option in the RANDOM statement.

If you specify more than one set of initial values, PROC MIXED performs a grid search of the likelihood surface and uses the best point on the grid for subsequent analysis. Specifying a large number of grid points can result in long computing times. The grid search feature is also useful for exploring the likelihood surface. See [Example 46.3](#) on page 2795.

The results from the PARMS statement are the values of the parameters on the specified grid (denoted by CovP1–CovPn), the residual variance (possibly estimated) for models with a residual variance parameter, and various functions of the likelihood.

For ODS purposes, the label of the “Parameter Search” table is “ParmSearch.”

You can specify the following options in the PARMS statement after a slash (/).

HOLD=*value-list*

EQCONS=*value-list*

specifies which parameter values PROC MIXED should hold to equal the specified values. For example, the statement

```
parms (5) (3) (2) (3) / hold=1,3;
```

constrains the first and third covariance parameters to equal 5 and 2, respectively.

LOGDETH

evaluates the log determinant of the Hessian matrix for each point specified in the PARMS statement. A Log Det H column is added to the “Parameter Search” table.

LOWERB=*value-list*

enables you to specify lower boundary constraints on the covariance parameters. The *value-list* specification is a list of numbers or missing values (.) separated by commas. You must list the numbers in the order that PROC MIXED uses for the covariance parameters, and each number corresponds to the lower boundary constraint. A missing value instructs PROC MIXED to use its default constraint, and if you do not specify numbers for all of the covariance parameters, PROC MIXED assumes the remaining ones are missing.

An example for which this option is useful is when you want to constrain the **G** matrix to be positive definite in order to avoid the more computationally intensive algorithms required when **G** becomes singular. The corresponding code for a random coefficients model is as follows:

```
proc mixed;
  class person;
  model y = time;
  random int time / type=fa0(2) sub=person;
  parms / lowerb=1e-4,.,1e-4;
run;
```

Here the FA0(2) structure is used in order to specify a Cholesky root parameterization for the 2×2 unstructured blocks in **G**. This parameterization ensures that the **G** matrix is nonnegative definite, and the PARMS statement then ensures that it is positive definite by constraining the two diagonal terms to be greater than or equal to $1E-4$.

NOBOUND

requests the removal of boundary constraints on covariance parameters. For example, variance components have a default lower boundary constraint of 0, and the NOBOUND option allows their estimates to be negative.

NOITER

requests that no Newton-Raphson iterations be performed and that PROC MIXED use the best value from the grid search to perform inferences. By default, iterations begin at the best value from the PARMS grid search.

NOPROFILE

specifies a different computational method for the residual variance during the grid search. By default, PROC MIXED estimates this parameter using the profile likelihood when appropriate. This estimate is displayed in the Variance column of the “Parameter Search” table. The NOPROFILE option suppresses the profiling and uses the actual value of the specified variance in the likelihood calculations.

OLS

requests starting values corresponding to the usual general linear model. Specifically, all variances and covariances are set to zero except for the residual variance, which is set equal to its ordinary least-squares (OLS) estimate. This option is useful when the default MIVQUE0 procedure produces poor starting values for the optimization process.

PARMSDATA=SAS-data-set

PDATA=SAS-data-set

reads in covariance parameter values from a SAS data set. The data set should contain the EST or COVP1–COVP n variables.

RATIOS

indicates that ratios with the residual variance are specified instead of the covariance parameters themselves. The default is to use the individual covariance parameters.

UPPERB=value-list

enables you to specify upper boundary constraints on the covariance parameters. The *value-list* specification is a list of numbers or missing values (.) separated by commas. You must list the numbers in the order that PROC MIXED uses for the covariance parameters, and each number corresponds to the upper boundary constraint. A missing value instructs PROC MIXED to use its default constraint, and if you do not specify numbers for all of the covariance parameters, PROC MIXED assumes that the remaining ones are missing.

PRIOR Statement

PRIOR < *distribution* >< / *options* > ;

The PRIOR statement enables you to carry out a sampling-based Bayesian analysis in PROC MIXED. It currently operates only with variance component models. The analysis produces a SAS data set containing a pseudo-random sample from the joint posterior density of the variance components and other parameters in the mixed model.

The posterior analysis is performed after all other PROC MIXED computations. It begins with the “Posterior Sampling Information” table, which provides basic information about the posterior sampling analysis, including the prior densities, sampling

algorithm, sample size, and random number seed. For ODS purposes, the name of this table is “Posterior.”

By default, PROC MIXED uses an independence chain algorithm in order to generate the posterior sample (Tierney 1994). This algorithm works by generating a pseudo-random proposal from a convenient base distribution, chosen to be as close as possible to the posterior. The proposal is then retained in the sample with probability proportional to the ratio of weights constructed by taking the ratio of the true posterior to the base density. If a proposal is not accepted, then a duplicate of the previous observation is added to the chain.

In selecting the base distribution, PROC MIXED makes use of the fact that the fixed-effects parameters can be analytically integrated out of the joint posterior, leaving the marginal posterior density of the variance components. In order to better approximate the marginal posterior density of the variance components, PROC MIXED transforms them using the MIVQUE(0) equations. You can display the selected transformation with the PTRANS option or specify your own with the TDATA= option. The density of the transformed parameters is then approximated by a product of inverted gamma densities (refer to Gelfand et al. 1990).

To determine the parameters for the inverted gamma densities, PROC MIXED evaluates the logarithm of the posterior density over a grid of points in each of the transformed parameters, and you can display the results of this search with the PSEARCH option. PROC MIXED then performs a linear regression of these values on the logarithm of the inverted gamma density. The resulting base densities are displayed in the “Base Densities” table; for ODS purposes, the name of this table is “BaseDen.” You can input different base densities with the BDATA= option.

At the end of the sampling, the “Acceptance Rates” table displays the acceptance rate computed as the number of accepted samples divided by the total number of samples generated. For ODS purposes, the label of the “Acceptance Rates” table is “AcceptanceRates.”

The OUT= option specifies the output data set containing the posterior sample. PROC MIXED automatically includes all variance component parameters in this data set (labeled COVP1–COVP n), the Type III F -statistics constructed as in Ghosh (1992) discussing Schervish (1992) (labeled T3F n), the log values of the posterior (labeled LOGF), the log of the base sampling density (labeled LOGG), and the log of their ratio (labeled LOGRATIO). If you specify the SOLUTION option in the MODEL statement, the data set also contains a random sample from the posterior density of the fixed-effects parameters (labeled BETA n), and if you specify the SOLUTION option in the RANDOM statement, the table contains a random sample from the posterior density of the random-effects parameters (labeled GAM n). PROC MIXED also generates additional variables corresponding to any CONTRAST, ESTIMATE, or LSMEANS statement that you specify.

Subsequently, you can use SAS/INSIGHT, or the UNIVARIATE, CAPABILITY, or KDE procedures to analyze the posterior sample.

The prior density of the variance components is, by default, a noninformative version of Jeffreys’ prior (Box and Tiao 1973). You can also specify informative pri-

ors with the DATA= option or a flat (equal to 1) prior for the variance components. The prior density of the fixed-effects parameters is assumed to be flat (equal to 1), and the resulting posterior is conditionally multivariate normal (conditioning on the variance component parameters) with mean $(\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{V}^{-1}\mathbf{y}$ and variance $(\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1}$.

The *distribution* argument in the PRIOR statement determines the prior density for the variance component parameters of your mixed model. Valid values are as follows.

DATA=

enables you to input the prior densities of the variance components used by the sampling algorithm. This data set must contain the TYPE and PARM1–PARM n variables, where n is the largest number of parameters among each of the base densities. The format of the DATA= data set matches that created by PROC MIXED in the “Base Densities” table, so you can output the densities from one run and use them as input for a subsequent run.

JEFFREYS

specifies a noninformative reference version of Jeffreys’ prior constructed using the square root of the determinant of the expected information matrix as in (1.3.92) of Box and Tiao (1973). This is the default prior.

FLAT

specifies a prior density equal to 1 everywhere, making the likelihood function the posterior.

You can specify the following options in the PRIOR statement after a slash (/).

ALG=IC | INDCHAIN**ALG=IS | IMPSAMP****ALG=RS | REJSAMP****ALG=RWC | RWCHAIN**

specifies the algorithm used for generating the posterior sample. The ALG=IC option requests an independence chain algorithm, and it is the default. The option ALG=IS requests importance sampling, ALG=RS requests rejection sampling, and ALG=RWC requests a random walk chain. For more information on these techniques, refer to Ripley (1987), Smith and Gelfand (1992), and Tierney (1994).

BDATA=

enables you to input the base densities used by the sampling algorithm. This data set must contain the TYPE and PARM1–PARM n variables, where n is the largest number of parameters among each of the base densities. The format of the BDATA= data set matches that created by PROC MIXED in the “Base Densities” table, so you can output the densities from one run and use them as input for a subsequent run.

GRID=(value-list)

specifies a grid of values over which to evaluate the posterior density. The *value-list* syntax is the same as in the [PARMS statement](#) (see page 2706), and you must specify an output data set name with the [OUTG=](#) option.

GRID=(value-list)

specifies a transformed grid of values over which to evaluate the posterior density. The *value-list* syntax is the same as in the [PARMS statement](#) (see page 2706), and you must specify an output data set name with the [OUTGT=](#) option.

IFACTOR=number

is an alias for the [SFACTOR=](#) option.

LOGNOTE=number

instructs PROC MIXED to write a note to the SAS log after it generates the sample corresponding to each multiple of *number*. This is useful for monitoring the progress of CPU-intensive runs.

LOGRBOUND=number

specifies the bounding constant for rejection sampling. The value of *number* equals the maximum of $\log(f/g)$ over the variance component parameter space, where f is the posterior density and g is the product inverted gamma densities used to perform rejection sampling.

When performing the rejection sampling, you may encounter the message

```
WARNING: The log ratio bound of LL was violated at sample XX.
```

When this occurs, PROC MIXED reruns an optimization algorithm to determine a new log upper bound and then restarts the rejection sampling. The resulting [OUT=](#) data set contains all observations that have been generated; therefore, assuming that you have requested N samples, you should retain only the final N observations in this data set for analysis purposes.

NSAMPLE=number

specifies the number of posterior samples to generate. The default is 1000, but more accurate results are obtained with larger samples such as 10000.

NSEARCH=number

specifies the number of posterior evaluations PROC MIXED makes for each transformed parameter in determining the parameters for the inverted gamma densities. The default is 20.

OUT=SAS-data-set

creates an output data set containing the sample from the posterior density.

OUTG=SAS-data-set

creates an output data set from the grid evaluations specified in the [GRID=](#) option.

OUTGT=SAS-data-set

creates an output data set from the transformed grid evaluations specified in the [GRIDT=](#) option.

PSEARCH

displays the search used to determine the parameters for the inverted gamma densities. For ODS purposes, the name of the table is "Search."

PTRANS

displays the transformation of the variance components. For ODS purposes, the name of the table is “Trans.”

SEED=number

specifies an integer used to start the pseudo-random number generator for the simulation. If you do not specify a seed, or specify a value less than or equal to zero, the seed is by default generated from reading the time of day from the computer clock. You should use a positive seed (less than $2^{31} - 1$) whenever you want to duplicate the sample in another run of PROC MIXED.

SFACTOR=number

enables you to adjust the range over which PROC MIXED searches the transformed parameters in order to determine the parameters for the inverted gamma densities. PROC MIXED determines the range by first transforming the estimates from the standard PROC MIXED analysis (REML, ML, or MIVQUE0, depending upon which estimation method you select). It then multiplies and divides the transformed estimates by $2 * number$ to obtain upper and lower bounds, respectively. Transformed values that produce negative variance components in the original scale are not included in the search. The default value is 1; *number* must be greater than 0.5.

TDATA=

enables you to input the transformation of the covariance parameters used by the sampling algorithm. This data set should contain the CovP1–CovP*n* variables. The format of the TDATA= data set matches that created by PROC MIXED in the “Trans” table, so you can output the transformation from one run and use it as input for a subsequent run.

TRANS=EXPECTED**TRANS=MIVQUE0****TRANS=OBSERVED**

specifies the particular algorithm used to determine the transformation of the covariance parameters. The default is MIVQUE0, indicating a transformation based on the MIVQUE(0) equations. The other two options indicate the type of Hessian matrix used in constructing the transformation via a Cholesky root.

UPDATE=number

is an alias for the LOGNOTE= option.

RANDOM Statement

RANDOM *random-effects* < / options > ;

The RANDOM statement defines the random effects constituting the γ vector in the mixed model. It can be used to specify traditional variance component models (as in the VARCOMP procedure) and to specify random coefficients. The random effects can be classification or continuous, and multiple RANDOM statements are possible.

Using notation from the “Mixed Models Theory” section beginning on page 2731, the purpose of the RANDOM statement is to define the **Z** matrix of the mixed model, the random effects in the γ vector, and the structure of **G**. The **Z** matrix is constructed

exactly as the \mathbf{X} matrix for the fixed effects, and the \mathbf{G} matrix is constructed to correspond with the effects constituting \mathbf{Z} . The structure of \mathbf{G} is defined by using the `TYPE=option` described on page 2715.

You can specify INTERCEPT (or INT) as a random effect to indicate the intercept. PROC MIXED does not include the intercept in the RANDOM statement by default as it does in the MODEL statement.

You can specify the following options in the RANDOM statement after a slash (/).

ALPHA=number

requests that a t -type confidence interval be constructed for each of the random effect estimates with confidence level $1 - \text{number}$. The value of *number* must be between 0 and 1; the default is 0.05.

CL

requests that t -type confidence limits be constructed for each of the random effect estimates. The confidence level is 0.95 by default; this can be changed with the `ALPHA=` option.

G

requests that the estimated \mathbf{G} matrix be displayed. PROC MIXED displays blanks for values that are 0. If you specify the `SUBJECT=` option, then the block of the \mathbf{G} matrix corresponding to the first subject is displayed. For ODS purposes, the name of the table is "G."

GC

displays the lower-triangular Cholesky root of the estimated \mathbf{G} matrix according to the rules listed under the `G option`. For ODS purposes, the name of the table is "CholG."

GCI

displays the inverse Cholesky root of the estimated \mathbf{G} matrix according to the rules listed under the `G option`. For ODS purposes, the name of the table is "InvCholG."

GCORR

displays the correlation matrix corresponding to the estimated \mathbf{G} matrix according to the rules listed under the `G option`. For ODS purposes, the name of the table is "GCorr."

GDATA=SAS-data-set

requests that the \mathbf{G} matrix be read in from a SAS data set. This \mathbf{G} matrix is assumed to be known; therefore, only \mathbf{R} -side parameters from effects in the REPEATED statement are included in the Newton-Raphson iterations. If no REPEATED statement is specified, then only a residual variance is estimated.

The information in the `GDATA=` data set can appear in one of two ways. The first is a sparse representation for which you include ROW, COL, and VALUE variables to indicate the row, column, and value of \mathbf{G} . All unspecified locations are assumed to be 0. The second representation is for dense matrices. In it you include ROW and COL1–COL n variables to indicate the row and columns of \mathbf{G} , which is a symmetric matrix of order n . For both representations, you must specify effects in the RANDOM

statement that generate a \mathbf{Z} matrix that contains n columns. See [Example 46.4](#) on page 2802.

If you have more than one RANDOM statement, only one GDATA= option is required on any one of them, and the data set you specify must contain the entire \mathbf{G} matrix defined by all of the RANDOM statements.

If the GDATA= data set contains variance ratios instead of the variances themselves, then use the RATIOS option.

Known parameters of \mathbf{G} can also be input using the PARMS statement with the HOLD= option.

GI

displays the inverse of the estimated \mathbf{G} matrix according to the rules listed under the [G option](#). For ODS purposes, the name of the table is “InvG.”

GROUP=effect

GRP=effect

defines an effect specifying heterogeneity in the covariance structure of \mathbf{G} . All observations having the same level of the group effect have the same covariance parameters. Each new level of the group effect produces a new set of covariance parameters with the same structure as the original group. You should exercise caution in defining the group effect, as strange covariance patterns can result with its misuse. Also, the group effect can greatly increase the number of estimated covariance parameters, which may adversely affect the optimization process.

Continuous variables are permitted as arguments to the GROUP= option. PROC MIXED does not sort by the values of the continuous variable; rather, it considers the data to be from a new subject or group whenever the value of the continuous variable changes from the previous observation. Using a continuous variable decreases execution time for models with a large number of subjects or groups and also prevents the production of a large “Class Levels Information” table.

LDATA=SAS-data-set

reads the coefficient matrices associated with the TYPE=LIN(*number*) option. The data set must contain the variables PARM, ROW, COL1–COLn, or PARM, ROW, COL, VALUE. The PARM variable denotes which of the *number* coefficient matrices is currently being constructed, and the ROW, COL1–COLn, or ROW, COL, VALUE variables specify the matrix values, as they do with the GDATA= option. Unspecified values of these matrices are set equal to 0.

NOFULLZ

eliminates the columns in \mathbf{Z} corresponding to missing levels of random effects involving CLASS variables. By default, these columns are included in \mathbf{Z} .

RATIOS

indicates that ratios with the residual variance are specified in the GDATA= data set instead of the covariance parameters themselves. The default GDATA= data set contains the individual covariance parameters.

SOLUTION**S**

requests that the solution for the random-effects parameters be produced. Using notation from the “[Mixed Models Theory](#)” section beginning on page 2731, these estimates are the empirical best linear unbiased predictors (EBLUPs) $\hat{\gamma} = \hat{\mathbf{G}}\mathbf{Z}'\hat{\mathbf{V}}^{-1}(\mathbf{y} - \mathbf{X}\hat{\beta})$. They can be useful for comparing the random effects from different experimental units and can also be treated as residuals in performing diagnostics for your mixed model.

The numbers displayed in the SE Pred column of the “Solution for Random Effects” table are not the standard errors of the $\hat{\gamma}$ displayed in the Estimate column; rather, they are the standard errors of predictions $\hat{\gamma}_i - \gamma_i$, where $\hat{\gamma}_i$ is the i th EBLUP and γ_i is the i th random-effect parameter.

SUBJECT=effect**SUB=effect**

identifies the subjects in your mixed model. Complete independence is assumed across subjects; thus, for the RANDOM statement, the SUBJECT= option produces a block-diagonal structure in \mathbf{G} with identical blocks. The \mathbf{Z} matrix is modified to accommodate this block-diagonality. In fact, specifying a subject effect is equivalent to nesting all other effects in the RANDOM statement within the subject effect.

Continuous variables are permitted as arguments to the SUBJECT= option. PROC MIXED does not sort by the values of the continuous variable; rather, it considers the data to be from a new subject or group whenever the value of the continuous variable changes from the previous observation. Using a continuous variable decreases execution time for models with a large number of subjects or groups and also prevents the production of a large “Class Levels Information” table.

When you specify the SUBJECT= option and a classification random effect, computations are usually much quicker if the levels of the random effect are duplicated within each level of the SUBJECT= effect.

TYPE=covariance-structure

specifies the covariance structure of \mathbf{G} . Valid values for *covariance-structure* and their descriptions are listed in [Table 46.5](#) on page 2721 and [Table 46.6](#) on page 2722. Although a variety of structures are available, most applications call for either TYPE=VC or TYPE=UN. The TYPE=VC (variance components) option is the default structure, and it models a different variance component for each random effect.

The TYPE=UN (unstructured) option is useful for correlated random coefficient models. For example,

```
random intercept age / type=un subject=person;
```

specifies a random intercept-slope model that has different variances for the intercept and slope and a covariance between them. You can also use TYPE=FA0(2) here to request a \mathbf{G} estimate that is constrained to be nonnegative definite.

If you are constructing your own columns of \mathbf{Z} with continuous variables, you can use the `TYPE=TOEP(1)` structure to group them together to have a common variance component. If you desire to have different covariance structures in different parts of \mathbf{G} , you must use multiple `RANDOM` statements with different `TYPE=` options.

V<=*value-list*>

requests that blocks of the estimated \mathbf{V} matrix be displayed. The first block determined by the `SUBJECT=` effect is the default displayed block. PROC MIXED displays entries that are 0 as blanks in the table.

You can optionally use the *value-list* specification, which indicates the subjects for which blocks of \mathbf{V} are to be displayed. For example, the statement

```
random int time / type=un subject=person v=1,3,7;
```

displays block matrices for the first, third, and seventh persons. The table name for ODS purposes is “V.”

VC<=*value-list*>

displays the Cholesky root of the blocks of the estimated \mathbf{V} matrix. The *value-list* specification is the same as in the `V= option`. The table name for ODS purposes is “CholV.”

VCI<=*value-list*>

displays the inverse of the Cholesky root of the blocks of the estimated \mathbf{V} matrix. The *value-list* specification is the same as in the `V= option`. The table name for ODS purposes is “InvCholV.”

VCORR<=*value-list*>

displays the correlation matrix corresponding to the blocks of the estimated \mathbf{V} matrix. The *value-list* specification is the same as in the `V= option`. The table name for ODS purposes is “VCorr.”

VI<=*value-list*>

displays the inverse of the blocks of the estimated \mathbf{V} matrix. The *value-list* specification is the same as in the `V= option`. The table name for ODS purposes is “InvV.”

REPEATED Statement

```
REPEATED < repeated-effect >< / options > ;
```

The `REPEATED` statement is used to specify the \mathbf{R} matrix in the mixed model. Its syntax is different from that of the `REPEATED` statement in PROC GLM. If no `REPEATED` statement is specified, \mathbf{R} is assumed to be equal to $\sigma^2\mathbf{I}$.

For many repeated measures models, no repeated effect is required in the `REPEATED` statement. Simply use the `SUBJECT=` option to define the blocks of \mathbf{R} and the `TYPE=` option to define their covariance structure. In this case, the repeated measures data must be similarly ordered for each subject, and you must indicate all missing response variables with periods in the input data set unless they all fall at the end of

a subject's repeated response profile. These requirements are necessary in order to inform PROC MIXED of the proper location of the observed repeated responses.

Specifying a repeated effect is useful when you do not want to indicate missing values with periods in the input data set. The repeated effect must contain only classification variables. Make sure that the levels of the repeated effect are different for each observation within a subject; otherwise, PROC MIXED constructs identical rows in **R** corresponding to the observations with the same level. This results in a singular **R** and an infinite likelihood.

Whether you specify a REPEATED effect or not, the rows of **R** for each subject are constructed in the order that they appear in the input data set.

You can specify the following options in the REPEATED statement after a slash (/).

GROUP=effect

GRP=effect

defines an effect specifying heterogeneity in the covariance structure of **R**. All observations having the same level of the GROUP effect have the same covariance parameters. Each new level of the GROUP effect produces a new set of covariance parameters with the same structure as the original group. You should exercise caution in properly defining the GROUP effect, as strange covariance patterns can result with its misuse. Also, the GROUP effect can greatly increase the number of estimated covariance parameters, which may adversely affect the optimization process.

Continuous variables are permitted as arguments to the GROUP= option. PROC MIXED does not sort by the values of the continuous variable; rather, it considers the data to be from a new subject or group whenever the value of the continuous variable changes from the previous observation. Using a continuous variable decreases execution time for models with a large number of subjects or groups and also prevents the production of a large "Class Levels Information" table.

HLM

produces a table of Hotelling-Lawley-McKeon statistics (McKeon 1974) for all fixed effects whose levels change across data having the same level of the SUBJECT= effect (the *within-subject* fixed effects). This option applies only when you specify a REPEATED statement with the TYPE=UN option and no RANDOM statements. For balanced data, this model is equivalent to the multivariate model for repeated measures in PROC GLM.

The Hotelling-Lawley-McKeon statistic has a slightly better F approximation than the Hotelling-Lawley-Pillai-Samson statistic (see the description of the [HLPS](#) option, which follows). Both of the Hotelling-Lawley statistics can perform much better in small samples than the default F statistic (Wright 1994).

Separate tables are produced for Type I, II, and III tests, according to the ones you select. For ODS purposes, the labels for these tables are "HLM1," "HLM2," and "HLM3," respectively.

HLPS

produces a table of Hotelling-Lawley-Pillai-Samson statistics (Pillai and Samson 1959) for all fixed effects whose levels change across data having the same level of the SUBJECT= effect (the *within-subject* fixed effects). This option applies only when you specify a REPEATED statement with the TYPE=UN option and no RANDOM statements. For balanced data, this model is equivalent to the multivariate model for repeated measures in PROC GLM, and this statistic is the same as the Hotelling-Lawley Trace statistic produced by PROC GLM.

Separate tables are produced for Type I, II, and III tests, according to the ones you select. For ODS purposes, the labels for these tables are “HLPS1,” “HLPS2,” and “HLPS3,” respectively.

LDATA=SAS-data-set

reads the coefficient matrices associated with the TYPE=LIN(*number*) option. The data set must contain the variables PARM, ROW, COL1–COLn, or PARM, ROW, COL, VALUE. The PARM variable denotes which of the *number* coefficient matrices is currently being constructed, and the ROW, COL1–COLn, or ROW, COL, VALUE variables specify the matrix values, as they do with the RANDOM statement option GDATA=. Unspecified values of these matrices are set equal to 0.

LOCAL**LOCAL=EXP(<effects>)****LOCAL=POM(POM-data-set)**

requests that a diagonal matrix be added to \mathbf{R} . With just the LOCAL option, this diagonal matrix equals $\sigma^2\mathbf{I}$, and σ^2 becomes an additional variance parameter that PROC MIXED profiles out of the likelihood provided that you do not specify the NOPROFILE option in the PROC MIXED statement. The LOCAL option is useful if you want to add an observational error to a time series structure (Jones and Boadi-Boateng 1991) or a nugget effect to a spatial structure (Cressie 1991).

The LOCAL=EXP(<effects>) option produces exponential local effects, also known as dispersion effects, in a log-linear variance model. These local effects have the form

$$\sigma^2 \text{diag}[\exp(\mathbf{U}\delta)]$$

where \mathbf{U} is the full-rank design matrix corresponding to the effects that you specify and δ are the parameters that PROC MIXED estimates. An intercept is not included in \mathbf{U} because it is accounted for by σ^2 . PROC MIXED constructs the full-rank \mathbf{U} in terms of 1s and –1s for classification effects. Be sure to scale continuous effects in \mathbf{U} sensibly.

The LOCAL=POM(*POM-data-set*) option specifies the power-of-the-mean structure. This structure possesses a variance of the form $\sigma^2|\mathbf{x}'_i\boldsymbol{\beta}^*|^\theta$ for the *i*th observation, where \mathbf{x}_i is the *i*th row of \mathbf{X} (the design matrix of the fixed effects), and $\boldsymbol{\beta}^*$ is an estimate of the fixed-effects parameters that you specify in *POM-data-set*.

The SAS data set specified by *POM-data-set* contains the numeric variable Estimate (in previous releases, the variable name was required to be EST), and it has at least as many observations as there are fixed-effects parameters. The first *p* observations

of the Estimate variable in *POM-data-set* are taken to be the elements of β^* , where p is the number of columns of \mathbf{X} . You must order these observations according to the non-full-rank parameterization of the MIXED procedure. One easy way to set up *POM-data-set* for a β^* corresponding to ordinary least squares is illustrated by the following code:

```
ods output SolutionF=sf;
proc mixed;
  class a;
  model y = a x / s;
run;

proc mixed;
  class a;
  model y = a x;
  repeated / local=pom(sf);
run;
```

Note that the generalized least-squares estimate of the fixed-effects parameters from the second PROC MIXED step usually is not the same as your specified β^* . However, you can iterate the POM fitting until the two estimates agree. Continuing from the previous example, the code for performing one step of this iteration is as follows.

```
ods output SolutionF=sf1;
proc mixed;
  class a;
  model y = a x / s;
  repeated / local=pom(sf);
run;

proc compare brief data=sf compare=sf1;
  var estimate;
run;

data sf;
  set sf1;
run;
```

Unfortunately, this iterative process does not always converge. For further details, refer to the description of pseudo-likelihood in Chapter 3 of Carroll and Ruppert (1988).

LOCALW

specifies that only the local effects and no others be weighted. By default, all effects are weighted. The LOCALW option is used in connection with the WEIGHT statement and the LOCAL option in the REPEATED statement

NONLOCALW

specifies that only the nonlocal effects and no others be weighted. By default, all effects are weighted. The NONLOCALW option is used in connection with the WEIGHT statement and the LOCAL option in the REPEATED statement

R<=*value-list*>

requests that blocks of the estimated **R** matrix be displayed. The first block determined by the SUBJECT= effect is the default displayed block. PROC MIXED displays blanks for value-lists that are 0.

The *value-list* indicates the subjects for which blocks of **R** are to be displayed. For example,

```
repeated / type=cs subject=person r=1,3,5;
```

displays block matrices for the first, third, and fifth persons. See the “[PARMS Statement](#)” section on page 2706 for the possible forms of *value-list*. The table name for ODS purposes is “R.”

RC<=*value-list*>

produces the Cholesky root of blocks of the estimated **R** matrix. The *value-list* specification is the same as with the [R option](#). The table name for ODS purposes is “CholR.”

RCI<=*value-list*>

produces the inverse Cholesky root of blocks of the estimated **R** matrix. The *value-list* specification is the same as with the [R option](#). The table name for ODS purposes is “InvCholR.”

RCORR<=*value-list*>

produces the correlation matrix corresponding to blocks of the estimated **R** matrix. The *value-list* specification is the same as with the [R option](#). The table name for ODS purposes is “RCorr.”

RI<=*value-list*>

produces the inverse of blocks of the estimated **R** matrix. The *value-list* specification is the same as with the [R option](#). The table name for ODS purposes is “InvR.”

SSCP

requests that an unstructured **R** matrix be estimated from the sum-of-squares-and-crossproducts matrix of the residuals. It applies only when you specify TYPE=UN and have no RANDOM statements. Also, you must have a sufficient number of subjects for the estimate to be positive definite.

This option is useful when the size of the blocks of **R** are large (for example, greater than 10) and you want to use or inspect an unstructured estimate that is much quicker to compute than the default REML estimate. The two estimates will agree for certain balanced data sets when you have a classification fixed effect defined across all time points within a subject.

SUBJECT=effect

SUB=effect

identifies the subjects in your mixed model. Complete independence is assumed across subjects; therefore, the SUBJECT= option produces a block-diagonal structure in **R** with identical blocks. When the SUBJECT= effect consists entirely of classification variables, the blocks of **R** correspond to observations sharing the same level of that effect. These blocks are sorted according to this effect as well.

Continuous variables are permitted as arguments to the SUBJECT= option. PROC MIXED does not sort by the values of the continuous variable; rather, it considers the data to be from a new subject or group whenever the value of the continuous variable changes from the previous observation. Using a continuous variable decreases execution time for models with a large number of subjects or groups and also prevents the production of a large “Class Levels Information” table.

If you want to model nonzero covariance among all of the observations in your SAS data set, specify SUBJECT=INTERCEPT to treat the data as if they are all from one subject. Be aware though that, in this case, PROC MIXED manipulates an **R** matrix with dimensions equal to the number of observations. If no SUBJECT= effect is specified, then every observation is assumed to be from a different subject and **R** is assumed to be diagonal. For this reason, you usually want to use the SUBJECT= option in the REPEATED statement.

TYPE=covariance-structure

specifies the covariance structure of the **R** matrix. The SUBJECT= option defines the blocks of **R**, and the TYPE= option specifies the structure of these blocks. Valid values for *covariance-structure* and their descriptions are provided in Table 46.5 and Table 46.6. The default structure is VC.

Table 46.5. Covariance Structures

Structure	Description	Parms	(i, j)th element
ANTE(1)	Ante-Dependence	2t - 1	$\sigma_i \sigma_j \prod_{k=i}^{j-1} \rho_k$
AR(1)	Autoregressive(1)	2	$\sigma^2 \rho^{ i-j }$
ARH(1)	Heterogeneous AR(1)	t + 1	$\sigma_i \sigma_j \rho^{ i-j }$
ARMA(1,1)	ARMA(1,1)	3	$\sigma^2 [\gamma \rho^{ i-j -1} 1(i \neq j) + 1(i=j)]$
CS	Compound Symmetry	2	$\sigma_1 + \sigma^2 1(i = j)$
CSH	Heterogeneous CS	t + 1	$\sigma_i \sigma_j [\rho 1(i \neq j) + 1(i=j)]$
FA(q)	Factor Analytic	$\frac{q}{2}(2t - q + 1) + t$	$\sum_{k=1}^{\min(i,j,q)} \lambda_{ik} \lambda_{jk} + \sigma_i^2 1(i = j)$
FA0(q)	No Diagonal FA	$\frac{q}{2}(2t - q + 1)$	$\sum_{k=1}^{\min(i,j,q)} \lambda_{ik} \lambda_{jk}$
FA1(q)	Equal Diagonal FA	$\frac{q}{2}(2t - q + 1) + 1$	$\sum_{k=1}^{\min(i,j,q)} \lambda_{ik} \lambda_{jk} + \sigma^2 1(i = j)$
HF	Huynh-Feldt	t + 1	$(\sigma_i^2 + \sigma_j^2)/2 + \lambda 1(i \neq j)$
LIN(q)	General Linear	q	$\sum_{k=1}^q \theta_k \mathbf{A}_{ij}$
TOEP	Toeplitz	t	$\sigma_{ i-j +1}$
TOEP(q)	Banded Toeplitz	q	$\sigma_{ i-j +1} 1(i - j < q)$
TOEPH	Heterogeneous TOEP	2t - 1	$\sigma_i \sigma_j \rho_{ i-j }$
TOEPH(q)	Banded Hetero TOEP	t + q - 1	$\sigma_i \sigma_j \rho_{ i-j } 1(i - j < q)$
UN	Unstructured	t(t + 1)/2	σ_{ij}
UN(q)	Banded	$\frac{q}{2}(2t - q + 1)$	$\sigma_{ij} 1(i - j < q)$
UNR	Unstructured Corrs	t(t + 1)/2	$\sigma_i \sigma_j \rho_{\max(i,j) \min(i,j)}$

Table 46.5. (continued)

Structure	Description	Parms	(i, j)th element
UNR(<i>q</i>)	Banded Correlations	$\frac{q}{2}(2t - q + 1)$	$\sigma_i \sigma_j \rho_{\max(i,j) \min(i,j)}$
UN@AR(1)	Direct Product AR(1)	$t_1(t_1 + 1)/2 + 1$	$\sigma_{i_1 j_1} \rho^{ i_2 - j_2 }$
UN@CS	Direct Product CS	$t_1(t_1 + 1)/2 + 1$	$\sigma_{i_1 j_1} (1 - \sigma^2 1(i_2 \neq j_2)), 0 \leq \sigma^2 \leq 1$
UN@UN	Direct Product UN	$t_1(t_1 + 1)/2 + t_2(t_2 + 1)/2 - 1$	$\sigma_{1, i_1 j_1} \sigma_{2, i_2 j_2}$
VC	Variance Components	<i>q</i>	$\sigma_k^2 1(i = j)$ and <i>i</i> corresponds to <i>k</i> th effect

In Table 46.5, “Parms” is the number of covariance parameters in the structure, *t* is the overall dimension of the covariance matrix, and $1(A)$ equals 1 when *A* is true and 0 otherwise. For example, $1(i = j)$ equals 1 when *i* = *j* and 0 otherwise, and $1(|i - j| < q)$ equals 1 when $|i - j| < q$ and 0 otherwise. For the TOEPH structures, $\rho_0 = 1$, and for the UNR structures, $\rho_{ii} = 1$ for all *i*. For the direct product structures, the subscripts “1” and “2” refer to the first and second structure in the direct product, respectively, and $i_1 = \text{int}((i + t_2 - 1)/t_2)$, $j_1 = \text{int}((j + t_2 - 1)/t_2)$, $i_2 = \text{mod}(i - 1, t_2) + 1$, and $j_2 = \text{mod}(j - 1, t_2) + 1$.

Table 46.6. Spatial Covariance Structures

Structure	Description	Parms	(i, j)th element
SP(EXP)(<i>c-list</i>)	Exponential	2	$\sigma^2 [\exp(-d_{ij}/\theta)]$
SP(EXPA)(<i>c-list</i>)	Anisotropic Exponential	$2c + 1$	$\sigma^2 \prod_{k=1}^c \exp[-\theta_k d(i, j, k)^{p_k}]$
SP(EXPGA)(<i>c</i> ₁ <i>c</i> ₂)	2D Exponential, Geometrically Anisotropic	4	$\sigma^2 [\exp(-d_{ij}(\theta, \lambda)/\rho)]$
SP(GAU)(<i>c-list</i>)	Gaussian	2	$\sigma^2 [\exp(-d_{ij}^2/\rho^2)]$
SP(GAUGA)(<i>c</i> ₁ <i>c</i> ₂)	2D Gaussian, Geometrically Anisotropic	4	$\sigma^2 [\exp(-d_{ij}(\theta, \lambda)^2/\rho^2)]$
SP(LIN)(<i>c-list</i>)	Linear	2	$\sigma^2 (1 - \rho d_{ij}) 1(\rho d_{ij} \leq 1)$
SP(LINL)(<i>c-list</i>)	Linear log	2	$\sigma^2 (1 - \rho \log(d_{ij})) \times 1(\rho \log(d_{ij}) \leq 1)$
SP(MATERN)(<i>c-list</i>)	Matérn	3	$\sigma^2 \frac{1}{\Gamma(\nu)} \left(\frac{d_{ij}}{2\rho}\right)^\nu 2K_\nu(d_{ij}/\rho)$
SP(MATHSW)(<i>c-list</i>)	Matérn (Handcock-Stein-Wallis)	3	$\sigma^2 \frac{1}{\Gamma(\nu)} \left(\frac{d_{ij}\sqrt{\nu}}{\rho}\right)^\nu 2K_\nu\left(\frac{2d_{ij}\sqrt{\nu}}{\rho}\right)$
SP(POW)(<i>c-list</i>)	Power	2	$\sigma^2 \rho^{d_{ij}}$
SP(POWA)(<i>c-list</i>)	Anisotropic Power	$c + 1$	$\sigma^2 \rho_1^{d(i,j,1)} \rho_2^{d(i,j,2)} \dots \rho_c^{d(i,j,c)}$
SP(SPH)(<i>c-list</i>)	Spherical	2	$\sigma^2 [1 - (\frac{3d_{ij}}{2\rho}) + (\frac{d_{ij}^3}{2\rho^3})] 1(d_{ij} \leq \rho)$
SP(SPHGA)(<i>c</i> ₁ <i>c</i> ₂)	2D Spherical, Geometrically Anisotropic	4	$\sigma^2 [1 - (\frac{3d_{ij}(\theta, \lambda)}{2\rho}) + (\frac{d_{ij}(\theta, \lambda)^3}{2\rho^3})] \times 1(d_{ij}(\theta, \lambda) \leq \rho)$

In Table 46.6, *c-list* contains the names of the numeric variables used as coordinates of the location of the observation in space, and d_{ij} is the Euclidean distance between the *i*th and *j*th vectors of these coordinates, which correspond to the *i*th and *j*th observations in the input data set. For SP(POWA) and SP(EXPA), *c* is the number of coordinates, and $d(i, j, k)$ is the absolute distance between the *k*th coordinate,

$k = 1, \dots, c$, of the i th and j th observations in the input data set. For the geometrically anisotropic structures SP(EXPGA), SP(GAUGA), and SP(SPHGA), exactly two spatial coordinate variables must be specified as c_1 and c_2 . Geometric anisotropy is corrected by applying a rotation θ and scaling λ to the coordinate system, and $d_{ij}(\theta, \lambda)$ represents the Euclidean distance between two points in the transformed space. SP(MATERN) and SP(MATHSW) represent covariance structures in a class defined by Matérn (refer to Matérn 1986, Handcock and Stein 1993, Handcock and Wallis 1994). The function K_ν is the modified Bessel function of the second kind of (real) order $\nu > 0$; the parameter ν governs the smoothness of the process (see below for more details).

Table 46.7 lists some examples of the structures in Table 46.5 and Table 46.6.

Table 46.7. Covariance Structure Examples

Description	Structure	Example
Variance Components	VC (default)	$\begin{bmatrix} \sigma_B^2 & 0 & 0 & 0 \\ 0 & \sigma_B^2 & 0 & 0 \\ 0 & 0 & \sigma_{AB}^2 & 0 \\ 0 & 0 & 0 & \sigma_{AB}^2 \end{bmatrix}$
Compound Symmetry	CS	$\begin{bmatrix} \sigma^2 + \sigma_1 & \sigma_1 & \sigma_1 & \sigma_1 \\ \sigma_1 & \sigma^2 + \sigma_1 & \sigma_1 & \sigma_1 \\ \sigma_1 & \sigma_1 & \sigma^2 + \sigma_1 & \sigma_1 \\ \sigma_1 & \sigma_1 & \sigma_1 & \sigma^2 + \sigma_1 \end{bmatrix}$
Unstructured	UN	$\begin{bmatrix} \sigma_1^2 & \sigma_{21} & \sigma_{31} & \sigma_{41} \\ \sigma_{21} & \sigma_2^2 & \sigma_{32} & \sigma_{42} \\ \sigma_{31} & \sigma_{32} & \sigma_3^2 & \sigma_{43} \\ \sigma_{41} & \sigma_{42} & \sigma_{43} & \sigma_4^2 \end{bmatrix}$
Banded Main Diagonal	UN(1)	$\begin{bmatrix} \sigma_1^2 & 0 & 0 & 0 \\ 0 & \sigma_2^2 & 0 & 0 \\ 0 & 0 & \sigma_3^2 & 0 \\ 0 & 0 & 0 & \sigma_4^2 \end{bmatrix}$
First-Order Autoregressive	AR(1)	$\sigma^2 \begin{bmatrix} 1 & \rho & \rho^2 & \rho^3 \\ \rho & 1 & \rho & \rho^2 \\ \rho^2 & \rho & 1 & \rho \\ \rho^3 & \rho^2 & \rho & 1 \end{bmatrix}$
Toeplitz	TOEP	$\begin{bmatrix} \sigma^2 & \sigma_1 & \sigma_2 & \sigma_3 \\ \sigma_1 & \sigma^2 & \sigma_1 & \sigma_2 \\ \sigma_2 & \sigma_1 & \sigma^2 & \sigma_1 \\ \sigma_3 & \sigma_2 & \sigma_1 & \sigma^2 \end{bmatrix}$
Toeplitz with Two Bands	TOEP(2)	$\begin{bmatrix} \sigma^2 & \sigma_1 & 0 & 0 \\ \sigma_1 & \sigma^2 & \sigma_1 & 0 \\ 0 & \sigma_1 & \sigma^2 & \sigma_1 \\ 0 & 0 & \sigma_1 & \sigma^2 \end{bmatrix}$

Unstructured Correlations	UNR	$\begin{bmatrix} \sigma_1^2 & \sigma_1\sigma_2\rho_{21} & \sigma_1\sigma_3\rho_{31} & \sigma_1\sigma_4\rho_{41} \\ \sigma_2\sigma_1\rho_{21} & \sigma_2^2 & \sigma_2\sigma_3\rho_{32} & \sigma_2\sigma_4\rho_{42} \\ \sigma_3\sigma_1\rho_{31} & \sigma_3\sigma_2\rho_{32} & \sigma_3^2 & \sigma_3\sigma_4\rho_{43} \\ \sigma_4\sigma_1\rho_{41} & \sigma_4\sigma_2\rho_{42} & \sigma_4\sigma_3\rho_{43} & \sigma_4^2 \end{bmatrix}$
Direct Product AR(1)	UN@AR(1)	$\begin{bmatrix} \sigma_1^2 & \sigma_{21} \\ \sigma_{21} & \sigma_2^2 \end{bmatrix} \otimes \begin{bmatrix} 1 & \rho & \rho^2 \\ \rho & 1 & \rho \\ \rho^2 & \rho & 1 \end{bmatrix} =$

Table 46.7. (continued)

Description	Structure	Example
		$\begin{bmatrix} \sigma_1^2 & \sigma_1^2\rho & \sigma_1^2\rho^2 & \sigma_{21} & \sigma_{21}\rho & \sigma_{21}\rho^2 \\ \sigma_1^2\rho & \sigma_1^2 & \sigma_1^2\rho & \sigma_{21}\rho & \sigma_{21} & \sigma_{21}\rho \\ \sigma_1^2\rho^2 & \sigma_1^2\rho & \sigma_1^2 & \sigma_{21}\rho^2 & \sigma_{21}\rho & \sigma_{21} \\ \sigma_{21} & \sigma_{21}\rho & \sigma_{21}\rho^2 & \sigma_2^2 & \sigma_2^2\rho & \sigma_2^2\rho^2 \\ \sigma_{21}\rho & \sigma_{21} & \sigma_{21}\rho & \sigma_2^2\rho & \sigma_2^2 & \sigma_2^2\rho \\ \sigma_{21}\rho^2 & \sigma_{21}\rho & \sigma_{21} & \sigma_2^2\rho^2 & \sigma_2^2\rho & \sigma_2^2 \end{bmatrix}$

The following provides some further information about these covariance structures:

TYPE=ANTE(1) specifies the first-order antedependence structure (refer to Kenward 1987, Patel 1991, and Macchiavelli and Arnold 1994). In Table 46.5, σ_i^2 is the i th variance parameter, and ρ_k is the k th autocorrelation parameter satisfying $|\rho_k| < 1$.

TYPE=AR(1) specifies a first-order autoregressive structure. PROC MIXED imposes the constraint $|\rho| < 1$ for stationarity.

TYPE=ARH(1) specifies a heterogeneous first-order autoregressive structure. As with TYPE=AR(1), PROC MIXED imposes the constraint $|\rho| < 1$ for stationarity.

TYPE=ARMA(1,1) specifies the first-order autoregressive moving average structure. In Table 46.5, ρ is the autoregressive parameter, γ models a moving average component, and σ^2 is the residual variance. In the notation of Fuller (1976, p. 68), $\rho = \theta_1$ and

$$\gamma = \frac{(1 + b_1\theta_1)(\theta_1 + b_1)}{1 + b_1^2 + 2b_1\theta_1}$$

The example in Table 46.7 and $|b_1| < 1$ imply that

$$b_1 = \frac{\beta - \sqrt{\beta^2 - 4\alpha^2}}{2\alpha}$$

where $\alpha = \gamma - \rho$ and $\beta = 1 + \rho^2 - 2\gamma\rho$. PROC MIXED imposes the constraints $|\rho| < 1$ and $|\gamma| < 1$ for stationarity, although for some values of ρ and γ in this region the resulting covariance matrix is not positive definite. When the estimated value of ρ becomes negative, the computed covariance is multiplied by $\cos(\pi d_{ij})$ to account for the negativity.

TYPE=CS specifies the compound-symmetry structure, which has constant variance and constant covariance.

TYPE=CSH specifies the heterogeneous compound-symmetry structure. This structure has a different variance parameter for each diagonal element, and it uses the square roots of these parameters in the off-diagonal entries. In Table 46.5, σ_i^2 is the i th variance parameter, and ρ is the correlation parameter satisfying $|\rho| < 1$.

- TYPE=FA(*q*)** specifies the factor-analytic structure with *q* factors (Jennrich and Schluchter 1986). This structure is of the form $\Lambda\Lambda' + \mathbf{D}$, where Λ is a $t \times q$ rectangular matrix and \mathbf{D} is a $t \times t$ diagonal matrix with *t* different parameters. When $q > 1$, the elements of Λ in its upper right-hand corner (that is, the elements in the *i*th row and *j*th column for $j > i$) are set to zero to fix the rotation of the structure.
- TYPE=FA0(*q*)** is similar to the FA(*q*) structure except that no diagonal matrix \mathbf{D} is included. When $q < t$, that is, when the number of factors is less than the dimension of the matrix, this structure is nonnegative definite but not of full rank. In this situation, you can use it for approximating an unstructured \mathbf{G} matrix in the RANDOM statement or for combining with the LOCAL option in the REPEATED statement. When $q = t$, you can use this structure to constrain \mathbf{G} to be nonnegative definite in the RANDOM statement.
- TYPE=FA1(*q*)** is similar to the FA(*q*) structure except that all of the elements in \mathbf{D} are constrained to be equal. This offers a useful and more parsimonious alternative to the full factor-analytic structure.
- TYPE=HF** specifies the Huynh-Feldt covariance structure (Huynh and Feldt 1970). This structure is similar to the CSH structure in that it has the same number of parameters and heterogeneity along the main diagonal. However, it constructs the off-diagonal elements by taking arithmetic rather than geometric means.
- You can perform a likelihood ratio test of the Huynh-Feldt conditions by running PROC MIXED twice, once with TYPE=HF and once with TYPE=UN, and then subtracting their respective values of -2 times the maximized likelihood.
- If PROC MIXED does not converge under your Huynh-Feldt model, you can specify your own starting values with the PARMs statement. The default MIVQUE(0) starting values can sometimes be poor for this structure. A good choice for starting values is often the parameter estimates corresponding to an initial fit using TYPE=CS.
- TYPE=LIN(*q*)** specifies the general linear covariance structure with *q* parameters (Helms and Edwards 1991). This structure consists of a linear combination of known matrices that are input with the LDATA= option. This structure is very general, and you need to make sure that the variance matrix is positive definite. By default, PROC MIXED sets the initial values of the parameters to 1. You can use the PARMs statement to specify other initial values.
- TYPE=SIMPLE** is an alias for TYPE=VC.
- TYPE=SP(EXPA)(*c-list*)** specifies the spatial anisotropic exponential structure, where *c-list* is a list of variables indicating the coordinates. This structure has (*i, j*)th element equal to

$$\sigma^2 \prod_{k=1}^c \exp[-\theta_k d(i, j, k)^{p_k}]$$

where c is the number of coordinates and $d(i, j, k)$ is the absolute distance between the k th coordinate ($k = 1, \dots, c$) of the i th and j th observations in the input data set. There are $2c + 1$ parameters to be estimated: θ_k, p_k ($k = 1, \dots, c$), and σ^2 .

You may want to constrain some of the EXPA parameters to known values. For example, suppose you have three coordinate variables C1, C2, and C3 and you want to constrain the powers p_k to equal 2, as in Sacks et al. (1989). Suppose further that you want to model covariance across the entire input data set and you suspect the θ_k and σ^2 estimates are close to 3, 4, 5, and 1, respectively. Then specify

```
repeated / type=sp(expa)(c1 c2 c3)
      subject=intercept;
parms (3) (4) (5) (2) (2) (2) (1) /
      hold=4,5,6;
```

TYPE=SP(EXPGA)(c_1 c_2)

TYPE=SP(GAUGA)(c_1 c_2)

TYPE=SP(SPHGA)(c_1 c_2) specify modifications of the isotropic SP(EXP), SP(SPH), and SP(GAU) covariance structures that allow for geometric anisotropy in two dimensions. The coordinates are specified by the variables c_1 and c_2 .

If the spatial process is geometrically anisotropic in $\mathbf{c} = [c_{i1}, c_{i2}]$, then it is isotropic in the coordinate system

$$\mathbf{A}\mathbf{c} = \begin{bmatrix} 1 & 0 \\ 0 & \lambda \end{bmatrix} \begin{bmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{bmatrix} \mathbf{c} = \mathbf{c}^*$$

for a properly chosen angle θ and scaling factor λ . Elliptical iso-correlation contours are thereby transformed to spherical contours, adding two parameters to the respective isotropic covariance structures. Euclidean distances (see [Table 46.6](#) on page 2722) are expressed in terms of \mathbf{c}^* .

The angle θ of the clockwise rotation is reported in radians, $0 \leq \theta \leq 2\pi$. The scaling parameter λ represents the ratio of the range parameters in the direction of the major and minor axis of the correlation contours. In other words, following a rotation of the coordinate system by angle θ , isotropy is achieved by compressing or magnifying distances in one coordinate by the factor λ .

Fixing $\lambda = 1.0$ reduces the models to isotropic ones for any angle of rotation. If the scaling parameter is held constant at 1.0, you should also hold constant the angle of rotation, e.g.,

```
repeated / type=sp(expga)(gxc gyc)
      subject=intercept;
parms (6) (1.0) (0.0) (1) / hold=2,3;
```

If λ is fixed at any other value than 1.0, the angle of rotation can be estimated. Specifying a starting grid of angles and scaling factors can considerably improve the convergence properties of the optimization algorithm for these models. Only a single random effect with geometrically anisotropic structure is permitted.

TYPE=SP(MATERN)(*c-list*)

TYPE=SP(MATHSW)(*c-list*) specifies covariance structures in the Matérn class of covariance functions (Matérn 1986). Two observations for the same subject (block of **R**) that are Euclidean distance d_{ij} apart have covariance

$$\sigma^2 \frac{1}{\Gamma(\nu)} \left(\frac{d_{ij}}{2\rho} \right)^\nu 2K_\nu(d_{ij}/\rho) \quad \nu > 0, \rho > 0,$$

where K_ν is the modified Bessel function of the second kind of (real) order $\nu > 0$. The smoothness (continuity) of a stochastic process with covariance function in this class increases with ν . The Matérn class thus enables data-driven estimation of the smoothness properties. The covariance is identical to the exponential model for $\nu = 0.5$ (TYPE=SP(EXP)(*c-list*)), while for $\nu = 1$ the model advocated by Whittle (1954) results. As $\nu \rightarrow \infty$ the model approaches the gaussian covariance structure (TYPE=SP(GAU)(*c-list*)).

The MATHSW structure represents the Matérn class in the parameterization of Handcock and Stein (1993) and Handcock and Wallis (1994),

$$\sigma^2 \frac{1}{\Gamma(\nu)} \left(\frac{d_{ij}\sqrt{\nu}}{\rho} \right)^\nu 2K_\nu \left(\frac{2d_{ij}\sqrt{\nu}}{\rho} \right)$$

Since computation of the function K_ν and its derivatives is numerically very intensive, fitting models with Matérn covariance structures can be more time consuming than for other spatial covariance structures. Good starting values are essential.

TYPE=SP(POW)(*c-list*)

TYPE=SP(POWA)(*c-list*) specifies the spatial power structures. When the estimated value of ρ becomes negative, the computed covariance is multiplied by $\cos(\pi d_{ij})$ to account for the negativity.

TYPE=TOEP<(q)> specifies a banded Toeplitz structure. This can be viewed as a moving-average structure with order equal to $q - 1$. The TYPE=TOEP option is a full Toeplitz matrix, which can be viewed as an autoregressive structure with order equal to the dimension of the matrix. The specification TYPE=TOEP(1) is the same as $\sigma^2 I$, where I is an identity matrix, and it can be useful for specifying the same variance component for several effects.

TYPE=TOEPH<(q)> specifies a heterogeneous banded Toeplitz structure. In Table 46.5, σ_i^2 is the i th variance parameter and ρ_j is the j th correlation parameter satisfying $|\rho_j| < 1$. If you specify the order parameter q , then PROC MIXED estimates only the first q bands of the matrix, setting all higher bands equal to 0. The option TOEPH(1) is equivalent to both the UN(1) and UNR(1) options.

TYPE=UN<(q)> specifies a completely general (unstructured) covariance matrix parameterized directly in terms of variances and covariances. The variances are constrained to be nonnegative, and the covariances are unconstrained. This structure is not constrained to be nonnegative definite in order to avoid nonlinear constraints; however, you can use the FA0 structure if you want this constraint to be imposed by a Cholesky factorization. If you specify the order parameter q , then PROC MIXED estimates only the first q bands of the matrix, setting all higher bands equal to 0.

TYPE=UNR<(q)> specifies a completely general (unstructured) covariance matrix parameterized in terms of variances and correlations. This structure fits the same model as the TYPE=UN(q) option but with a different parameterization. The i th variance parameter is σ_i^2 . The parameter ρ_{jk} is the correlation between the j th and k th measurements; it satisfies $|\rho_{jk}| < 1$. If you specify the order parameter r , then PROC MIXED estimates only the first q bands of the matrix, setting all higher bands equal to zero.

TYPE=UN@AR(1)

TYPE=UN@CS

TYPE=UN@UN specify direct (Kronecker) product structures designed for multivariate repeated measures (refer to Galecki 1994). These structures are constructed by taking the Kronecker product of an unstructured matrix (modeling covariance across the multivariate observations) with an additional covariance matrix (modeling covariance across time or another factor). The upper left value in the second matrix is constrained to equal 1 to identify the model. Refer to *SAS/IML User's Guide, First Edition*, for more details on direct products.

To use these structures in the REPEATED statement, you must specify two distinct REPEATED effects, both of which must be included in the CLASS statement. The first effect indicates the multivariate observations, and the second identifies the levels of time or some additional factor. Note that the input data set must still be constructed in “univariate” format; that is, all dependent observations are still listed observation-wise in one single variable. Although this construction provides for general modeling possibilities, it forces you to construct variables indicating both dimensions of the Kronecker product.

For example, suppose your observed data consist of heights and weights of several children measured over several successive years.

Your input data set should then contain variables similar to the following:

- *Y*, all of the heights and weights, with a separate observation for each
- *Var*, indicating whether the measurement is a height or a weight
- *Year*, indicating the year of measurement
- *Child*, indicating the child on which the measurement was taken

Your PROC MIXED code for a Kronecker AR(1) structure across years would then be

```
proc mixed;
  class Var Year Child;
  model Y = Var Year Var*Year;
  repeated Var Year / type=un@ar(1)
                    subject=Child;
run;
```

You should nearly always want to model different means for the multivariate observations, hence the inclusion of *Var* in the MODEL statement. The preceding mean model consists of cell means for all combinations of VAR and YEAR.

TYPE=VC specifies standard variance components and is the default structure for both the RANDOM and REPEATED statements. In the RANDOM statement, a distinct variance component is assigned to each effect. In the REPEATED statement, this structure is usually used only with the GROUP= option to specify a heterogeneous variance model.

Jennrich and Schluchter (1986) provide general information about the use of covariance structures, and Wolfinger (1996) presents details about many of the heterogeneous structures. Marx and Thompson (1987), Cressie (1991), and Zimmerman and Harville (1991) discuss spatial structures.

WEIGHT Statement

WEIGHT *variable* ;

If you do not specify a REPEATED statement, the WEIGHT statement operates exactly like the one in PROC GLM. In this case PROC MIXED replaces $X'X$ and $Z'Z$ with $X'WX$ and $Z'WZ$, where W is the diagonal weight matrix. If you specify a REPEATED statement, then the WEIGHT statement replaces R with LRL , where L is a diagonal matrix with elements $W^{-1/2}$. Observations with nonpositive or missing weights are not included in the PROC MIXED analysis.

Details

Mixed Models Theory

This section provides an overview of a likelihood-based approach to general linear mixed models. This approach simplifies and unifies many common statistical analyses, including those involving repeated measures, random effects, and random coefficients. The basic assumption is that the data are linearly related to unobserved multivariate normal random variables. Extensions to nonlinear and nonnormal situations are possible but are not discussed here. Additional theory and examples are provided in Littell et al. (1996), Verbeke and Molenberghs (1997 2000), and Brown and Prescott (1999).

Matrix Notation

Suppose that you observe n data points y_1, \dots, y_n and that you want to explain them using n values for each of p explanatory variables $x_{11}, \dots, x_{1p}, x_{21}, \dots, x_{2p}, \dots, x_{n1}, \dots, x_{np}$. The x_{ij} values may be either regression-type continuous variables or dummy variables indicating class membership. The standard linear model for this setup is

$$y_i = \sum_{j=1}^p x_{ij}\beta_j + \epsilon_i \quad i = 1, \dots, n$$

where β_1, \dots, β_p are unknown *fixed-effects* parameters to be estimated and $\epsilon_1, \dots, \epsilon_n$ are unknown independent and identically distributed normal (Gaussian) random variables with mean 0 and variance σ^2 .

The preceding equations can be written simultaneously using vectors and a matrix, as follows:

$$\begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_n \end{bmatrix} = \begin{bmatrix} x_{11} & x_{12} & \dots & x_{1p} \\ x_{21} & x_{22} & \dots & x_{2p} \\ \vdots & \vdots & & \vdots \\ x_{n1} & x_{n2} & \dots & x_{np} \end{bmatrix} \begin{bmatrix} \beta_1 \\ \beta_2 \\ \vdots \\ \beta_p \end{bmatrix} + \begin{bmatrix} \epsilon_1 \\ \epsilon_2 \\ \vdots \\ \epsilon_n \end{bmatrix}$$

For convenience, simplicity, and extendibility, this entire system is written as

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}$$

where \mathbf{y} denotes the vector of observed y_i 's, \mathbf{X} is the known matrix of x_{ij} 's, $\boldsymbol{\beta}$ is the unknown fixed-effects parameter vector, and $\boldsymbol{\epsilon}$ is the unobserved vector of independent and identically distributed Gaussian random errors.

In addition to denoting data, random variables, and explanatory variables in the preceding fashion, the subsequent development makes use of basic matrix operators such as transpose ($'$), inverse ($^{-1}$), generalized inverse ($^{-}$), determinant ($|\cdot|$), and matrix multiplication. Refer to Searle (1982) for details on these and other matrix techniques.

Formulation of the Mixed Model

The previous general linear model is certainly a useful one (Searle 1971), and it is the one fitted by the GLM procedure. However, many times the distributional assumption about ϵ is too restrictive. The mixed model extends the general linear model by allowing a more flexible specification of the covariance matrix of ϵ . In other words, it allows for both correlation and heterogeneous variances, although you still assume normality.

The mixed model is written as

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\boldsymbol{\gamma} + \boldsymbol{\epsilon}$$

where everything is the same as in the general linear model except for the addition of the known design matrix, \mathbf{Z} , and the vector of unknown *random-effects parameters*, $\boldsymbol{\gamma}$. The matrix \mathbf{Z} can contain either continuous or dummy variables, just like \mathbf{X} . The name *mixed model* comes from the fact that the model contains both fixed-effects parameters, $\boldsymbol{\beta}$, and random-effects parameters, $\boldsymbol{\gamma}$. Refer to Henderson (1990) and Searle, Casella, and McCulloch (1992) for historical developments of the mixed model.

A key assumption in the foregoing analysis is that $\boldsymbol{\gamma}$ and $\boldsymbol{\epsilon}$ are normally distributed with

$$\begin{aligned} E \begin{bmatrix} \boldsymbol{\gamma} \\ \boldsymbol{\epsilon} \end{bmatrix} &= \begin{bmatrix} \mathbf{0} \\ \mathbf{0} \end{bmatrix} \\ \text{Var} \begin{bmatrix} \boldsymbol{\gamma} \\ \boldsymbol{\epsilon} \end{bmatrix} &= \begin{bmatrix} \mathbf{G} & \mathbf{0} \\ \mathbf{0} & \mathbf{R} \end{bmatrix} \end{aligned}$$

The variance of \mathbf{y} is, therefore, $\mathbf{V} = \mathbf{ZGZ}' + \mathbf{R}$. You can model \mathbf{V} by setting up the random-effects design matrix \mathbf{Z} and by specifying covariance structures for \mathbf{G} and \mathbf{R} .

Note that this is a general specification of the mixed model, in contrast to many texts and articles that discuss only simple random effects. Simple random effects are a special case of the general specification with \mathbf{Z} containing dummy variables, \mathbf{G} containing variance components in a diagonal structure, and $\mathbf{R} = \sigma^2\mathbf{I}_n$, where \mathbf{I}_n denotes the $n \times n$ identity matrix. The general linear model is a further special case with $\mathbf{Z} = \mathbf{0}$ and $\mathbf{R} = \sigma^2\mathbf{I}_n$.

The following two examples illustrate the most common formulations of the general linear mixed model.

However, it requires knowledge of \mathbf{V} and, therefore, knowledge of \mathbf{G} and \mathbf{R} . Lacking such information, one approach is to use *estimated* GLS, in which you insert some reasonable estimate for \mathbf{V} into the minimization problem. The goal thus becomes finding a reasonable estimate of \mathbf{G} and \mathbf{R} .

In many situations, the best approach is to use *likelihood-based* methods, exploiting the assumption that γ and ϵ are normally distributed (Hartley and Rao 1967; Patterson and Thompson 1971; Harville 1977; Laird and Ware 1982; Jennrich and Schluchter 1986). PROC MIXED implements two likelihood-based methods: *maximum likelihood* (ML) and *restricted/residual maximum likelihood* (REML). A favorable theoretical property of ML and REML is that they accommodate data that are missing at random (Rubin 1976; Little 1995).

PROC MIXED constructs an objective function associated with ML or REML and maximizes it over all unknown parameters. Using calculus, it is possible to reduce this maximization problem to one over only the parameters in \mathbf{G} and \mathbf{R} . The corresponding log-likelihood functions are as follows:

$$\begin{aligned} \text{ML: } l(\mathbf{G}, \mathbf{R}) &= -\frac{1}{2} \log |\mathbf{V}| - \frac{1}{2} \mathbf{r}' \mathbf{V}^{-1} \mathbf{r} - \frac{n}{2} \log(2\pi) \\ \text{REML: } l_R(\mathbf{G}, \mathbf{R}) &= -\frac{1}{2} \log |\mathbf{V}| - \frac{1}{2} \log |\mathbf{X}' \mathbf{V}^{-1} \mathbf{X}| \\ &\quad - \frac{1}{2} \mathbf{r}' \mathbf{V}^{-1} \mathbf{r} - \frac{n-p}{2} \log(2\pi) \end{aligned}$$

where $\mathbf{r} = \mathbf{y} - \mathbf{X}(\mathbf{X}' \mathbf{V}^{-1} \mathbf{X})^{-1} \mathbf{X}' \mathbf{V}^{-1} \mathbf{y}$ and p is the rank of \mathbf{X} . PROC MIXED actually minimizes -2 times these functions using a ridge-stabilized Newton-Raphson algorithm. Lindstrom and Bates (1988) provide reasons for preferring Newton-Raphson to the Expectation-Maximum (EM) algorithm described in Dempster, Laird, and Rubin (1977) and Laird, Lange, and Stram (1987), as well as analytical details for implementing a QR-decomposition approach to the problem. Wolfinger, Tobias, and Sall (1994) present the sweep-based algorithms that are implemented in PROC MIXED.

One advantage of using the Newton-Raphson algorithm is that the second derivative matrix of the objective function evaluated at the optima is available upon completion. Denoting this matrix \mathbf{H} , the asymptotic theory of maximum likelihood (refer to Serfling 1980) shows that $2\mathbf{H}^{-1}$ is an asymptotic variance-covariance matrix of the estimated parameters of \mathbf{G} and \mathbf{R} . Thus, tests and confidence intervals based on asymptotic normality can be obtained. However, these can be unreliable in small samples, especially for parameters such as variance components which have sampling distributions that tend to be skewed to the right.

If a residual variance σ^2 is a part of your mixed model, it can usually be *profiled* out of the likelihood. This means solving analytically for the optimal σ^2 and plugging this expression back into the likelihood formula (refer to Wolfinger, Tobias, and Sall 1994). This reduces the number of optimization parameters by one and can improve convergence properties. PROC MIXED profiles the residual variance out of the log likelihood whenever it appears reasonable to do so. This includes the case when \mathbf{R} equals $\sigma^2 \mathbf{I}$ and when it has blocks with a compound symmetry, time series, or spatial

structure. PROC MIXED does not profile the log likelihood when \mathbf{R} has unstructured blocks, when you use the HOLD= or NOITER option in the PARMS statement, or when you use the NOPROFILE option in the PROC MIXED statement.

Instead of ML or REML, you can use the noniterative MIVQUE0 method to estimate \mathbf{G} and \mathbf{R} (Rao 1972; LaMotte 1973; Wolfinger, Tobias, and Sall 1994). In fact, by default PROC MIXED uses MIVQUE0 estimates as starting values for the ML and REML procedures. For variance component models, another estimation method involves equating Type I, II, or III expected mean squares to their observed values and solving the resulting system. However, Swallow and Monahan (1984) present simulation evidence favoring REML and ML over MIVQUE0 and other method-of-moment estimators.

Estimating β and γ in the Mixed Model

ML, REML, MIVQUE0, or Type1–Type3 provide estimates of \mathbf{G} and \mathbf{R} , which are denoted $\hat{\mathbf{G}}$ and $\hat{\mathbf{R}}$, respectively. To obtain estimates of β and γ , the standard method is to solve the *mixed model equations* (Henderson 1984):

$$\begin{bmatrix} \mathbf{X}'\hat{\mathbf{R}}^{-1}\mathbf{X} & \mathbf{X}'\hat{\mathbf{R}}^{-1}\mathbf{Z} \\ \mathbf{Z}'\hat{\mathbf{R}}^{-1}\mathbf{X} & \mathbf{Z}'\hat{\mathbf{R}}^{-1}\mathbf{Z} + \hat{\mathbf{G}}^{-1} \end{bmatrix} \begin{bmatrix} \hat{\beta} \\ \hat{\gamma} \end{bmatrix} = \begin{bmatrix} \mathbf{X}'\hat{\mathbf{R}}^{-1}\mathbf{y} \\ \mathbf{Z}'\hat{\mathbf{R}}^{-1}\mathbf{y} \end{bmatrix}$$

The solutions can also be written as

$$\begin{aligned} \hat{\beta} &= (\mathbf{X}'\hat{\mathbf{V}}^{-1}\mathbf{X})^{-1}\mathbf{X}'\hat{\mathbf{V}}^{-1}\mathbf{y} \\ \hat{\gamma} &= \hat{\mathbf{G}}\mathbf{Z}'\hat{\mathbf{V}}^{-1}(\mathbf{y} - \mathbf{X}\hat{\beta}) \end{aligned}$$

and have connections with empirical Bayes estimators (Laird and Ware 1982, Carlin and Louis 1996).

Note that the mixed model equations are extended normal equations and that the preceding expression assumes that $\hat{\mathbf{G}}$ is nonsingular. For the extreme case when the eigenvalues of $\hat{\mathbf{G}}$ are very large, $\hat{\mathbf{G}}^{-1}$ contributes very little to the equations and $\hat{\gamma}$ is close to what it would be if γ actually contained fixed-effects parameters. On the other hand, when the eigenvalues of $\hat{\mathbf{G}}$ are very small, $\hat{\mathbf{G}}^{-1}$ dominates the equations and $\hat{\gamma}$ is close to 0. For intermediate cases, $\hat{\mathbf{G}}^{-1}$ can be viewed as shrinking the fixed-effects estimates of γ towards 0 (Robinson 1991).

If $\hat{\mathbf{G}}$ is singular, then the mixed model equations are modified (Henderson 1984) as follows:

$$\begin{bmatrix} \mathbf{X}'\hat{\mathbf{R}}^{-1}\mathbf{X} & \mathbf{X}'\hat{\mathbf{R}}^{-1}\mathbf{Z}\hat{\mathbf{L}} \\ \hat{\mathbf{L}}'\mathbf{Z}'\hat{\mathbf{R}}^{-1}\mathbf{X} & \hat{\mathbf{L}}'\mathbf{Z}'\hat{\mathbf{R}}^{-1}\mathbf{Z}\hat{\mathbf{L}} + \mathbf{I} \end{bmatrix} \begin{bmatrix} \hat{\beta} \\ \hat{\tau} \end{bmatrix} = \begin{bmatrix} \mathbf{X}'\hat{\mathbf{R}}^{-1}\mathbf{y} \\ \hat{\mathbf{L}}'\mathbf{Z}'\hat{\mathbf{R}}^{-1}\mathbf{y} \end{bmatrix}$$

where $\hat{\mathbf{L}}$ is the lower-triangular Cholesky root of $\hat{\mathbf{G}}$, satisfying $\hat{\mathbf{G}} = \hat{\mathbf{L}}\hat{\mathbf{L}}'$. Both $\hat{\tau}$ and a generalized inverse of the left-hand-side coefficient matrix are then transformed using $\hat{\mathbf{L}}$ to determine $\hat{\gamma}$.

An example of when the singular form of the equations is necessary is when a variance component estimate falls on the boundary constraint of 0.

Model Selection

The previous section on estimation assumes the specification of a mixed model in terms of \mathbf{X} , \mathbf{Z} , \mathbf{G} , and \mathbf{R} . Even though \mathbf{X} and \mathbf{Z} have known elements, their specific form and construction is flexible, and several possibilities may present themselves for a particular data set. Likewise, several different covariance structures for \mathbf{G} and \mathbf{R} might be reasonable.

Space does not permit a thorough discussion of model selection, but a few brief comments and references are in order. First, subject matter considerations and objectives are of great importance when selecting a model; refer to Diggle (1988) and Lindsey (1993).

Second, when the data themselves are looked to for guidance, many of the graphical methods and diagnostics appropriate for the general linear model extend to the mixed model setting as well (Christensen, Pearson, and Johnson 1992).

Finally, a likelihood-based approach to the mixed model provides several statistical measures for model adequacy as well. The most common of these are the likelihood ratio test and Akaike's and Schwarz's criteria (Bozdogan 1987; Wolfinger 1993, Keselman et al. 1998, 1999).

Statistical Properties

If \mathbf{G} and \mathbf{R} are known, $\hat{\beta}$ is the *best linear unbiased estimator* (BLUE) of β , and $\hat{\gamma}$ is the *best linear unbiased predictor* (BLUP) of γ (Searle 1971; Harville 1988, 1990; Robinson 1991; McLean, Sanders, and Stroup 1991). Here, "best" means minimum mean squared error. The covariance matrix of $(\hat{\beta} - \beta, \hat{\gamma} - \gamma)$ is

$$\mathbf{C} = \begin{bmatrix} \mathbf{X}'\mathbf{R}^{-1}\mathbf{X} & \mathbf{X}'\mathbf{R}^{-1}\mathbf{Z} \\ \mathbf{Z}'\mathbf{R}^{-1}\mathbf{X} & \mathbf{Z}'\mathbf{R}^{-1}\mathbf{Z} + \mathbf{G}^{-1} \end{bmatrix}^{-}$$

where $^{-}$ denotes a generalized inverse (refer to Searle 1971).

However, \mathbf{G} and \mathbf{R} are usually unknown and are estimated using one of the aforementioned methods. These estimates, $\hat{\mathbf{G}}$ and $\hat{\mathbf{R}}$, are therefore simply substituted into the preceding expression to obtain

$$\hat{\mathbf{C}} = \begin{bmatrix} \mathbf{X}'\hat{\mathbf{R}}^{-1}\mathbf{X} & \mathbf{X}'\hat{\mathbf{R}}^{-1}\mathbf{Z} \\ \mathbf{Z}'\hat{\mathbf{R}}^{-1}\mathbf{X} & \mathbf{Z}'\hat{\mathbf{R}}^{-1}\mathbf{Z} + \hat{\mathbf{G}}^{-1} \end{bmatrix}^{-}$$

as the approximate variance-covariance matrix of $(\hat{\beta} - \beta, \hat{\gamma} - \gamma)$. In this case, the BLUE and BLUP acronyms no longer apply, but the word *empirical* is often added to indicate such an approximation. The appropriate acronyms thus become EBLUE and EBLUP.

McLean and Sanders (1988) show that $\hat{\mathbf{C}}$ can also be written as

$$\hat{\mathbf{C}} = \begin{bmatrix} \hat{\mathbf{C}}_{11} & \hat{\mathbf{C}}'_{21} \\ \hat{\mathbf{C}}_{21} & \hat{\mathbf{C}}_{22} \end{bmatrix}$$

where

$$\begin{aligned}\widehat{\mathbf{C}}_{11} &= (\mathbf{X}'\widehat{\mathbf{V}}^{-1}\mathbf{X})^{-1} \\ \widehat{\mathbf{C}}_{21} &= -\widehat{\mathbf{G}}\mathbf{Z}'\widehat{\mathbf{V}}^{-1}\mathbf{X}\widehat{\mathbf{C}}_{11} \\ \widehat{\mathbf{C}}_{22} &= (\mathbf{Z}'\widehat{\mathbf{R}}^{-1}\mathbf{Z} + \widehat{\mathbf{G}}^{-1})^{-1} - \widehat{\mathbf{C}}_{21}\mathbf{X}'\widehat{\mathbf{V}}^{-1}\mathbf{Z}\widehat{\mathbf{G}}\end{aligned}$$

Note that $\widehat{\mathbf{C}}_{11}$ is the familiar estimated generalized least-squares formula for the variance-covariance matrix of $\widehat{\boldsymbol{\beta}}$.

As a cautionary note, $\widehat{\mathbf{C}}$ tends to underestimate the true sampling variability of $(\widehat{\boldsymbol{\beta}} \ \widehat{\boldsymbol{\gamma}})$ because no account is made for the uncertainty in estimating \mathbf{G} and \mathbf{R} . Although inflation factors have been proposed (Kackar and Harville 1984; Kass and Steffey 1989; Prasad and Rao 1990), they tend to be small for data sets that are fairly well balanced. PROC MIXED does not compute any inflation factors by default, but rather accounts for the downward bias by using the approximate t and F statistics described subsequently. The DDFM=KENWARDROGER option in the MODEL statement prompts PROC MIXED to compute a specific inflation factor along with Satterthwaite-based degrees of freedom.

Inference and Test Statistics

For inferences concerning the covariance parameters in your model, you can use likelihood-based statistics. One common likelihood-based statistic is the *Wald Z*, which is computed as the parameter estimate divided by its asymptotic standard error. The asymptotic standard errors are computed from the inverse of the second derivative matrix of the likelihood with respect to each of the covariance parameters. The Wald Z is valid for large samples, but it can be unreliable for small data sets and for parameters such as variance components, which are known to have a skewed or bounded sampling distribution.

A better alternative is the likelihood ratio χ^2 . This statistic compares two covariance models, one a special case of the other. To compute it, you must run PROC MIXED twice, once for each of the two models, and then subtract the corresponding values of -2 times the log likelihoods. You can use either ML or REML to construct this statistic, which tests whether the full model is necessary beyond the reduced model.

As long as the reduced model does not occur on the boundary of the covariance parameter space, the χ^2 statistic computed in this fashion has a large-sample sampling distribution that is χ^2 with degrees of freedom equal to the difference in the number of covariance parameters between the two models. If the reduced model does occur on the boundary of the covariance parameter space, the asymptotic distribution becomes a mixture of χ^2 distributions (Self and Liang 1987). A common example of this is when you are testing that a variance component equals its lower boundary constraint of 0.

A final possibility for obtaining inferences concerning the covariance parameters is to simulate or resample data from your model and construct empirical sampling distributions of the parameters. The SAS macro language and the ODS system are useful tools in this regard.

For inferences concerning the fixed- and random-effects parameters in the mixed model, consider estimable linear combinations of the following form:

$$\mathbf{L} \begin{bmatrix} \boldsymbol{\beta} \\ \boldsymbol{\gamma} \end{bmatrix}$$

The estimability requirement (Searle 1971) applies only to the $\boldsymbol{\beta}$ -portion of \mathbf{L} , as any linear combination of $\boldsymbol{\gamma}$ is estimable. Such a formulation in terms of a general \mathbf{L} matrix encompasses a wide variety of common inferential procedures such as those employed with Type I–Type III tests and LS-means. The CONTRAST and ESTIMATE statements in PROC MIXED enable you to specify your own \mathbf{L} matrices. Typically, inference on fixed-effects is the focus, and, in this case, the $\boldsymbol{\gamma}$ -portion of \mathbf{L} is assumed to contain all 0s.

Statistical inferences are obtained by testing the hypothesis

$$H : \mathbf{L} \begin{bmatrix} \boldsymbol{\beta} \\ \boldsymbol{\gamma} \end{bmatrix} = 0$$

or by constructing point and interval estimates.

When \mathbf{L} consists of a single row, a general t -statistic can be constructed as follows (refer to McLean and Sanders 1988, Stroup 1989a):

$$t = \frac{\mathbf{L} \begin{bmatrix} \hat{\boldsymbol{\beta}} \\ \hat{\boldsymbol{\gamma}} \end{bmatrix}}{\sqrt{\mathbf{L}\hat{\mathbf{C}}\mathbf{L}'}}$$

Under the assumed normality of $\boldsymbol{\gamma}$ and $\boldsymbol{\epsilon}$, t has an exact t -distribution only for data exhibiting certain types of balance and for some special unbalanced cases. In general, t is only approximately t -distributed, and its degrees of freedom must be estimated. See the [DDFM= option](#) on page 2693 for a description of the various degrees-of-freedom methods available in PROC MIXED.

With $\hat{\nu}$ being the approximate degrees of freedom, the associated confidence interval is

$$\mathbf{L} \begin{bmatrix} \hat{\boldsymbol{\beta}} \\ \hat{\boldsymbol{\gamma}} \end{bmatrix} \pm t_{\hat{\nu}, \alpha/2} \sqrt{\mathbf{L}\hat{\mathbf{C}}\mathbf{L}'}$$

where $t_{\hat{\nu}, \alpha/2}$ is the $(1 - \alpha/2)$ 100th percentile of the $t_{\hat{\nu}}$ -distribution.

When the rank of \mathbf{L} is greater than 1, PROC MIXED constructs the following general F -statistic:

$$F = \frac{\begin{bmatrix} \hat{\boldsymbol{\beta}} \\ \hat{\boldsymbol{\gamma}} \end{bmatrix}' \mathbf{L}' (\mathbf{L}\hat{\mathbf{C}}\mathbf{L}')^{-1} \mathbf{L} \begin{bmatrix} \hat{\boldsymbol{\beta}} \\ \hat{\boldsymbol{\gamma}} \end{bmatrix}}{\text{rank}(\mathbf{L})}$$

Analogous to t , F in general has an approximate F -distribution with $\text{rank}(\mathbf{L})$ numerator degrees of freedom and \hat{v} denominator degrees of freedom.

The t - and F -statistics enable you to make inferences about your fixed effects, which account for the variance-covariance model you select. An alternative is the χ^2 statistic associated with the likelihood ratio test. This statistic compares two fixed-effects models, one a special case of the other. It is computed just as when comparing different covariance models, although you should use ML and not REML here because the penalty term associated with restricted likelihoods depends upon the fixed-effects specification.

Parameterization of Mixed Models

Recall that a mixed model is of the form

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\boldsymbol{\gamma} + \boldsymbol{\epsilon}$$

where \mathbf{y} represents univariate data, $\boldsymbol{\beta}$ is an unknown vector of fixed effects with known model matrix \mathbf{X} , $\boldsymbol{\gamma}$ is an unknown vector of random effects with known model matrix \mathbf{Z} , and $\boldsymbol{\epsilon}$ is an unknown random error vector.

PROC MIXED constructs a mixed model according to the specifications in the MODEL, RANDOM, and REPEATED statements. Each effect in the MODEL statement generates one or more columns in the model matrix \mathbf{X} , and each effect in the RANDOM statement generates one or more columns in the model matrix \mathbf{Z} . Effects in the REPEATED statement do not generate model matrices; they serve only to index observations within subjects. This section shows precisely how PROC MIXED builds \mathbf{X} and \mathbf{Z} .

Intercept

By default, all models automatically include a column of 1s in \mathbf{X} to estimate a fixed-effect intercept parameter μ . You can use the NOINT option in the MODEL statement to suppress this intercept. The NOINT option is useful when you are specifying a classification effect in the MODEL statement and you want the parameter estimate to be in terms of the mean response for each level of that effect, rather than in terms of a deviation from an overall mean.

By contrast, the intercept is not included by default in \mathbf{Z} . To obtain a column of 1s in \mathbf{Z} , you must specify in the RANDOM statement either the INTERCEPT effect or some effect that has only one level.

Regression Effects

Numeric variables, or polynomial terms involving them, may be included in the model as regression effects (covariates). The actual values of such terms are included as columns of the model matrices \mathbf{X} and \mathbf{Z} . You can use the bar operator with a regression effect to generate polynomial effects. For instance, $X|X|X$ expands to X $X*X$ $X*X*X$, a cubic model.

Main Effects

If a class variable has m levels, PROC MIXED generates m columns in the model matrix for its main effect. Each column is an indicator variable for a given level. The order of the columns is the sort order of the values of their levels and can be controlled with the ORDER= option in the PROC MIXED statement. The following table is an example.

Data		I	A		B		
A	B	μ	A1	A2	B1	B2	B3
1	1	1	1	0	1	0	0
1	2	1	1	0	0	1	0
1	3	1	1	0	0	0	1
2	1	1	0	1	1	0	0
2	2	1	0	1	0	1	0
2	3	1	0	1	0	0	1

Typically, there are more columns for these effects than there are degrees of freedom for them. In other words, PROC MIXED uses an over-parameterized model.

Interaction Effects

Often a model includes interaction (crossed) effects. With an interaction, PROC MIXED first reorders the terms to correspond to the order of the variables in the CLASS statement. Thus, $B*A$ becomes $A*B$ if A precedes B in the CLASS statement. Then, PROC MIXED generates columns for all combinations of levels that occur in the data. The order of the columns is such that the rightmost variables in the cross index faster than the leftmost variables. Empty columns (that would contain all 0s) are not generated for X , but they are for Z .

Data		I	A		B			A*B					
A	B	μ	A1	A2	B1	B2	B3	A1B1	A1B2	A1B3	A2B1	A2B2	A2B3
1	1	1	1	0	1	0	0	1	0	0	0	0	0
1	2	1	1	0	0	1	0	0	1	0	0	0	0
1	3	1	1	0	0	0	1	0	0	1	0	0	0
2	1	1	0	1	1	0	0	0	0	0	1	0	0
2	2	1	0	1	0	1	0	0	0	0	0	1	0
2	3	1	0	1	0	0	1	0	0	0	0	0	1

In the preceding matrix, main-effects columns are not linearly independent of crossed-effect columns; in fact, the column space for the crossed effects contains the space of the main effect.

When your model contains many interaction effects, you may be able to code them more parsimoniously using the bar operator (|). The bar operator generates all possible interaction effects. For example, A|B|C expands to A B A*B C A*C B*C A*B*C. To eliminate higher-order interaction effects, use the at sign (@) in conjunction with the bar operator. For instance, A|B|C|D@2 expands to A B A*B C A*C B*C D A*D B*D C*D.

Nested Effects

Nested effects are generated in the same manner as crossed effects. Hence, the design columns generated by the following two statements are the same (but the ordering of the columns is different):

```

model Y=A B(A);

model Y=A A*B;
    
```

The nesting operator in PROC MIXED is more a notational convenience than an operation distinct from crossing. Nested effects are typically characterized by the property that the nested variables never appear as main effects. The order of the variables within nesting parentheses is made to correspond to the order of these variables in the CLASS statement. The order of the columns is such that variables outside the parentheses index faster than those inside the parentheses, and the rightmost nested variables index faster than the leftmost variables.

Data		I	A		B(A)					
A	B	μ	A1	A2	B1A1	B2A1	B3A1	B1A2	B2A2	B3A2
1	1	1	1	0	1	0	0	0	0	0
1	2	1	1	0	0	1	0	0	0	0
1	3	1	1	0	0	0	1	0	0	0
2	1	1	0	1	0	0	0	1	0	0
2	2	1	0	1	0	0	0	0	1	0
2	3	1	0	1	0	0	0	0	0	1

Note that nested effects are often distinguished from interaction effects by the implied randomization structure of the design. That is, they usually indicate random effects within a fixed-effects framework. The fact that random effects can be modeled directly in the RANDOM statement may make the specification of nested effects in the MODEL statement unnecessary.

Continuous-Nesting-Class Effects

When a continuous variable nests with a class variable, the design columns are constructed by multiplying the continuous values into the design columns for the class effect.

Data		I	A		X(A)	
X	A	μ	A1	A2	X(A1)	X(A2)
21	1	1	1	0	21	0
24	1	1	1	0	24	0
22	1	1	1	0	22	0
28	2	1	0	1	0	28
19	2	1	0	1	0	19
23	2	1	0	1	0	23

This model estimates a separate slope for X within each level of A.

Continuous-by-Class Effects

Continuous-by-class effects generate the same design columns as continuous-nesting-class effects. The two models are made different by the presence of the continuous variable as a regressor by itself, as well as a contributor to a compound effect.

Data		I	X	A		X*A	
X	A	μ	X	A1	A2	X*A1	X*A2
21	1	1	21	1	0	21	0
24	1	1	24	1	0	24	0
22	1	1	22	1	0	22	0
28	2	1	28	0	1	0	28
19	2	1	19	0	1	0	19
23	2	1	23	0	1	0	23

You can use continuous-by-class effects to test for homogeneity of slopes.

General Effects

An example that combines all the effects is $X1*X2*A*B*C(D E)$. The continuous list comes first, followed by the crossed list, followed by the nested list in parentheses. You should be aware of the sequencing of parameters when you use the CONTRAST or ESTIMATE statements to compute some function of the parameter estimates.

Effects may be renamed by PROC MIXED to correspond to ordering rules. For example, $B*A(E D)$ may be renamed $A*B(D E)$ to satisfy the following:

- Class variables that occur outside parentheses (crossed effects) are sorted in the order in which they appear in the CLASS statement.
- Variables within parentheses (nested effects) are sorted in the order in which they appear in the CLASS statement.

The sequencing of the parameters generated by an effect can be described by which variables have their levels indexed faster:

- Variables in the crossed list index faster than variables in the nested list.

- Within a crossed or nested list, variables to the right index faster than variables to the left.

For example, suppose a model includes four effects—A, B, C, and D—each having two levels, 1 and 2. If the CLASS statement is

```
class A B C D;
```

then the order of the parameters for the effect B*A(C D), which is renamed A*B(C D), is

$$\begin{aligned} A_1 B_1 C_1 D_1 &\rightarrow A_1 B_2 C_1 D_1 \rightarrow A_2 B_1 C_1 D_1 \rightarrow A_2 B_2 C_1 D_1 \rightarrow \\ A_1 B_1 C_1 D_2 &\rightarrow A_1 B_2 C_1 D_2 \rightarrow A_2 B_1 C_1 D_2 \rightarrow A_2 B_2 C_1 D_2 \rightarrow \\ A_1 B_1 C_2 D_1 &\rightarrow A_1 B_2 C_2 D_1 \rightarrow A_2 B_1 C_2 D_1 \rightarrow A_2 B_2 C_2 D_1 \rightarrow \\ A_1 B_1 C_2 D_2 &\rightarrow A_1 B_2 C_2 D_2 \rightarrow A_2 B_1 C_2 D_2 \rightarrow A_2 B_2 C_2 D_2 \end{aligned}$$

Note that first the crossed effects B and A are sorted in the order in which they appear in the CLASS statement so that A precedes B in the parameter list. Then, for each combination of the nested effects in turn, combinations of A and B appear. The B effect moves fastest because it is rightmost in the cross list. Then A moves next fastest, and D moves next fastest. The C effect is the slowest since it is leftmost in the nested list.

When numeric levels are used, levels are sorted by their character format, which may not correspond to their numeric sort sequence (for example, noninteger levels). Therefore, it is advisable to include a desired format for numeric levels or to use the ORDER=INTERNAL option in the PROC MIXED statement to ensure that levels are sorted by their internal values.

Implications of the Non-Full-Rank Parameterization

For models with fixed-effects involving class variables, there are more design columns in \mathbf{X} constructed than there are degrees of freedom for the effect. Thus, there are linear dependencies among the columns of \mathbf{X} . In this event, all of the parameters are not estimable; there is an infinite number of solutions to the mixed model equations. PROC MIXED uses a generalized (g2) inverse to obtain values for the estimates (Searle 1971). The solution values are not displayed unless you specify the SOLUTION option in the MODEL statement. The solution has the characteristic that estimates are 0 whenever the design column for that parameter is a linear combination of previous columns. With this parameterization, hypothesis tests are constructed to test linear functions of the parameters that are estimable.

Some procedures (such as the CATMOD procedure) reparameterize models to full rank using restrictions on the parameters. PROC GLM and PROC MIXED do not reparameterize, making the hypotheses that are commonly tested more understandable. Refer to Goodnight (1978) for additional reasons for not reparameterizing.

Missing Level Combinations

PROC MIXED handles missing level combinations of classification variables similarly to the way PROC GLM does. Both procedures delete fixed-effects parameters corresponding to missing levels in order to preserve estimability. However, PROC MIXED does not delete missing level combinations for random-effects parameters because linear combinations of the random-effects parameters are always estimable. These conventions can affect the way you specify your CONTRAST and ESTIMATE coefficients.

Default Output

The following sections describe the output PROC MIXED produces by default. This output is organized into various tables, and they are discussed in order of appearance.

Model Information

The “Model Information” table describes the model, some of the variables it involves, and the method used in fitting it. It also lists the method (profile, fit, factor, or none) for handling the residual variance in the model. The *profile* method concentrates the residual variance out of the optimization problem, whereas the *fit* method retains it as a parameter in the optimization. The *factor* method keeps the residual fixed, and *none* is displayed when a residual variance is not a part of the model.

The “Model Information” table also has a row labeled Fixed Effects SE Method. This row describes the method used to compute the approximate standard errors for the fixed-effects parameter estimates and related functions of them. The two possibilities for this row are Model-Based, which is the default method, and Empirical, which results from using the EMPIRICAL option in the PROC MIXED statement.

For ODS purposes, the label of the “Model Information” table is “ModelInfo.”

Class Level Information

The “Class Level Information” table lists the levels of every variable specified in the CLASS statement. You should check this information to make sure the data are correct. You can adjust the order of the CLASS variable levels with the ORDER= option in the PROC MIXED statement. For ODS purposes, the label of the “Class Level Information” table is “ClassLevels.”

Dimensions

The “Dimensions” table lists the sizes of relevant matrices. This table can be useful in determining CPU time and memory requirements. For ODS purposes, the label of the “Dimensions” table is “Dimensions.”

Number of Observations

The “Number of Observations” table shows the number of observations read from the data set and the number of observations used in fitting the model.

Iteration History

The “Iteration History” table describes the optimization of the [residual log likelihood or log likelihood](#) described on page 2738. The function to be minimized (the *objective function*) is $-2l$ for ML and $-2l_R$ for REML; the column name of the objective function in the “Iteration History” table is “-2 Log Like” for ML and “-2 Res Log Like” for REML. The minimization is performed using a ridge-stabilized Newton-Raphson algorithm, and the rows of this table describe the iterations that this algorithm takes in order to minimize the objective function.

The Evaluations column of the “Iteration History” table tells how many times the objective function is evaluated during each iteration.

The Criterion column of the “Iteration History” table is, by default, a relative Hessian convergence quantity given by

$$\frac{\mathbf{g}'_k \mathbf{H}_k^{-1} \mathbf{g}_k}{|f_k|}$$

where f_k is the value of the objective function at iteration k , \mathbf{g}_k is the gradient (first derivative) of f_k , and \mathbf{H}_k is the Hessian (second derivative) of f_k . If \mathbf{H}_k is singular, then PROC MIXED uses the following relative quantity:

$$\frac{\mathbf{g}'_k \mathbf{g}_k}{|f_k|}$$

To prevent the division by $|f_k|$, use the ABSOLUTE option in the PROC MIXED statement. To use a relative function or gradient criterion, use the CONVF or CONVG options, respectively.

The Hessian criterion is considered superior to function and gradient criteria because it measures orthogonality rather than lack of progress (Bates and Watts 1988). Provided the initial estimate is feasible and the maximum number of iterations is not exceeded, the Newton-Raphson algorithm is considered to have converged when the criterion is less than the tolerance specified with the CONVF, CONVG, or CONVH option in the PROC MIXED statement. The default tolerance is $1\text{E}-8$. If convergence is not achieved, PROC MIXED displays the estimates of the parameters at the last iteration.

A convergence criterion that is missing indicates that a boundary constraint has been dropped; it is usually not a cause for concern.

If you specify the ITDETAILS option in the PROC MIXED statement, then the covariance parameter estimates at each iteration are included as additional columns in the “Iteration History” table.

For ODS purposes, the label of the “Iteration History” table is “IterHistory.”

Covariance Parameter Estimates

The “Covariance Parameter Estimates” table contains the estimates of the parameters in \mathbf{G} and \mathbf{R} (see the “[Estimating G and R in the Mixed Model](#)” section on page 2737). Their values are labeled in the “Cov Parm” table along with Subject and Group information if applicable. The estimates are displayed in the Estimate column and are the results of one of the following estimation methods: REML, ML, MIVQUE0, SSCP, Type1, Type2, or Type3.

If you specify the RATIO option in the PROC MIXED statement, the Ratio column is added to the table listing the ratios of each parameter estimate to that of the residual variance.

Requesting the COVTEST option in the PROC MIXED statement produces the Std Error, Z Value, and Pr Z columns. The Std Error column contains the approximate standard errors of the covariance parameter estimates. These are the square roots of the diagonal elements of the observed inverse Fisher information matrix, which equals $2\mathbf{H}^{-1}$, where \mathbf{H} is the Hessian matrix. The \mathbf{H} matrix consists of the second derivatives of the objective function with respect to the covariance parameters; refer to Wolfinger, Tobias, and Sall (1994) for formulas. When you use the SCORING= option and PROC MIXED converges without stopping the scoring algorithm, PROC MIXED uses the expected Hessian matrix to compute the covariance matrix instead of the observed Hessian. The observed or expected inverse Fisher information matrix can be viewed as an asymptotic covariance matrix of the estimates.

The Z Value column is the estimate divided by its approximate standard error, and the Pr Z column is the one- or two-tailed area of the standard Gaussian density outside of the Z-value. The MIXED procedure computes one-sided p-values for the residual variance and for covariance parameters with a lower bound of 0. The procedure computes two-sided p-values otherwise. These statistics constitute Wald tests of the covariance parameters, and they are valid only asymptotically.

Caution: Wald tests can be unreliable in small samples.

For ODS purposes, the label of the “Covariance Parameter Estimates” table is “CovParms.”

Fit Statistics

The “Fit Statistics” table provides some statistics about the estimated mixed model. Expressions for the -2 times the log likelihood are provided in the “[Estimating G and R in the Mixed Model](#)” section on page 2737. If the log likelihood is an extremely large number, then PROC MIXED has deemed the estimated \mathbf{V} matrix to be singular. In this case, all subsequent results should be viewed with caution.

In addition, the “Fit Statistics” table lists three information criteria: AIC, AICC, and BIC, all in smaller-is-better form. Expressions for these criteria are described under the [IC option](#) on page 2676.

For ODS purposes, the label of the “Model Fitting Information” table is “FitStatistics.”

Null Model Likelihood Ratio Test

If one covariance model is a submodel of another, you can carry out a likelihood ratio test for the significance of the more general model by computing -2 times the difference between their log likelihoods. Then compare this statistic to the χ^2 distribution with degrees of freedom equal to the difference in the number of parameters for the two models.

This test is reported in the “Null Model Likelihood Ratio Test” table to determine whether it is necessary to model the covariance structure of the data at all. The “Chi-Square” value is -2 times the log likelihood from the null model minus -2 times the log likelihood from the fitted model, where the null model is the one with only the fixed effects listed in the MODEL statement and $\mathbf{R} = \sigma^2\mathbf{I}$. This statistic has an asymptotic χ^2 -distribution with $q - 1$ degrees of freedom, where q is the effective number of covariance parameters (those not estimated to be on a boundary constraint). The $\text{Pr} > \text{ChiSq}$ column contains the upper-tail area from this distribution. This p -value can be used to assess the significance of the model fit.

This test is not produced for cases where the null hypothesis lies on the boundary of the parameter space, which is typically for variance component models. This is because the standard asymptotic theory does not apply in this case (Self and Liang 1987, Case 5).

If you specify a PARMs statement, PROC MIXED constructs a likelihood ratio test between the best model from the grid search and the final fitted model and reports the results in the “Parameter Search” table.

For ODS purposes, the label of the “Null Model Likelihood Ratio Test” table is “LRT.”

Type 3 Tests of Fixed Effects

The “Type 3 Tests of Fixed Effects” table contains hypothesis tests for the significance of each of the fixed effects, that is, those effects you specify in the MODEL statement. By default, PROC MIXED computes these tests by first constructing a Type III \mathbf{L} matrix (see Chapter 11, “The Four Types of Estimable Functions,”) for each effect. This \mathbf{L} matrix is then used to compute the following F -statistic:

$$F = \frac{\hat{\boldsymbol{\beta}}' \mathbf{L}' [\mathbf{L}(\mathbf{X}' \hat{\mathbf{V}}^{-1} \mathbf{X})^{-1} \mathbf{L}]^{-1} \mathbf{L} \hat{\boldsymbol{\beta}}}{\text{rank}(\mathbf{L})}$$

A p -value for the test is computed as the tail area beyond this statistic from an F -distribution with NDF and DDF degrees of freedom. The numerator degrees of freedom (NDF) is the row rank of \mathbf{L} , and the denominator degrees of freedom is computed using one of the methods described under the [DDFM= option](#) on page 2693. Small values of the p -value (typically less than 0.05 or 0.01) indicate a significant effect.

You can use the HTYPE= option in the MODEL statement to obtain tables of Type I (sequential) tests and Type II (adjusted) tests in addition to or instead of the table of Type III (partial) tests.

You can use the CHISQ option in the MODEL statement to obtain Wald χ^2 tests of the fixed effects. These are carried out by using the numerator of the F -statistic and comparing it with the χ^2 distribution with NDF degrees of freedom. It is more liberal than the F -test because it effectively assumes an infinite denominator degrees of freedom.

For ODS purposes, the label of the “Type 1 Tests of Fixed Effects” through the “Type 3 Tests of Fixed Effects” tables are “Tests1” through “Tests3,” respectively.

ODS Table Names

Each table created by PROC MIXED has a name associated with it, and you must use this name to reference the table when using ODS statements. These names are listed in Table 46.8.

Table 46.8. ODS Tables Produced in PROC MIXED

Table Name	Description	Required Statement / Option
AccRates	acceptance rates for posterior sampling	PRIOR
AsyCorr	asymptotic correlation matrix of covariance parameters	PROC MIXED ASYCORR
AsyCov	asymptotic covariance matrix of covariance parameters	PROC MIXED ASYCOV
Base	base densities used for posterior sampling	PRIOR
Bound	computed bound for posterior rejection sampling	PRIOR
CholG	Cholesky root of the estimated G matrix	RANDOM / GC
CholR	Cholesky root of blocks of the estimated R matrix	REPEATED / RC
CholV	Cholesky root of blocks of the estimated V matrix	RANDOM / VC
ClassLevels	level information from the CLASS statement	default output
Coef	L matrix coefficients	E option on MODEL, CONTRAST, ESTIMATE, or LSMEANS
Contrasts	results from the CONTRAST statements	CONTRAST
ConvergenceStatus	convergence status	default
CorrB	approximate correlation matrix of fixed-effects parameter estimates	MODEL / CORRB
CovB	approximate covariance matrix of fixed-effects parameter estimates	MODEL / COVB
CovParms	estimated covariance parameters	default output
Diffs	differences of LS-means	LSMEANS / DIFF (or PDIFF)
Dimensions	dimensions of the model	default output
Estimates	results from ESTIMATE statements	ESTIMATE

Table 46.8. (continued)

Table Name	Description	Required Statement / Option
FitStatistics	fit statistics	default
G	estimated G matrix	RANDOM / G
GCorr	correlation matrix from the estimated G matrix	RANDOM / GCORR
HLM1	Type 1 Hotelling-Lawley-McKeon tests of fixed effects	MODEL / HTYPE=1 and REPEATED / HLM TYPE=UN
HLM2	Type 2 Hotelling-Lawley-McKeon tests of fixed effects	MODEL / HTYPE=2 and REPEATED / HLM TYPE=UN
HLM3	Type 3 Hotelling-Lawley-McKeon tests of fixed effects	REPEATED / HLM TYPE=UN
HLPS1	Type 1 Hotelling-Lawley-Pillai-Samson tests of fixed effects	MODEL / HTYPE=1 and REPEATED / HLPS TYPE=UN
HLPS2	Type 2 Hotelling-Lawley-Pillai-Samson tests of fixed effects	MODEL / HTYPE=1 and REPEATED / HLPS TYPE=UN
HLPS3	Type 3 Hotelling-Lawley-Pillai-Samson tests of fixed effects	REPEATED / HLPS TYPE=UN
Influence	influence diagnostics	MODEL / INFLUENCE
InfoCrit	information criteria	PROC MIXED IC
InvCholG	inverse Cholesky root of the estimated G matrix	RANDOM / GCI
InvCholR	inverse Cholesky root of blocks of the estimated R matrix	REPEATED / RCI
InvCholV	inverse Cholesky root of blocks of the estimated V matrix	RANDOM / VCI
InvCovB	inverse of approximate covariance matrix of fixed-effects parameter estimates	MODEL / COVBI
InvG	inverse of the estimated G matrix	RANDOM / GI
InvR	inverse of blocks of the estimated R matrix	REPEATED / RI
InvV	inverse of blocks of the estimated V matrix	RANDOM / VI
IterHistory	iteration history	default output
LComponents	single degree of freedom estimates corresponding to rows of the L matrix for fixed effects	MODEL / LCOMPONENTS
LRT	likelihood ratio test	default output
LSMeans	LS-means	LSMEANS
MMEq	mixed model equations	PROC MIXED MMEQ
MMEqSol	mixed model equations solution	PROC MIXED MMEQSOL
ModelInfo	model information	default output
NObs	number of observations read and used	default output
ParmSearch	parameter search values	PARMS

Table 46.8. (continued)

Table Name	Description	Required Statement / Option
Posterior	posterior sampling information	PRIOR
R	blocks of the estimated R matrix	REPEATED / R
RCorr	correlation matrix from blocks of the estimated R matrix	REPEATED / RCORR
Search	posterior density search table	PRIOR / PSEARCH
Slices	tests of LS-means slices	LSMEANS / SLICE=
SolutionF	fixed effects solution vector	MODEL / S
SolutionR	random effects solution vector	RANDOM / S
Tests1	Type 1 tests of fixed effects	MODEL / HTYPE=1
Tests2	Type 2 tests of fixed effects	MODEL / HTYPE=2
Tests3	Type 3 tests of fixed effects	default output
Type1	Type 1 analysis of variance	PROC MIXED METHOD=TYPE1
Type2	Type 2 analysis of variance	PROC MIXED METHOD=TYPE2
Type3	Type 3 analysis of variance	PROC MIXED METHOD=TYPE3
Trans	transformation of covariance parameters	PRIOR / PTRANS
V	blocks of the estimated V matrix	RANDOM / V
VCorr	correlation matrix from blocks of the estimated V matrix	RANDOM / VCORR

In Table 46.8, “Coef” refers to multiple tables produced by the E, E1, E2, or E3 options in the MODEL statement and the E option in the CONTRAST, ESTIMATE, and LSMEANS statements. You can create one large data set of these tables with a statement similar to

```
ods output Coef=c;
```

To create separate data sets, use

```
ods output Coef(match_all)=c;
```

Here the resulting data sets are named C, C1, C2, etc. The same principles apply to data sets created from the “R,” “CholR,” “InvCholR,” “RCorr,” “InvR,” “V,” “CholV,” “InvCholV,” “VCorr,” and “InvV” tables.

In Table 46.8, the following changes have occurred from Version 6. The “Predicted,” “PredMeans,” and “Sample” tables from Version 6 no longer exist and have been replaced by output data sets; see descriptions of the MODEL statement options [OUTPRED=](#) on page 2703 and [OUTPREDM=](#) on page 2704 and the PRIOR statement option [OUT=](#) on page 2711 for more details. The “ML” and “REML” tables from Version 6 have been replaced by the “IterHistory” table. The “Tests,” “HLM,” and “HLPS” tables from Version 6 have been renamed “Tests3,” “HLM3,” and “HLPS3.”

Table 46.9 lists the variable names associated with the data sets created when you use the ODS OUTPUT option in conjunction with the preceding tables. In Table 46.9, *n* is used to denote a generic number that is dependent upon the particular data set and model you select, and it can assume a different value each time it is used (even within the same table). The phrase *model specific* appears in rows of the affected tables to indicate that columns in these tables depend upon the variables you specify in the model.

Caution: There exists a danger of name collisions with the variables in the *model specific* tables in Table 46.9 and variables in your input data set. You should avoid using input variables with the same names as the variables in these tables.

Table 46.9. Variable Names for the ODS Tables Produced in PROC MIXED

Table Name	Variables
AsyCorr	Row, CovParm, CovP1–CovPn
AsyCov	Row, CovParm, CovP1–CovPn

VCorr	Index, Row, Col1–Coln

Some of the variables listed in [Table 46.9](#) are created only when you have specified certain options in the relevant PROC MIXED statements.

Converting from Previous Releases

The following changes have occurred in variables listed in [Table 46.9](#) from Version 6. Nearly all underscores have been removed from variable names in order to be compatible and consistent with other procedures. Some of the variable names have been changed (for example, T has been changed to tValue and PT to Probt) for the same reason. You may have to modify some of your Version 6 code to accommodate these changes.

In Version 6, PROC MIXED used a MAKE statement to save displayed output as data sets. The MAKE statement is now obsolete and may not be supported in future releases. Use the ODS OUTPUT statement instead. The following table shows typical conversions in order to replace the MAKE statement in Version 6 code with ODS statements.

Table 46.10. ODS Conversions for PROC MIXED

Version 6 Syntax	Versions 7 and 8 Syntax
make 'covparms' out=cp;	ods output covparms=cp;
make 'covparms' out=cp noprint;	ods listing exclude covparms;
%global _print_; %let _print_=off;	ods output covparms=cp;
%global _print_; %let _print_=on;	ods listing close;
	ods listing;

ODS Graphics (Experimental)

This section describes the use of ODS for creating diagnostic plots with the MIXED procedure. These graphics are experimental in this release, meaning that both the graphical results and the syntax for specifying them are subject to change in a future release.

To request these graphs you must specify the ODS GRAPHICS statement. In addition you must specify the relevant options of the PROC MIXED or MODEL statement ([Table 46.11](#)). To request plots of studentized residuals, for example, specify the experimental RESIDUAL option of the MODEL statement. To obtain graphical displays of leave-one-out parameter estimates, specify the experimental INFLUENCE option with the ESTIMATES suboption.

For more information on the ODS GRAPHICS statement, see Chapter 15, “Statistical Graphics Using ODS.” ODS names of the various graphics are given in the “ODS Graph Names” section (page 2762).

Residual Plots

With the experimental graphics features the MIXED procedure can generate panels of residual diagnostics. Each panel consists of a plot of residuals versus predicted values, a histogram with Normal density overlaid, a Q-Q plot, and summary residual and fit statistics (Figure 46.15). The plots are produced even if the OUTP= and OUTPM= options of the MODEL statement are not specified. Three such panels are produced for the marginal residuals which would be added to the OUTPM= data set. The panels display the raw, studentized, and Pearson residuals (see “Residual Diagnostics”). In models with RANDOM effects where EBLUPs can be used for prediction, the raw, studentized and Pearson conditional residuals are also plotted.

Recall the example in the “Getting Started” section on page 2665. The following statements generate six 2×2 panels of residual graphs.

```
ods html;
ods graphics on;

proc mixed;
  class Family Gender;
  model Height = Gender / residual;
  random Family Family*Gender;
run;

ods graphics off;
ods html close;
```

The graphical displays are requested by specifying the experimental ODS GRAPHICS statement. The panel for the marginal studentized residuals is shown in Figure 46.15 and the panel for the conditional studentized residuals in Figure 46.16.

Figure 46.15. Marginal Studentized Residual Panel (Experimental)

Figure 46.16. Conditional Studentized Residual Panel (Experimental)

A similar panel display for the scaled residuals is produced when you specify the experimental VCIRY option of the MODEL statement; see option VCIRY on page 2705 for more details.

The “Residual Statistics” in the lower right-hand corner inset provides descriptive statistics for the set of residuals that is displayed. Note that residuals in a mixed model do not necessarily sum to zero, even if the model contains an intercept.

Influence Plots

With the experimental graphics features the MIXED procedure can generate one or more panels of influence graphics. The type and number of panels produced depends on the modifiers of the INFLUENCE option. Plots related to covariance parameters are produced when diagnostics are computed by iterative methods (ITER=). The estimates of the fixed effects—and covariance parameters when updates are iterative—are plotted when the ESTIMATES modifier is specified.

The two types of panel graphs produced by the INFLUENCE option are shown in Figure 46.17 and Figure 46.18. The diagnostics panel shows an overall influence statistic (likelihood distance) and diagnostics for the fixed effects (CookD and COVRATIO). The statistics produced depend on suboptions of the INFLUENCE option (see Example 46.8 for the statements and options that produced Figure 46.17). Reference lines are drawn at zero for PRESS residuals and COVTRACE, and at one for COVRATIO. A reference line for likelihood distances is drawn at the 75th percentile of a chi-square distribution with m degrees of freedom if the largest displacement value in the “Influence” table is close to or larger than that percentile. The number m equals the number of parameters being updated.

Figure 46.17. Influence Diagnostics (Experimental)

Figure 46.18. Delete Estimates (Experimental)

The second type of influence panel plot is obtained when you specify the ESTIMATES suboption (Figure 46.18). It shows the delete-estimates for each updated model parameter. Reference lines are drawn at the full data estimates. For noniterative influence analyses with profiled residual variance, the delete-case root mean square error is also plotted.

For the SAS statements that produce influence plots and for variations of these graphs see Example 46.7 and Example 46.8.

Box Plots

You can specify the BOXPLOT option in the PROC MIXED statement.

BOXPLOT <(suboptions)>

requests box plots of observed and residual values $\mathbf{Y} - \mathbf{X}\hat{\boldsymbol{\beta}}$ for effects that consist of single CLASS variables. This includes SUBJECT= and GROUP= effects.

For models with a RANDOM statement you also obtain box plots of the conditional residuals $\mathbf{Y} - \mathbf{X}\hat{\boldsymbol{\beta}} - \mathbf{Z}\hat{\boldsymbol{\gamma}}$. The box plots are constructed from studentized residuals when the RESIDUAL option of the MODEL statement is specified.

The following suboptions modify the appearance of the plots:

DATALABEL | NODATALABEL

determines whether to place observation labels next to far outliers. Far outliers are labeled by default.

FILL | NOFILL

determines whether the boxes are filled. The default is FILL.

NPANEL=*n*

limits the number of boxes per plot. The default is to place box plots for all levels of a factor in a common panel.

See Example 46.8 for an application.

ODS Graph Names

The MIXED procedure assigns a name to each graph it creates using ODS. You can use these names to reference the graphs when using ODS. The names are listed in Table 46.11.

To request these graphs, you must specify the ODS GRAPHICS statement in addition to the options indicated in Table 46.11. For more information on the ODS GRAPHICS statement, see Chapter 15, “Statistical Graphics Using ODS.”

Table 46.11. ODS Graphics Produced by PROC MIXED

ODS Graph Name	Plot Description	Option
BoxPlot1,2,...	Box plots	BOXPLOT
InfluenceEstCovPPanel1,2,...	Covariance parameter delete estimates	MODEL / INFLUENCE(EST ITER= <i>n</i>)
InfluenceEstParmPanel1,2,...	Fixed effects delete estimates	MODEL / INFLUENCE(EST)

RawResidualPanel	Marginal residuals	MODEL / RESIDUAL
ScaledResidualPanel	Scaled residuals	MODEL / VCIRY
StudentizedCondResidualPanel	Studentized conditional residuals	MODEL / RESIDUAL
StudentizedResidualPanel	Studentized marginal residuals	MODEL / RESIDUAL

Residuals and Influence Diagnostics (Experimental)

Residual Diagnostics

Consider a residual vector of the form $\tilde{\mathbf{e}} = \mathbf{P}\mathbf{Y}$, where \mathbf{P} is a projection matrix, possibly an oblique projector. A typical element \tilde{e}_i with variance v_i and estimated variance \hat{v}_i is said to be *standardized* as

$$\frac{\tilde{e}_i}{\sqrt{\text{var}[\tilde{e}_i]}} = \frac{\tilde{e}_i}{\sqrt{v_i}}$$

and *studentized* as

$$\frac{\tilde{e}_i}{\sqrt{\hat{v}_i}}$$

External studentization uses an estimate of $\text{var}[\tilde{e}_i]$ which does not involve the i th observation. Externally studentized residuals are often preferred over studentized residuals because they have well-known distributional properties in standard linear models for independent data.

Residuals that are scaled by the estimated variance of the response, i.e., $\tilde{e}_i / \sqrt{\widehat{\text{var}}[Y_i]}$, are referred to as Pearson-type residuals.

Marginal and Conditional Residuals

The marginal and conditional means in the linear mixed model are $E[\mathbf{Y}] = \mathbf{X}\boldsymbol{\beta}$ and $E[\mathbf{Y}|\boldsymbol{\gamma}] = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\boldsymbol{\gamma}$, respectively. Accordingly, the vector \mathbf{r}_m of marginal residuals is defined as

$$\mathbf{r}_m = \mathbf{Y} - \mathbf{X}\hat{\boldsymbol{\beta}}$$

and the vector \mathbf{r}_c of conditional residuals is

$$\mathbf{r}_c = \mathbf{Y} - \mathbf{X}\hat{\boldsymbol{\beta}} - \mathbf{Z}\hat{\boldsymbol{\gamma}} = \mathbf{r}_m - \mathbf{Z}\hat{\boldsymbol{\gamma}}$$

Following Gregoire, Schabenberger, and Barrett (1995), let $\mathbf{Q} = \mathbf{X}(\mathbf{X}'\hat{\mathbf{V}}^{-1}\mathbf{X})^{-1}\mathbf{X}'$ and $\mathbf{K} = \mathbf{I} - \mathbf{Z}\hat{\mathbf{G}}\mathbf{Z}'\hat{\mathbf{V}}^{-1}$. Then

$$\begin{aligned}\widehat{\text{var}}[\mathbf{r}_m] &= \hat{\mathbf{V}} - \mathbf{Q} \\ \widehat{\text{var}}[\mathbf{r}_c] &= \mathbf{K}(\hat{\mathbf{V}} - \mathbf{Q})\mathbf{K}'\end{aligned}$$

For an individual observation the raw, studentized, and Pearson residuals computed by the RESIDUAL option of the MODEL statement are given in the following table.

Type of Residual	Marginal	Conditional
Raw	$r_{mi} = Y_i - \mathbf{x}_i'\hat{\boldsymbol{\beta}}$	$r_{ci} = r_{mi} - \mathbf{z}_i'\hat{\boldsymbol{\gamma}}$
Studentized	$r_{mi}^{student} = \frac{r_{mi}}{\sqrt{\widehat{\text{var}}[r_{mi}]}}$	$r_{ci}^{student} = \frac{r_{ci}}{\sqrt{\widehat{\text{var}}[r_{ci}]}}$
Pearson	$r_{mi}^{pearson} = \frac{r_{mi}}{\sqrt{\widehat{\text{var}}[Y_i]}}$	$r_{ci}^{pearson} = \frac{r_{ci}}{\sqrt{\widehat{\text{var}}[Y_i \boldsymbol{\gamma}]}}$

When the OUTPM= option of the MODEL statement is specified in addition to the RESIDUAL option, r_{mi} , $r_{mi}^{student}$, and $r_{mi}^{pearson}$ are added to the data set as variables Resid, StudentResid, and PearsonResid, respectively. When the OUTP= option is specified, r_{ci} , $r_{ci}^{student}$, and $r_{ci}^{pearson}$ are added to the data set.

Scaled Residuals

For correlated data, a set of scaled quantities can be defined through the Cholesky decomposition of the variance-covariance matrix. Since fitted residuals in linear models are rank-deficient, it is customary to draw on the variance-covariance matrix of the data. If $\text{var}[\mathbf{Y}] = \mathbf{V}$ and $\mathbf{C}'\mathbf{C} = \mathbf{V}$, then $\mathbf{C}'^{-1}\mathbf{Y}$ has uniform dispersion and its elements are uncorrelated.

Scaled residuals in a mixed model are meaningful for quantities based on the marginal distribution of the data. Let $\hat{\mathbf{C}}$ denote the Cholesky root of $\hat{\mathbf{V}}$, so that $\hat{\mathbf{C}}'\hat{\mathbf{C}} = \hat{\mathbf{V}}$, and define

$$\begin{aligned}\mathbf{Y}_c &= \hat{\mathbf{C}}'^{-1}\mathbf{Y} \\ \mathbf{r}_{m(c)} &= \hat{\mathbf{C}}'^{-1}\mathbf{r}_m\end{aligned}$$

By analogy with other scalings, the inverse Cholesky decomposition can also be applied to the residual vector, $\widehat{\mathbf{C}}'^{-1}\mathbf{r}_m$, although \mathbf{V} is not the variance-covariance matrix of \mathbf{r}_m .

To diagnose whether the covariance structure of the model has been specified correctly can be difficult based on \mathbf{Y}_c , since the inverse Cholesky transformation affects the expected value of \mathbf{Y}_c . You can draw on $\mathbf{r}_{m(c)}$ as a vector of (approximately) uncorrelated data with constant mean.

When the OUTPM= option of the MODEL statement is specified in addition to the VCIRY option, \mathbf{Y}_c is added as variable ScaledDep and $\mathbf{r}_{m(c)}$ is added as ScaledResid to the data set.

Influence Diagnostics

The Basic Idea and Statistics

The general idea of quantifying the influence of one or more observations relies on computing parameter estimates based on all data points, removing the cases in question from the data, refitting the model, and computing statistics based on the change between full-data and reduced-data estimation. Influence statistics can be coarsely grouped by the aspect of estimation which is their primary target:

- overall measures compare changes in objective functions: (restricted) likelihood distance (Cook and Weisberg 1982, Ch. 5.2)
- influence on parameter estimates: Cook's D (Cook 1977, 1979), MDFFITS (Belsley, Kuh, and Welsch 1980, p. 32)
- influence on precision of estimates: CovRatio and CovTrace
- influence on fitted and predicted values: PRESS residual, PRESS statistic (Allen 1974), DFFITS (Belsley, Kuh, and Welsch 1980, p. 15)
- outlier properties: Internally and externally studentized residuals, leverage

For linear models for uncorrelated data, it is not necessary to refit the model after removing a data point in order to measure the impact of an observation on the model. The change in fixed effect estimates, residuals, residual sums of squares, and the variance-covariance matrix of the fixed effects can be computed based on the fit to the full data alone. By contrast, in mixed models several important complications arise. Data points can impact not only the fixed effects but also the covariance parameter estimates on which the fixed effects estimates depend. Furthermore, closed-form expressions for computing the change in important model quantities may not be available.

This section provides background material for the various influence diagnostics available with the MIXED procedure. See the section “[Mixed Models Theory](#)” beginning on page 2731 for relevant expressions and definitions. The parameter vector $\boldsymbol{\theta}$ denotes all unknown parameters in the \mathbf{R} and \mathbf{G} matrix.

The observations whose influence is being ascertained are represented by the set U and referred to simply as “the observations in U .” The estimate of a parameter vector,

for example, β , obtained from all observations except those in the set U is denoted $\hat{\beta}_{(U)}$. In case of a matrix \mathbf{A} , the notation $\mathbf{A}_{(U)}$ represents the matrix with the rows in U removed; these rows are collected in \mathbf{A}_U . If \mathbf{A} is symmetric, then notation $\mathbf{A}_{(U)}$ implies removal of rows and columns. The vector Y_U comprises the responses of the data points being removed, and $\mathbf{V}_{(U)}$ is the variance-covariance matrix of the remaining observations. When $k = 1$, lowercase notation emphasizes that single points are removed, e.g., $\mathbf{A}_{(u)}$.

Managing the Covariance Parameters

An important component of influence diagnostics in the mixed model is the estimated variance-covariance matrix $\mathbf{V} = \mathbf{ZGZ}' + \mathbf{R}$. To make the dependence on the vector of covariance parameters explicit, write it as $\mathbf{V}(\boldsymbol{\theta})$. If one parameter, σ^2 , is profiled or factored out of \mathbf{V} , the remaining parameters are denoted as $\boldsymbol{\theta}^*$. Notice that in a model where \mathbf{G} is diagonal and $\mathbf{R} = \sigma^2\mathbf{I}$, the parameter vector $\boldsymbol{\theta}^*$ contains the ratios of each variance component and σ^2 (see Wolfinger, Tobias, and Sall 1994). When ITER=0, two scenarios are distinguished:

1. If the residual variance is not profiled, either because the model does not contain a residual variance or because it is part of the Newton-Raphson iterations, then $\hat{\boldsymbol{\theta}}_{(U)} \equiv \hat{\boldsymbol{\theta}}$.
2. If the residual variance is profiled then $\hat{\boldsymbol{\theta}}_{(U)}^* \equiv \hat{\boldsymbol{\theta}}^*$ and $\hat{\sigma}_{(U)}^2 \neq \hat{\sigma}^2$. Influence statistics such as Cook's D and internally studentized residuals are based on $\mathbf{V}(\hat{\boldsymbol{\theta}})$ whereas externally studentized residuals and the DFFITS statistic are based on $\mathbf{V}(\hat{\boldsymbol{\theta}}_{(U)}) = \sigma_{(U)}^2 \mathbf{V}(\hat{\boldsymbol{\theta}}^*)$. In a random components model with uncorrelated errors, for example, the computation of $\mathbf{V}(\hat{\boldsymbol{\theta}}_{(U)})$ involves scaling of $\hat{\mathbf{G}}$ and $\hat{\mathbf{R}}$ by the full data estimate $\hat{\sigma}^2$ and multiplying the result with the reduced-data estimate $\hat{\sigma}_{(U)}^2$.

Certain statistics, such as MDFFITS, COVRATIO, and COVTRACE, require an estimate of the variance of the fixed effects that is based on the reduced number of observations. For example, $\mathbf{V}(\hat{\boldsymbol{\theta}}_{(U)})$ is evaluated at the reduced-data parameter estimates but computed for the entire data set. The matrix $\mathbf{V}_{(U)}(\hat{\boldsymbol{\theta}}_{(U)})$, on the other hand, has rows and columns corresponding to the points in U removed. The resulting matrix is evaluated at the delete-case estimates.

When influence analysis is iterative, the entire vector $\boldsymbol{\theta}$ is updated, whether the residual variance is profiled or not. The matrices to be distinguished here are $\mathbf{V}(\hat{\boldsymbol{\theta}})$, $\mathbf{V}(\hat{\boldsymbol{\theta}}_{(U)})$, and $\mathbf{V}_{(U)}(\hat{\boldsymbol{\theta}}_{(U)})$, with unambiguous notation.

Predicted Values, PRESS Residual, and PRESS Statistic

An unconditional predicted value is $\hat{y}_i = \mathbf{x}_i' \hat{\boldsymbol{\beta}}$, where the vector \mathbf{x}_i is the i th row of \mathbf{X} . The (raw) residual is given as $\hat{\epsilon}_i = y_i - \hat{y}_i$ and the PRESS residual is

$$\hat{\epsilon}_{i(U)} = y_i - \mathbf{x}_i' \hat{\boldsymbol{\beta}}_{(U)}$$

The PRESS statistic is the sum of the squared PRESS residuals,

$$PRESS = \sum_{i \in U} \hat{\epsilon}_{i(U)}^2$$

where the sum is over the observations in U .

If EFFECT=, SIZE=, or KEEP= are not specified, PROC MIXED computes the PRESS residual for each observation selected through SELECT= (or all observations if SELECT= is not given). If EFFECT=, SIZE=, or KEEP= are specified, the procedure computes PRESS.

Leverage

For the general mixed model, leverage can be defined through the projection matrix that results from a transformation of the model with the inverse of the Cholesky decomposition of \mathbf{V} , or through an oblique projector. The MIXED procedure follows the latter path in the computation of influence diagnostics. The leverage value reported for the i th observation is the i th diagonal entry of the matrix

$$\mathbf{H} = \mathbf{X}(\mathbf{X}'\mathbf{V}(\hat{\boldsymbol{\theta}})^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{V}(\hat{\boldsymbol{\theta}})^{-1}$$

which is the weight of the observation in contributing to its own predicted value, $\mathbf{H} = d\hat{\mathbf{Y}}/d\mathbf{Y}$.

While \mathbf{H} is idempotent, it is generally not symmetric and thus not a projection matrix in the narrow sense.

The properties of these leverages are generalizations of the properties in models with diagonal variance-covariance matrices. For example, $\hat{\mathbf{Y}} = \mathbf{H}\mathbf{Y}$, and in a model with intercept and $\mathbf{V} = \sigma^2\mathbf{I}$, the leverage values

$$h_{ii} = \mathbf{x}_i'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}_i$$

are $h_{ii}^l = 1/n \leq h_{ii} \leq 1 = h_{ii}^u$ and $\sum_{i=1}^n h_{ii} = \text{rank}(\mathbf{X})$. The lower bound for h_{ii} is achieved in an intercept-only model, the upper bound in a saturated model. The trace of \mathbf{H} equals the rank of \mathbf{X} .

If ν_{ij} denotes the element in row i , column j of \mathbf{V}^{-1} , then for a model containing only an intercept the diagonal elements of \mathbf{H} are

$$h_{ii} = \frac{\sum_{j=1}^n \nu_{ij}}{\sum_{i=1}^n \sum_{j=1}^n \nu_{ij}}$$

Because $\sum_{j=1}^n \nu_{ij}$ is a sum of elements in the i th row of the inverse variance-covariance matrix h_{ii} can be negative, even if the correlations among data points are nonnegative. In case of a saturated model with $\mathbf{X} = \mathbf{I}$, $h_{ii} = 1.0$.

Internally and Externally Studentized Residuals

See the section “Residual Diagnostics” on page 2763 for the distinction between standardization, studentization, and scaling of residuals. Internally studentized marginal and conditional residuals are computed with the RESIDUAL option of the MIXED procedure (p. 2763). The INFLUENCE option computes internally and externally studentized marginal residuals.

The computation of internally studentized residuals relies on the diagonal entries of $\mathbf{V}(\hat{\boldsymbol{\theta}}) - \mathbf{Q}(\hat{\boldsymbol{\theta}})$ where $\mathbf{Q}(\hat{\boldsymbol{\theta}}) = \mathbf{X}(\mathbf{X}'\mathbf{V}(\hat{\boldsymbol{\theta}})^{-1}\mathbf{X})^{-1}\mathbf{X}'$. Externally studentized residuals require iterative influence analysis or a profiled residual variance. In the former case the studentization is based on $\mathbf{V}(\hat{\boldsymbol{\theta}}_U)$; in the latter case it is based on $\sigma_{(U)}^2 \mathbf{V}(\hat{\boldsymbol{\theta}}^*)$.

Cook's D

Cook's D statistic is an invariant norm that measures the influence of observations in U on a vector of parameter estimates (Cook 1977). In case of the fixed effects coefficients, let

$$\boldsymbol{\delta}_{(U)} = \hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(U)}$$

Then the MIXED procedure computes

$$D(\boldsymbol{\beta}) = \boldsymbol{\delta}'_{(U)} \widehat{\text{var}}[\hat{\boldsymbol{\beta}}]^{-} \boldsymbol{\delta}_{(U)} / \text{rank}(\mathbf{X})$$

where $\widehat{\text{var}}[\hat{\boldsymbol{\beta}}]^{-}$ is the matrix that results from sweeping $(\mathbf{X}'\mathbf{V}(\hat{\boldsymbol{\theta}})^{-1}\mathbf{X})^{-}$.

If \mathbf{V} is known, Cook's D can be calibrated according to a chi-square distribution with degrees of freedom equal to the rank of \mathbf{X} (Christensen, Pearson, and Johnson 1992). For estimated \mathbf{V} the calibration can be carried out according to an $F(\text{rank}(\mathbf{X}), n - \text{rank}(\mathbf{X}))$ distribution. To interpret D on a familiar scale, Cook (1979) and Cook and Weisberg (1982, p. 116) refer to the 50th percentile of the reference distribution. If D is equal to that percentile, then removing the points in U moves the fixed effects coefficient vector from the center of the confidence region to the 50% confidence ellipsoid (Myers 1990, p. 262).

In the case of iterative influence analysis, the MIXED procedure also computes a D -type statistic for the covariance parameters. If $\boldsymbol{\Gamma}$ is the asymptotic variance-covariance matrix of $\hat{\boldsymbol{\theta}}$, then MIXED computes

$$D_{\boldsymbol{\theta}} = (\hat{\boldsymbol{\theta}} - \hat{\boldsymbol{\theta}}_{(U)})' \hat{\boldsymbol{\Gamma}}^{-1} (\hat{\boldsymbol{\theta}} - \hat{\boldsymbol{\theta}}_{(U)})$$

DFFITS and MDFFITS

A DFFIT measures the change in predicted values due to removal of data points. If this change is standardized by the externally estimated standard error of the predicted value in the full data, the DFFITS statistic of Belsley, Kuh, and Welsch (1980, p. 15) results:

$$\text{DFFITS}_i = (\hat{y}_i - \hat{y}_{i(u)}) / \text{ese}(\hat{y}_i)$$

The MIXED procedure computes DFFITS when the EFFECT= or SIZE= modifiers of the INFLUENCE option are not in effect. In general, an external estimate of the estimated standard error is used. When $ITER > 0$, the estimate is

$$ese(\hat{y}_i) = \sqrt{\mathbf{x}'_i (\mathbf{X}'\mathbf{V}(\hat{\boldsymbol{\theta}}_{(u)})^{-1}\mathbf{X})^{-1} \mathbf{x}_i}$$

When $ITER=0$ and σ^2 is profiled, then

$$ese(\hat{y}_i) = \hat{\sigma}_{(u)} \sqrt{\mathbf{x}'_i (\mathbf{X}'\mathbf{V}(\hat{\boldsymbol{\theta}}^*)^{-1}\mathbf{X})^{-1} \mathbf{x}_i}$$

When the EFFECT=, SIZE=, or KEEP= modifiers are specified, the MIXED procedure computes a multivariate version suitable for the deletion of multiple data points. The statistic, termed MDFFITS after the MDFFIT statistic of Belsley, Kuh, and Welsch (1980, p. 32), is closely related to Cook's D . Consider the case $\mathbf{V} = \sigma^2\mathbf{V}(\boldsymbol{\theta}^*)$ so that

$$\text{var}[\hat{\boldsymbol{\beta}}] = \sigma^2 (\mathbf{X}'\mathbf{V}(\boldsymbol{\theta}^*)^{-1}\mathbf{X})^{-1}$$

and let $\widetilde{\text{var}}[\hat{\boldsymbol{\beta}}_{(U)}]$ be an estimate of $\text{var}[\hat{\boldsymbol{\beta}}_{(U)}]$ that does not use the observations in U . The MDFFITS statistic is then computed as

$$\text{MDFFITS}(\boldsymbol{\beta}) = \boldsymbol{\delta}'_{(U)} \widetilde{\text{var}}[\hat{\boldsymbol{\beta}}_{(U)}]^{-1} \boldsymbol{\delta}_{(U)} / \text{rank}(\mathbf{X})$$

If $ITER=0$ and σ^2 is profiled, then $\widetilde{\text{var}}[\hat{\boldsymbol{\beta}}_{(U)}]^{-1}$ is obtained by sweeping

$$\hat{\sigma}_{(U)}^2 (\mathbf{X}'_{(U)} \mathbf{V}_{(U)}(\hat{\boldsymbol{\theta}}^*)^{-1} \mathbf{X}_{(U)})^{-1}$$

The underlying idea is that if $\boldsymbol{\theta}^*$ were known, then

$$(\mathbf{X}'_{(U)} \mathbf{V}_{(U)}(\boldsymbol{\theta}^*)^{-1} \mathbf{X}_{(U)})^{-1}$$

would be $\text{var}[\hat{\boldsymbol{\beta}}]/\sigma^2$ in a generalized least squares regression with all but the data in U .

In the case of iterative influence analysis, $\widetilde{\text{var}}[\hat{\boldsymbol{\beta}}_{(U)}]$ is evaluated at $\hat{\boldsymbol{\theta}}_{(U)}$. Furthermore, a MDFFITS-type statistic is then computed for the covariance parameters:

$$\text{MDFFITS}(\boldsymbol{\theta}) = (\hat{\boldsymbol{\theta}} - \hat{\boldsymbol{\theta}}_{(U)})' \widetilde{\text{var}}[\hat{\boldsymbol{\theta}}_{(U)}]^{-1} (\hat{\boldsymbol{\theta}} - \hat{\boldsymbol{\theta}}_{(U)})$$

Covariance Ratio and Trace

These statistics depend on the availability of an external estimate of \mathbf{V} , or at least of σ^2 . Whereas Cook's D and MDFFITS measure the impact of data points on a vector of parameter estimates, the covariance-based statistics measure impact on their precision. Following Christensen, Pearson, and Johnson (1992), the MIXED procedure computes

$$\begin{aligned}\text{COVTRACE}(\boldsymbol{\beta}) &= |\text{trace}(\widehat{\text{var}}[\widehat{\boldsymbol{\beta}}]^{-1} \widehat{\text{var}}[\widehat{\boldsymbol{\beta}}_{(U)}]) - \text{rank}(\mathbf{X})| \\ \text{COVRATIO}(\boldsymbol{\beta}) &= \frac{\det_{n_s}(\widehat{\text{var}}[\widehat{\boldsymbol{\beta}}_{(U)}])}{\det_{n_s}(\widehat{\text{var}}[\widehat{\boldsymbol{\beta}}])}\end{aligned}$$

where $\det_{n_s}(\mathbf{M})$ denotes the determinant of the nonsingular part of matrix \mathbf{M} .

In the case of iterative influence analysis these statistics are also computed for the covariance parameter estimates. If q denotes the rank of $\widehat{\text{var}}[\widehat{\boldsymbol{\theta}}]$, then

$$\begin{aligned}\text{COVTRACE}(\boldsymbol{\theta}) &= |\text{trace}(\widehat{\text{var}}[\widehat{\boldsymbol{\theta}}]^{-1} \widehat{\text{var}}[\widehat{\boldsymbol{\theta}}_{(U)}]) - q| \\ \text{COVRATIO}(\boldsymbol{\theta}) &= \frac{\det_{n_s}(\widehat{\text{var}}[\widehat{\boldsymbol{\theta}}_{(U)}])}{\det_{n_s}(\widehat{\text{var}}[\widehat{\boldsymbol{\theta}}])}\end{aligned}$$

Likelihood Distances

The log-likelihood function l and restricted log-likelihood function l_R of the linear mixed model are given in the section “[Estimating G and R in the Mixed Model](#)” beginning on page 2737. Denote as $\boldsymbol{\psi}$ the collection of all parameters, i.e., the fixed effects $\boldsymbol{\beta}$ and the covariance parameters $\boldsymbol{\theta}$. Twice the difference between the (restricted) log-likelihood evaluated at the full-data estimates $\widehat{\boldsymbol{\psi}}$ and at the reduced-data estimates $\widehat{\boldsymbol{\psi}}_{(U)}$ is known as the (restricted) likelihood distance:

$$\begin{aligned}RLD_{(U)} &= 2\{l_R(\widehat{\boldsymbol{\psi}}) - l_R(\widehat{\boldsymbol{\psi}}_{(U)})\} \\ LD_{(U)} &= 2\{l(\widehat{\boldsymbol{\psi}}) - l(\widehat{\boldsymbol{\psi}}_{(U)})\}\end{aligned}$$

Cook and Weisberg (1982, Ch. 5.2) refer to these differences as *likelihood distances*, Beckman, Nachtsheim, and Cook (1987) term the measures *likelihood displacements*. If the number of elements in $\boldsymbol{\psi}$ that are subject to updating following point removal is q , then likelihood displacements can be compared against cutoffs from a chi-square distribution with q degrees of freedom. Notice that this reference distribution does not depend on the number of observations removed from the analysis, but rather on the number of model parameters that are updated. The likelihood displacement gives twice the amount by which the log-likelihood of the full data changes if one were to utilize an estimate based on fewer data points. It is thus a global, summary measure of the influence of the observations in U jointly on all parameters.

Unless METHOD=ML, the MIXED procedure computes the likelihood displacement based on the residual (=restricted) log likelihood, even if METHOD=MIVQUE0 or METHOD=TYPE1, TYPE2, or TYPE3.

Noniterative Update Formulas

Update formulas that do not require refitting of the model are available for the cases where $\mathbf{V} = \sigma^2\mathbf{I}$, \mathbf{V} is known, or \mathbf{V}^* is known. When ITER=0 and these update formulas can be invoked, the MIXED procedure uses the computational devices that are outlined in the following paragraphs. It is then assumed that the variance-covariance matrix of the fixed effects has the form $(\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^-$. When DDFM=KENWARDROGER, this is not the case; the estimated variance-covariance matrix is then inflated to better represent the uncertainty in the estimated covariance parameters. Influence statistics when DDFM=KENWARDROGER should iteratively update the covariance parameters (ITER > 0). The dependence of \mathbf{V} on θ is suppressed in the sequel for brevity.

Updating the Fixed Effects

Denote by \mathbf{U} the $(n \times k)$ matrix that is assembled from k columns of the identity matrix. Each column of \mathbf{U} corresponds to the removal of one data point. The point being targeted by the i th column of \mathbf{U} corresponds to the row in which a 1 appears. Furthermore, define

$$\begin{aligned}\mathbf{\Omega} &= (\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^- \\ \mathbf{Q} &= \mathbf{X}\mathbf{\Omega}\mathbf{X}' \\ \mathbf{P} &= \mathbf{V}^{-1}(\mathbf{V} - \mathbf{Q})\mathbf{V}^{-1}\end{aligned}$$

The change in the fixed effects estimates following removal of the observations in U is

$$\hat{\beta} - \hat{\beta}_{(U)} = \mathbf{\Omega}\mathbf{X}'\mathbf{V}^{-1}\mathbf{U}(\mathbf{U}'\mathbf{P}\mathbf{U})^{-1}\mathbf{U}'\mathbf{V}^{-1}(\mathbf{y} - \mathbf{X}\hat{\beta})$$

Using results in Cook and Weisberg (1982, A2) you can further compute

$$\tilde{\mathbf{\Omega}} = (\mathbf{X}'_{(U)}\mathbf{V}_{(U)}^{-1}\mathbf{X}_{(U)})^- = \mathbf{\Omega} + \mathbf{\Omega}\mathbf{X}'\mathbf{V}^{-1}\mathbf{U}(\mathbf{U}'\mathbf{P}\mathbf{U})^{-1}\mathbf{U}'\mathbf{V}^{-1}\mathbf{X}\mathbf{\Omega}$$

If \mathbf{X} is $(n \times p)$ of rank $m < p$, then $\mathbf{\Omega}$ is deficient in rank and the MIXED procedure computes needed quantities in $\tilde{\mathbf{\Omega}}$ by sweeping (Goodnight 1979). If the rank of the $(k \times k)$ matrix $\mathbf{U}'\mathbf{P}\mathbf{U}$ is less than k , the removal of the observations introduces a new singularity, whether \mathbf{X} is of full rank or not. The solution vectors $\hat{\beta}$ and $\hat{\beta}_{(U)}$ then do not have the same expected values and should not be compared. When the MIXED procedure encounters this situation, influence diagnostics that depend on the choice of generalized inverse are not computed. The procedure also monitors the singularity criteria when sweeping the rows of $(\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^-$ and of $(\mathbf{X}'_{(U)}\mathbf{V}_{(U)}^{-1}\mathbf{X}_{(U)})^-$. If a new singularity is encountered or a former singularity disappears, no influence statistics are computed.

Residual Variance

When σ^2 is profiled out of the marginal variance-covariance matrix, a closed-form estimate of σ^2 that is based on only the remaining observations can be computed provided $\mathbf{V}^* = \mathbf{V}(\hat{\boldsymbol{\theta}}^*)$ is known. Hurtado (1993, Thm. 5.2) shows that

$$(n - q - r)\hat{\sigma}_{(U)}^2 = (n - q)\hat{\sigma}^2 - \hat{\boldsymbol{\epsilon}}_U'(\hat{\sigma}^2\mathbf{U}'\mathbf{P}\mathbf{U})^{-1}\hat{\boldsymbol{\epsilon}}_U$$

and $\hat{\boldsymbol{\epsilon}}_U = \mathbf{U}'\mathbf{V}^{*-1}(\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}})$. In the case of maximum likelihood estimation $q = 0$ and for REML estimation $q = \text{rank}(\mathbf{X})$. The constant r equals the rank of $(\mathbf{U}'\mathbf{P}\mathbf{U})$ for REML estimation and the number of effective observations that are removed if METHOD=ML.

Likelihood Distances

For noniterative methods the following computational devices are used to compute (restricted) likelihood distances provided that the residual variance σ^2 is profiled.

The log-likelihood function $l(\hat{\boldsymbol{\theta}})$ evaluated at the full-data and reduced-data estimates can be written as

$$\begin{aligned} l(\hat{\boldsymbol{\psi}}) &= -\frac{n}{2}\log(\hat{\sigma}^2) - \frac{1}{2}\log|\mathbf{V}^*| - \frac{1}{2}(\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}})'\mathbf{V}^{*-1}(\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}})/\hat{\sigma}^2 \\ &\quad - \frac{n}{2}\log(2\pi) \\ l(\hat{\boldsymbol{\psi}}_{(U)}) &= -\frac{n}{2}\log(\hat{\sigma}_{(U)}^2) - \frac{1}{2}\log|\mathbf{V}^*| \\ &\quad - \frac{1}{2}(\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}_{(U)})'\mathbf{V}^{*-1}(\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}_{(U)})/\hat{\sigma}_{(U)}^2 - \frac{n}{2}\log(2\pi) \end{aligned}$$

Notice that $l(\hat{\boldsymbol{\theta}}_{(U)})$ evaluates the log-likelihood for n data points at the reduced-data estimates. It is not the log-likelihood obtained by fitting the model to the reduced data. The likelihood distance is then

$$LD_{(U)} = n \log\left\{\frac{\hat{\sigma}_{(U)}^2}{\hat{\sigma}^2}\right\} - n + (\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}_{(U)})'\mathbf{V}^{*-1}(\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}_{(U)})/\hat{\sigma}_{(U)}^2$$

Expressions for $RLD_{(U)}$ in noniterative influence analysis are derived along the same lines.

Computational Issues

Computational Method

In addition to numerous matrix-multiplication routines, PROC MIXED frequently uses the sweep operator (Goodnight 1979) and the Cholesky root (Golub and Van Loan 1989). The routines perform a modified W transformation (Goodnight and Hemmerle 1979) for **G**-side likelihood calculations and a direct method for **R**-side likelihood calculations. For the Type III *F*-tests, PROC MIXED uses the algorithm described in Chapter 32, “The GLM Procedure.”

PROC MIXED uses a ridge-stabilized Newton-Raphson algorithm to optimize either a full (ML) or residual (REML) likelihood function. The Newton-Raphson algorithm is preferred to the EM algorithm (Lindstrom and Bates 1988). PROC MIXED profiles the likelihood with respect to the fixed effects and also with respect to the residual variance whenever it appears reasonable to do so. The residual profiling can be avoided by using the NOPROFILE option of the PROC MIXED statement. PROC MIXED uses the MIVQUE0 method (Rao 1972; Giesbrecht 1989) to compute initial values.

The likelihoods that PROC MIXED optimizes are usually well-defined continuous functions with a single optimum. The Newton-Raphson algorithm typically performs well and finds the optimum in a few iterations. It is a quadratically converging algorithm, meaning that the error of the approximation near the optimum is squared at each iteration. The quadratic convergence property is evident when the convergence criterion drops to zero by factors of 10 or more.

Table 46.12. Notation for Order Calculations

Symbol	Number
p	columns of \mathbf{X}
g	columns of \mathbf{Z}
N	observations
q	covariance parameters
t	maximum observations per subject
S	subjects

Using the notation from Table 46.12, the following are estimates of the computational speed of the algorithms used in PROC MIXED. For likelihood calculations, the crossproducts matrix construction is of order $N(p+g)^2$ and the sweep operations are of order $(p+g)^3$. The first derivative calculations for parameters in \mathbf{G} are of order qg^3 for ML and $q(g^3 + pg^2 + p^2g)$ for REML. If you specify a subject effect in the RANDOM statement and if you are not using the REPEATED statement, then replace g by g/S and q by qS in these calculations. The first derivative calculations for parameters in \mathbf{R} are of order $qS(t^3 + gt^2 + g^2t)$ for ML and $qS(t^3 + (p+g)t^2 + (p^2 + g^2)t)$ for REML. For the second derivatives, replace q by $q(q+1)/2$ in the first derivative expressions. When you specify both \mathbf{G} - and \mathbf{R} -side parameters (that is, when you use both the RANDOM and REPEATED statements), then additional calculations are required of an order equal to the sum of the orders for \mathbf{G} and \mathbf{R} . Considerable execution times may result in this case.

For further details about the computational techniques used in PROC MIXED, refer to Wolfinger, Tobias, and Sall (1994).

Parameter Constraints

By default, some covariance parameters are assumed to satisfy certain boundary constraints during the Newton-Raphson algorithm. For example, variance components are constrained to be nonnegative and autoregressive parameters are constrained to be between -1 and 1 . You can remove these constraints with the NOBOUND option in the PARMs statement, but this may lead to estimates that produce an infinite likelihood. You can also introduce or change boundary constraints with the LOWERB= and UPPERB= options in the PARMs statement.

During the Newton-Raphson algorithm, a parameter may be set equal to one of its boundary constraints for a few iterations and then it may move away from the boundary. You see a missing value in the Criterion column of the “Iteration History” table whenever a boundary constraint is dropped.

For some data sets the final estimate of a parameter may equal one of its boundary constraints. This is usually not a cause for concern, but it may lead you to consider a different model. For instance, a variance component estimate can equal zero; in this case, you may want to drop the corresponding random effect from the model. However, be aware that changing the model in this fashion can impact degrees of freedom calculations.

Convergence Problems

For some data sets, the Newton-Raphson algorithm can fail to converge. Non-convergence can result from a number of causes, including flat or ridged likelihood surfaces and ill-conditioned data.

It is also possible for PROC MIXED to converge to a point that is not the global optimum of the likelihood, although this usually occurs only with the spatial covariance structures.

If you experience convergence problems, the following points may be helpful:

- One useful tool is the PARMs statement, which lets you input initial values for the covariance parameters and performs a grid search over the likelihood surface.
- Sometimes the Newton-Raphson algorithm does not perform well when two of the covariance parameters are on a different scale; that is, they are several orders of magnitude apart. This is because the Hessian matrix is processed jointly for the two parameters, and elements of it corresponding to one of the parameters can become close to internal tolerances in PROC MIXED. In this case, you can improve stability by rescaling the effects in the model so that the covariance parameters are on the same scale.
- Data that is extremely large or extremely small can adversely affect results because of the internal tolerances in PROC MIXED. Rescaling it can improve stability.
- For stubborn problems, you may want to specify ODS OUTPUT COVPARMS= data-set-name to output the “CovParms” table as a precautionary measure. That way, if the problem does not converge, you can read the final parameter values back into a new run with the PARMsDATA= option in the PARMs statement.
- Fisher scoring can be more robust than Newton-Raphson to poor MIVQUE(0) starting values. Specifying a SCORING= value of 5 or so may help to recover from poor starting values.
- Tuning the singularity options SINGULAR=, SINGCHOL=, and SINGRES= in the MODEL statement may improve the stability of the optimization process.

- Tuning the MAXITER= and MAXFUNC= options in the PROC MIXED statement can save resources. Also, the ITDETAILS option displays the values of all of the parameters at each iteration.
- Using the NOPROFILE and NOBOUND options in the PROC MIXED statement may help convergence, although they can produce unusual results.
- Although the CONVH convergence criterion usually gives the best results, you may want to try CONVF or CONVG, possibly along with the ABSOLUTE option.
- If the convergence criterion bottoms out at a relatively small value such as $1E-7$ but never gets less than $1E-8$, you may want to specify CONVH= $1E-6$ in the PROC MIXED statement to get results; however, interpret the results with caution.
- An infinite likelihood during the iteration process means that the Newton-Raphson algorithm has stepped into a region where either the \mathbf{R} or \mathbf{V} matrix is nonpositive definite. This is usually no cause for concern as long as iterations continue. If PROC MIXED stops because of an infinite likelihood, recheck your model to make sure that no observations from the same subject are producing identical rows in \mathbf{R} or \mathbf{V} and that you have enough data to estimate the particular covariance structure you have selected. Any time that the final estimated likelihood is infinite, subsequent results should be interpreted with caution.
- A nonpositive definite Hessian matrix can indicate a surface saddlepoint or linear dependencies among the parameters.
- A warning message about the singularities of \mathbf{X} changing indicates that there is some linear dependency in the estimate of $\mathbf{X}'\hat{\mathbf{V}}^{-1}\mathbf{X}$ that is not found in $\mathbf{X}'\mathbf{X}$. This can adversely affect the likelihood calculations and optimization process. If you encounter this problem, make sure that your model specification is reasonable and that you have enough data to estimate the particular covariance structure you have selected. Rearranging effects in the MODEL statement so that the most significant ones are first can help because PROC MIXED sweeps the estimate of $\mathbf{X}'\mathbf{V}^{-1}\mathbf{X}$ in the order of the MODEL effects and the sweep is more stable if larger pivots are dealt with first. If this does not help, specifying starting values with the PARMS statement can place the optimization on a different and possibly more stable path.
- Lack of convergence may indicate model misspecification or a violation of the normality assumption.

Memory

Let p be the number of columns in \mathbf{X} , and let g be the number of columns in \mathbf{Z} . For large models, most of the memory resources are required for holding symmetric matrices of order p , g , and $p + g$. The approximate memory requirement in bytes is

$$40(p^2 + g^2) + 32(p + g)^2$$

If you have a large model that exceeds the memory capacity of your computer, see the suggestions listed under “Computing Time.”

Computing Time

PROC MIXED is computationally intensive, and execution times can be long. In addition to the CPU time used in collecting sums and cross products and in solving the mixed model equations (as in PROC GLM), considerable CPU time is often required to compute the likelihood function and its derivatives. These latter computations are performed for every Newton-Raphson iteration.

If you have a model that takes too long to run, the following suggestions may be helpful:

- Examine the “Model Information” table to find out the number of columns in the **X** and **Z** matrices. A large number of columns in either matrix can greatly increase computing time. You may want to eliminate some higher order effects if they are too large.
- If you have a **Z** matrix with a lot of columns, use the **DDFM=BW** option in the MODEL statement to eliminate the time required for the containment method.
- If possible, “factor out” a common effect from the effects in the RANDOM statement and make it the **SUBJECT=** effect. This creates a block-diagonal **G** matrix and can often speed calculations.
- If possible, use the same or nested **SUBJECT=** effects in all RANDOM and REPEATED statements.
- If your data set is very large, you may want to analyze it in pieces. The **BY** statement can help implement this strategy.
- In general, specify random effects with a lot of levels in the REPEATED statement and those with a few levels in the RANDOM statement.
- The **METHOD=MIVQUE0** option runs faster than either the **METHOD=REML** or **METHOD=ML** option because it is noniterative.
- You can specify known values for the covariance parameters using the **HOLD=** or **NOITER** option in the PARMS statement or the **GDATA=** option in the RANDOM statement. This eliminates the need for iteration.
- The **LOGNOTE** option in the PROC MIXED statement writes periodic messages to the SAS log concerning the status of the calculations. It can help you diagnose where the slow down is occurring.

Examples

The following are basic examples of the use of PROC MIXED. More examples and details can be found in Littell et al. (1996), Wolfinger (1997), Verbeke and Molenberghs (1997, 2000), Murray (1998), Singer (1998), Sullivan, Dukes, and Losina (1999), and Brown and Prescott (1999).

Example 46.1. Split-Plot Design

PROC MIXED can fit a variety of mixed models. One of the most common mixed models is the split-plot design. The split-plot design involves two experimental factors, **A** and **B**. Levels of **A** are randomly assigned to whole plots (main plots), and levels of **B** are randomly assigned to split plots (subplots) within each whole plot. The design provides more precise information about **B** than about **A**, and it often arises when **A** can be applied only to large experimental units. An example is where **A** represents irrigation levels for large plots of land and **B** represents different crop varieties planted in each large plot.

Consider the following data from Stroup (1989a), which arise from a balanced split-plot design with the whole plots arranged in a randomized complete-block design. The variable **A** is the whole-plot factor, and the variable **B** is the subplot factor. A traditional analysis of these data involves the construction of the whole-plot error (**A*Block**) to test **A** and the pooled residual error (**B*Block** and **A*B*Block**) to test **B** and **A*B**. To carry out this analysis with PROC GLM, you must use a TEST statement to obtain the correct *F*-test for **A**.

Performing a mixed model analysis with PROC MIXED eliminates the need for the error term construction. PROC MIXED estimates variance components for **Block**, **A*Block**, and the residual, and it automatically incorporates the correct error terms into test statistics.

```

data sp;
  input Block A B Y @@;
  datalines;
1 1 1 56 1 1 2 41
1 2 1 50 1 2 2 36
1 3 1 39 1 3 2 35
2 1 1 30 2 1 2 25
2 2 1 36 2 2 2 28
2 3 1 33 2 3 2 30
3 1 1 32 3 1 2 24
3 2 1 31 3 2 2 27
3 3 1 15 3 3 2 19
4 1 1 30 4 1 2 25
4 2 1 35 4 2 2 30
4 3 1 17 4 3 2 18
;

```

```

proc mixed;
  class A B Block;
  model Y = A B A*B;
  random Block A*Block;
run;

```

The variables **A**, **B**, and **Block** are listed as classification variables in the **CLASS** statement. The columns of model matrix **X** consist of indicator variables corresponding to the levels of the fixed effects **A**, **B**, and **A*B** listed on the right-hand side in the **MODEL** statement. The dependent variable **Y** is listed on the left-hand side in the **MODEL** statement.

The columns of the model matrix **Z** consist of indicator variables corresponding to the levels of the random effects **Block** and **A*Block**. The **G** matrix is diagonal and contains the variance components of **Block** and **A*Block**. The **R** matrix is also diagonal and contains the residual variance.

The SAS code produces [Output 46.1.1](#).

Output 46.1.1. Split-Plot Example

The Mixed Procedure	
Model Information	
Data Set	WORK.SP
Dependent Variable	Y
Covariance Structure	Variance Components
Estimation Method	REML
Residual Variance Method	Profile
Fixed Effects SE Method	Model-Based
Degrees of Freedom Method	Containment

The “Model Information” table lists basic information about the split-plot model. REML is used to estimate the variance components, and the residual variances are profiled out of the optimization.

The Mixed Procedure		
Class Level Information		
Class	Levels	Values
A	3	1 2 3
B	2	1 2
Block	4	1 2 3 4

The “Class Level Information” table lists the levels of all variables specified in the **CLASS** statement. You can check this table to make sure that the data are correct.

The Mixed Procedure	
Dimensions	
Covariance Parameters	3
Columns in X	12
Columns in Z	16
Subjects	1
Max Obs Per Subject	24

The “Dimensions” table lists the magnitudes of various vectors and matrices. The **X** matrix is seen to be 24×12 , and the **Z** matrix is 24×16 .

The Mixed Procedure	
Number of Observations	
Number of Observations Read	24
Number of Observations Used	24
Number of Observations Not Used	0

The “Number of Observations” table shows that all observations read from the data set are used in the analysis.

The Mixed Procedure				
Iteration History				
Iteration	Evaluations	-2 Res	Log Like	Criterion
0	1	139.81461222		
1	1	119.76184570		0.00000000
Convergence criteria met.				

PROC MIXED estimates the variance components for **Block**, **A*Block**, and the residual by REML. The REML estimates are the values that maximize the likelihood of a set of linearly independent error contrasts, and they provide a correction for the downward bias found in the usual maximum likelihood estimates. The objective function is -2 times the logarithm of the restricted likelihood, and PROC MIXED minimizes this objective function to obtain the estimates.

The minimization method is the Newton-Raphson algorithm, which uses the first and second derivatives of the objective function to iteratively find its minimum. The “Iteration History” table records the steps of that optimization process. For this example, only one iteration is required to obtain the estimates. The Evaluations column reveals that the restricted likelihood is evaluated once for each of the iterations. A criterion of 0 indicates that the Newton-Raphson algorithm has converged.

The Mixed Procedure	
Covariance Parameter Estimates	
Cov Parm	Estimate
Block	62.3958
A*Block	15.3819
Residual	9.3611

The REML estimates for the variance components of Block, A*Block, and the residual are 62.40, 15.38, and 9.36, respectively, as listed in the Estimate column of the “Covariance Parameter Estimates” table.

The Mixed Procedure	
Fit Statistics	
-2 Res Log Likelihood	119.8
AIC (smaller is better)	125.8
AICC (smaller is better)	127.5
BIC (smaller is better)	123.9

The “Fitting Information” table lists several pieces of information about the fitted mixed model, including the residual log likelihood. Akaike’s and Schwarz’s criteria can be used to compare different models; the ones with smaller values are preferred.

The Mixed Procedure				
Type 3 Tests of Fixed Effects				
Effect	Num DF	Den DF	F Value	Pr > F
A	2	6	4.07	0.0764
B	1	9	19.39	0.0017
A*B	2	9	4.02	0.0566

Finally, the fixed effects are tested using Type III estimable functions. The tests match the one obtained from the following PROC GLM code:

```
proc glm data=sp;
  class A B Block;
  model Y = A B A*B Block A*Block;
  test h=A e=A*Block;
run;
```

You can continue this analysis by producing solutions for the fixed and random effects and then testing various linear combinations of them by using the CONTRAST

and ESTIMATE statements. If you use the same CONTRAST and ESTIMATE statements with PROC GLM, the test statistics correspond to the fixed-effects-only model. The test statistics from PROC MIXED incorporate the random effects.

The various “inference space” contrasts given by Stroup (1989a) can be implemented via the ESTIMATE statement. Consider the following examples:

```
estimate 'a1 mean narrow'
  intercept 1 A 1 B .5 .5 A*B .5 .5 |
  Block      .25 .25 .25 .25
  A*Block    .25 .25 .25 .25 0 0 0 0 0 0 0 0;

estimate 'a1 mean intermed'
  intercept 1 A 1 B .5 .5 A*B .5 .5 |
  Block      .25 .25 .25 .25;

estimate 'a1 mean broad'
  intercept 1 a 1 b .5 .5 A*B .5 .5;
```

These statements result in [Output 46.1.2](#).

Output 46.1.2. Inference Space Results

The Mixed Procedure					
Estimates					
Label	Estimate	Standard Error	DF	t Value	Pr > t
a1 mean narrow	32.8750	1.0817	9	30.39	<.0001
a1 mean intermed	32.8750	2.2396	9	14.68	<.0001
a1 mean broad	32.8750	4.5403	9	7.24	<.0001

Note that all the estimates are equal, but their standard errors increase with the size of the inference space. The narrow inference space consists of the observed levels of **Block** and **A*Block**, and the *t*-statistic value of 30.39 applies only to these levels. This is the same *t*-statistic computed by PROC GLM, because it computes standard errors from the narrow inference space. The intermediate inference space consists of the observed levels of **Block** and the entire population of levels from which **A*Block** are sampled. The *t*-statistic value of 14.68 applies to this intermediate space. The broad inference space consists of arbitrary random levels of both **Block** and **A*Block**, and the *t*-statistic value of 7.24 is appropriate. Note that the larger the inference space, the weaker the conclusion. However, the broad inference space is usually the one of interest, and even in this space conclusive results are common. The highly significant *p*-value for 'a1 mean broad' is an example. You can also obtain the 'a1 mean broad' result by specifying **A** in an LSMEANS statement. For more discussion of the inference space concept, refer to McLean, Sanders, and Stroup (1991).

The following statements illustrate another feature of the RANDOM statement. Recall that the basic code for a split-plot design with whole plots arranged in randomized blocks is as follows.

```
proc mixed;
  class A B Block;
  model Y = A B A*B;
  random Block A*Block;
run;
```

An equivalent way of specifying this model is

```
proc mixed data=sp;
  class A B Block;
  model Y = A B A*B;
  random intercept A / subject=Block;
run;
```

In general, if all of the effects in the RANDOM statement can be nested within one effect, you can specify that one effect using the SUBJECT= option. The subject effect is, in a sense, “factored out” of the random effects. The specification using the SUBJECT= effect can result in quicker execution times for large problems because PROC MIXED is able to perform the likelihood calculations separately for each subject.

Example 46.2. Repeated Measures

The following data are from Pothoff and Roy (1964) and consist of growth measurements for 11 girls and 16 boys at ages 8, 10, 12, and 14. Some of the observations are suspect (for example, the third observation for person 20); however, all of the data are used here for comparison purposes.

The analysis strategy employs a linear growth curve model for the boys and girls as well as a variance-covariance model that incorporates correlations for all of the observations arising from the same person. The data are assumed to be Gaussian, and their likelihood is maximized to estimate the model parameters. Refer to Jennrich and Schluchter (1986), Louis (1988), Crowder and Hand (1990), Diggle, Liang, and Zeger (1994), and Everitt (1995) for overviews of this approach to repeated measures. Jennrich and Schluchter present results for the Pothoff and Roy data from various covariance structures. The PROC MIXED code to fit an unstructured variance matrix (their Model 2) is as follows:

```

data pr;
  input Person Gender $ y1 y2 y3 y4;
  y=y1; Age=8; output;
  y=y2; Age=10; output;
  y=y3; Age=12; output;
  y=y4; Age=14; output;
  drop y1-y4;
  datalines;
1  F  21.0  20.0  21.5  23.0
2  F  21.0  21.5  24.0  25.5
3  F  20.5  24.0  24.5  26.0
4  F  23.5  24.5  25.0  26.5
5  F  21.5  23.0  22.5  23.5
6  F  20.0  21.0  21.0  22.5
7  F  21.5  22.5  23.0  25.0
8  F  23.0  23.0  23.5  24.0
9  F  20.0  21.0  22.0  21.5
10 F  16.5  19.0  19.0  19.5
11 F  24.5  25.0  28.0  28.0
12 M  26.0  25.0  29.0  31.0
13 M  21.5  22.5  23.0  26.5
14 M  23.0  22.5  24.0  27.5
15 M  25.5  27.5  26.5  27.0
16 M  20.0  23.5  22.5  26.0
17 M  24.5  25.5  27.0  28.5
18 M  22.0  22.0  24.5  26.5
19 M  24.0  21.5  24.5  25.5
20 M  23.0  20.5  31.0  26.0
21 M  27.5  28.0  31.0  31.5
22 M  23.0  23.0  23.5  25.0
23 M  21.5  23.5  24.0  28.0
24 M  17.0  24.5  26.0  29.5
25 M  22.5  25.5  25.5  26.0
26 M  23.0  24.5  26.0  30.0
27 M  22.0  21.5  23.5  25.0
;

proc mixed data=pr method=ml covtest;
  class Person Gender;
  model y = Gender Age Gender*Age / s;
  repeated / type=un subject=Person r;
run;

```

To follow Jennrich and Schluchter, this example uses maximum likelihood (METHOD=ML) instead of the default REML to estimate the unknown covariance parameters. The COVTEST option requests asymptotic tests of all of the covariance parameters.

The MODEL statement first lists the dependent variable Y. The fixed effects are then listed after the equals sign. The variable **Gender** requests a different intercept for the girls and boys, **Age** models an overall linear growth trend, and **Gender*Age** makes the slopes different over time. It is actually not necessary to specify **Age** separately, but doing so enables PROC MIXED to carry out a test for heterogeneous slopes. The **S** option requests the display of the fixed-effects solution vector.

The REPEATED statement contains no effects, taking advantage of the default assumption that the observations are ordered similarly for each subject. The TYPE=UN option requests an unstructured block for each SUBJECT=Person. The R matrix is, therefore, block diagonal with 27 blocks, each block consisting of identical 4×4 unstructured matrices. The 10 parameters of these unstructured blocks make up the covariance parameters estimated by maximum likelihood. The R option requests that the first block of R be displayed.

The results from this analysis are shown in [Output 46.2.1](#).

Output 46.2.1. Repeated Measures with Unstructured Covariance Matrix

The Mixed Procedure	
Model Information	
Data Set	WORK.PR
Dependent Variable	Y
Covariance Structure	Unstructured
Subject Effect	Person
Estimation Method	ML
Residual Variance Method	None
Fixed Effects SE Method	Model-Based
Degrees of Freedom Method	Between-Within

The covariance structure is listed as “Unstructured” here, and no residual variance is used with this structure. The default degrees-of-freedom method here is “Between-Within.”

The Mixed Procedure			
Class Level Information			
Class	Levels	Values	
Person	27	1 2 3 4 5 6 7 8 9 10 11 12 13	14 15 16 17 18 19 20 21 22 23
		24 25 26 27	
Gender	2	F M	

Note that Person has 27 levels and Gender has 2.

The Mixed Procedure	
Dimensions	
Covariance Parameters	10
Columns in X	6
Columns in Z	0
Subjects	27
Max Obs Per Subject	4

The 10 covariance parameters result from the 4×4 unstructured blocks of \mathbf{R} . There is no \mathbf{Z} matrix for this model, and each of the 27 subjects has a maximum of 4 observations.

The Mixed Procedure	
Number of Observations	
Number of Observations Read	108
Number of Observations Used	108
Number of Observations Not Used	0

The Mixed Procedure			
Iteration History			
Iteration	Evaluations	-2 Log Like	Criterion
0	1	478.24175986	
1	2	419.47721707	0.00000152
2	1	419.47704812	0.00000000
Convergence criteria met.			

Three Newton-Raphson iterations are required to find the maximum likelihood estimates. The default relative Hessian criterion has a final value less than $1\text{E}-8$, indicating the convergence of the Newton-Raphson algorithm and the attainment of an optimum.

The Mixed Procedure				
Estimated R Matrix for Person 1				
Row	Col1	Col2	Col3	Col4
1	5.1192	2.4409	3.6105	2.5222
2	2.4409	3.9279	2.7175	3.0624
3	3.6105	2.7175	5.9798	3.8235
4	2.5222	3.0624	3.8235	4.6180

The preceding 4×4 matrix is the estimated unstructured covariance matrix. It is the estimate of the first block of \mathbf{R} , and the other 26 blocks all have the same estimate.

The Mixed Procedure					
Covariance Parameter Estimates					
Cov Parm	Subject	Estimate	Standard Error	Z Value	Pr > Z
UN(1,1)	Person	5.1192	1.4169	3.61	0.0002
UN(2,1)	Person	2.4409	0.9835	2.48	0.0131
UN(2,2)	Person	3.9279	1.0824	3.63	0.0001
UN(3,1)	Person	3.6105	1.2767	2.83	0.0047
UN(3,2)	Person	2.7175	1.0740	2.53	0.0114
UN(3,3)	Person	5.9798	1.6279	3.67	0.0001
UN(4,1)	Person	2.5222	1.0649	2.37	0.0179
UN(4,2)	Person	3.0624	1.0135	3.02	0.0025
UN(4,3)	Person	3.8235	1.2508	3.06	0.0022
UN(4,4)	Person	4.6180	1.2573	3.67	0.0001

The preceding table lists the 10 estimated covariance parameters in order; note their correspondence to the first block of **R** displayed previously. The parameter estimates are labeled according to their location in the block in the Cov Parm column, and all of these estimates are associated with **Person** as the subject effect. The Std Error column lists approximate standard errors of the covariance parameters obtained from the inverse Hessian matrix. These standard errors lead to approximate Wald Z-statistics, which are compared with the standard normal distribution. The results of these tests indicate that all the parameters are significantly different from 0; however, the Wald test can be unreliable in small samples.

To carry out Wald tests of various linear combinations of these parameters, use the following procedure. First, run the code again, adding the **ASYCOV** option and an **ODS** statement:

```
ods output CovParms=cp AsyCov=asy;
proc mixed data=pr method=ml covtest asycov;
  class Person Gender;
  model y = Gender Age Gender*Age / s;
  repeated / type=un subject=Person r;
run;
```

This creates two data sets, **cp** and **asy**, which contain the covariance parameter estimates and their asymptotic variance covariance matrix, respectively. Then read these data sets into the SAS/IML matrix programming language as follows:

```
proc iml;
  use cp;
  read all var {Estimate} into est;
  use asy;
  read all var ('CovP1':'CovP10') into asy;
```

You can then construct your desired linear combinations and corresponding quadratic forms with the **asy** matrix.

The Mixed Procedure		
Fit Statistics		
-2 Log Likelihood		419.5
AIC (smaller is better)		447.5
AICC (smaller is better)		452.0
BIC (smaller is better)		465.6
Null Model Likelihood Ratio Test		
DF	Chi-Square	Pr > ChiSq
9	58.76	<.0001

The null model likelihood ratio test (LRT) is highly significant for this model, indicating that the unstructured covariance matrix is preferred to the diagonal one of the ordinary least-squares null model. The degrees of freedom for this test is 9, which is the difference between 10 and the 1 parameter for the null model's diagonal matrix.

The Mixed Procedure						
Solution for Fixed Effects						
Effect	Gender	Estimate	Standard Error	DF	t Value	Pr > t
Intercept		15.8423	0.9356	25	16.93	<.0001
Gender	F	1.5831	1.4658	25	1.08	0.2904
Gender	M	0
Age		0.8268	0.07911	25	10.45	<.0001
Age*Gender	F	-0.3504	0.1239	25	-2.83	0.0091
Age*Gender	M	0

The preceding table lists the solution vector for the fixed effects. The estimate of the boys' intercept is 15.84, while that for the girls is $15.84 + 1.58 = 17.42$. Similarly, the estimate for the boys' slope is 0.827, while that for the girls is $0.827 - 0.350 = 0.477$. Thus the girls' starting point is larger than that for the boys, but their growth rate is about half that of the boys.

Note that two of the estimates equal 0; this is a result of the overparameterized model used by PROC MIXED. You can obtain a full-rank parameterization by using the following MODEL statement:

```
model y = Gender Gender*Age / noint s;
```

Here, the NOINT option causes the different intercepts to be fit directly as the two levels of Gender. However, this alternative specification results in different tests for these effects.

The Mixed Procedure				
Type 3 Tests of Fixed Effects				
Effect	Num DF	Den DF	F Value	Pr > F
Gender	1	25	1.17	0.2904
Age	1	25	110.54	<.0001
Age*Gender	1	25	7.99	0.0091

The “Type 3 Tests of Fixed Effects” table displays Type III tests for all of the fixed effects. These tests are partial in the sense that they account for all of the other fixed effects in the model. In addition, you can use the HTYPE= option in the MODEL statement to obtain Type I (sequential) or Type II (also partial) tests of effects.

It is usually best to consider higher-order terms first, and in this case the **Age*Gender** test reveals a difference between the slopes that is statistically significant at the 1% level. Note that the p -value for this test (0.0091) is the same as the p -value in the “Age*Gender F” row in the “Solution for Fixed Effects” table and that the F -statistic (7.99) is the square of the t -statistic (-2.83), ignoring rounding error. Similar connections are evident among the other rows in these two tables.

The **Age** test is one for an overall growth curve accounting for possible heterogeneous slopes, and it is highly significant. Finally, the **Gender** row tests the null hypothesis of a common intercept, and this hypothesis cannot be rejected from these data.

As an alternative to the F -tests shown here, you can carry out likelihood ratio tests of various hypotheses by fitting the reduced models, subtracting $-2 \log$ likelihoods, and comparing the resulting statistics with χ^2 distributions.

Since the different levels of the repeated effect represent different years, it is natural to try fitting a time series model to the data within each subject. To obtain time series structures in **R**, you can replace TYPE=UN with TYPE=AR(1) or TYPE=TOEP to obtain the first- or n th-order autoregressive covariance matrices, respectively. For example, the code to fit an AR(1) structure is

```
proc mixed data=pr method=ml;
  class Person Gender;
  model y = Gender Age Gender*Age / s;
  repeated / type=ar(1) sub=Person r;
run;
```

To fit a random coefficients model, use the following code:

```

proc mixed data=pr method=ml;
  class Person Gender;
  model y = Gender Age Gender*Age / s;
  random intercept Age / type=un sub=Person g;
run;

```

This specifies an unstructured covariance matrix for the random intercept and slope. In mixed model notation, \mathbf{G} is block diagonal with identical 2×2 unstructured blocks for each person. By default, \mathbf{R} becomes $\sigma^2 \mathbf{I}$. See [Example 46.5](#) for further information on this model.

Finally, you can fit a compound symmetry structure by using `TYPE=CS`.

```

proc mixed data=pr method=ml covtest;
  class Person Gender;
  model y = Gender Age Gender*Age / s;
  repeated / type=cs subject=Person r;
run;

```

The results from this analysis are shown in [Output 46.2.2](#).

Output 46.2.2. Repeated Measures with Compound Symmetry Structure

The Mixed Procedure	
Model Information	
Data Set	WORK.PR
Dependent Variable	Y
Covariance Structure	Compound Symmetry
Subject Effect	Person
Estimation Method	ML
Residual Variance Method	Profile
Fixed Effects SE Method	Model-Based
Degrees of Freedom Method	Between-Within

The “Model Information” table is the same as before except for the change in “Covariance Structure.”

Class		Levels	Values
Person	27		1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18 19 20 21 22 23 24 25 26 27
Gender	2		F M

Dimensions	
Covariance Parameters	2
Columns in X	6
Columns in Z	0
Subjects	27
Max Obs Per Subject	4

Number of Observations	
Number of Observations Read	108
Number of Observations Used	108
Number of Observations Not Used	0

The compound symmetry structure has two parameters.

The Mixed Procedure			
Iteration History			
Iteration	Evaluations	-2 Log Like	Criterion
0	1	478.24175986	
1	1	428.63905802	0.00000000

Convergence criteria met.

Since the data are balanced, only one step is required to find the estimates.

The Mixed Procedure				
Estimated R Matrix for Person 1				
Row	Col1	Col2	Col3	Col4
1	4.9052	3.0306	3.0306	3.0306
2	3.0306	4.9052	3.0306	3.0306
3	3.0306	3.0306	4.9052	3.0306
4	3.0306	3.0306	3.0306	4.9052

Note the compound symmetry structure here, which consists of a common covariance with a diagonal enhancement.

The Mixed Procedure					
Covariance Parameter Estimates					
Cov Parm	Subject	Estimate	Standard Error	Z Value	Pr Z
CS	Person	3.0306	0.9552	3.17	0.0015
Residual		1.8746	0.2946	6.36	<.0001

The common covariance is estimated to be 3.0306, as listed in the CS row of the preceding table, and the residual variance is estimated to be 1.8746, as listed in the Residual row. You can use these two numbers to estimate the intraclass correlation coefficient (ICC) for this model. Here, the ICC estimate equals $3.0306 / (3.0306 + 1.8746) = 0.6178$. You can also obtain this number by adding the RCORR option to the REPEATED statement.

The Mixed Procedure	
Fit Statistics	
-2 Log Likelihood	428.6
AIC (smaller is better)	440.6
AICC (smaller is better)	441.5
BIC (smaller is better)	448.4
Null Model Likelihood Ratio Test	
DF	Chi-Square Pr > ChiSq
1	49.60 <.0001

In this case, the null model LRT has only one degree of freedom, corresponding to the common covariance parameter. The test indicates that modeling this extra covariance is superior to fitting the simple null model.

The Mixed Procedure						
Solution for Fixed Effects						
Effect	Gender	Estimate	Standard Error	DF	t Value	Pr > t
Intercept		16.3406	0.9631	25	16.97	<.0001
Gender	F	1.0321	1.5089	25	0.68	0.5003
Gender	M	0
Age		0.7844	0.07654	79	10.25	<.0001
Age*Gender	F	-0.3048	0.1199	79	-2.54	0.0130
Age*Gender	M	0

Note that the fixed effects estimates and their standard errors are not very different from those in the preceding unstructured example.

The Mixed Procedure				
Type 3 Tests of Fixed Effects				
Effect	Num DF	Den DF	F Value	Pr > F
Gender	1	25	0.47	0.5003
Age	1	79	111.10	<.0001
Age*Gender	1	79	6.46	0.0130

The F -tests are also similar to those from the preceding unstructured example. Again, the slopes are significantly different but the intercepts are not.

You can fit the same compound symmetry model with the following specification using the RANDOM statement:

```
proc mixed data=pr method=ml;
  class Person Gender;
  model y = Gender Age Gender*Age / s;
  random Person;
run;
```

Compound symmetry is the structure that Jennrich and Schluchter deemed best among the ones they fit. To carry the analysis one step further, you can use the GROUP= option to specify heterogeneity of this structure across girls and boys.

```
proc mixed data=pr method=ml;
  class Person Gender;
  model y = Gender Age Gender*Age / s;
  repeated / type=cs subject=Person group=Gender;
run;
```

The results from this analysis are shown in [Output 46.2.3](#).

Output 46.2.3. Repeated Measures with Heterogeneous Structures

The Mixed Procedure	
Model Information	
Data Set	WORK.PR
Dependent Variable	Y
Covariance Structure	Compound Symmetry
Subject Effect	Person
Group Effect	Gender
Estimation Method	ML
Residual Variance Method	None
Fixed Effects SE Method	Model-Based
Degrees of Freedom Method	Between-Within

Note that Gender is listed as a “Group Effect.”

The Mixed Procedure	
Class Level Information	
Class	Levels Values
Person	27 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18 19 20 21 22 23 24 25 26 27
Gender	2 F M
Dimensions	
Covariance Parameters	4
Columns in X	6
Columns in Z	0
Subjects	27
Max Obs Per Subject	4
Number of Observations	
Number of Observations Read	108
Number of Observations Used	108
Number of Observations Not Used	0

The four covariance parameters result from the two compound symmetry structures corresponding to the two levels of Gender.

The Mixed Procedure			
Iteration History			
Iteration	Evaluations	-2 Log Like	Criterion
0	1	478.24175986	
1	1	408.81297228	0.00000000

Convergence criteria met.

Even with the heterogeneity, only one iteration is required for convergence.

The Mixed Procedure			
Covariance Parameter Estimates			
Cov Parm	Subject	Group	Estimate
Variance	Person	Gender F	0.5900
CS	Person	Gender F	3.8804
Variance	Person	Gender M	2.7577
CS	Person	Gender M	2.4463

The preceding table lists the heterogeneous estimates. Note that both the common covariance and the diagonal enhancement differ between girls and boys.

The Mixed Procedure	
Fit Statistics	
-2 Log Likelihood	408.8
AIC (smaller is better)	424.8
AICC (smaller is better)	426.3
BIC (smaller is better)	435.2

Null Model Likelihood Ratio Test		
DF	Chi-Square	Pr > ChiSq
3	69.43	<.0001

Both Akaike's Information Criterion (424.8) and Schwarz's Bayesian Criterion (435.2) are smaller for this model than for the homogeneous compound symmetry model (440.6 and 448.4, respectively). This indicates that the heterogeneous model is more appropriate. To construct the likelihood ratio test between the two models, subtract the -2 log likelihood values: $428.6 - 408.8 = 19.8$. Comparing this value with the χ^2 distribution with two degrees of freedom yields a p -value less than 0.0001, again favoring the heterogeneous model.

The Mixed Procedure						
Solution for Fixed Effects						
Effect	Gender	Estimate	Standard Error	DF	t Value	Pr > t
Intercept		16.3406	1.1130	25	14.68	<.0001
Gender	F	1.0321	1.3890	25	0.74	0.4644
Gender	M	0
Age		0.7844	0.09283	79	8.45	<.0001
Age*Gender	F	-0.3048	0.1063	79	-2.87	0.0053
Age*Gender	M	0

Note that the fixed effects estimates are the same as in the homogeneous case, but the standard errors are different.

The Mixed Procedure				
Type 3 Tests of Fixed Effects				
Effect	Num DF	Den DF	F Value	Pr > F
Gender	1	25	0.55	0.4644
Age	1	79	141.37	<.0001
Age*Gender	1	79	8.22	0.0053

The fixed effects tests are similar to those from previous models, although the *p*-values do change as a result of specifying a different covariance structure. It is important for you to select a reasonable covariance structure in order to obtain valid inferences for your fixed effects.

Example 46.3. Plotting the Likelihood

The data for this example are from Hemmerle and Hartley (1973) and are also used as an example for the VARCOMP procedure. The response variable consists of measurements from an oven experiment, and the model contains a fixed effect A and random effects B and A*B.

The SAS code is as follows:

```

data hh;
  input a b y @@;
  datalines;
1 1 237 1 1 254 1 1 246
1 2 178 1 2 179
2 1 208 2 1 178 2 1 187
2 2 146 2 2 145 2 2 141
3 1 186 3 1 183
3 2 142 3 2 125 3 2 136
;

```

```
ods output ParmSearch=parms;
proc mixed data=hh asycov mmeq mmeqsol covtest;
  class a b;
  model y = a / outp=predicted;
  random b a*b;
  lsmeans a;
  parms (17 to 20 by .1) (.3 to .4 by .005) (1.0);
run;

proc print data=predicted;
run;
```

The ASYCOV option in the PROC statement requests the asymptotic variance matrix of the covariance parameter estimates. This matrix is the observed inverse Fisher information matrix, which equals $2\mathbf{H}^{-1}$, where \mathbf{H} is the Hessian matrix of the objective function evaluated at the final covariance parameter estimates. The MMEQ and MMEQSOL options in the PROC statement request that the mixed model equations and their solution be displayed.

The OUTP= option in the MODEL statement produces the data set predicted, containing the predicted values. Least-squares means (LSMEANS) are requested for A. The PARMs and ODS statements are used to construct a data set containing the likelihood surface.

The results from this analysis are shown in [Output 46.3.1](#).

Output 46.3.1. Plotting the Likelihood

The Mixed Procedure	
Model Information	
Data Set	WORK.HH
Dependent Variable	Y
Covariance Structure	Variance Components
Estimation Method	REML
Residual Variance Method	Profile
Fixed Effects SE Method	Model-Based
Degrees of Freedom Method	Containment

The “Model Information” table lists details about this variance components model.

The Mixed Procedure		
Class Level Information		
Class	Levels	Values
a	3	1 2 3
b	2	1 2

The “Class Level Information” table lists the levels for A and B.

The Mixed Procedure	
Dimensions	
Covariance Parameters	3
Columns in X	4
Columns in Z	8
Subjects	1
Max Obs Per Subject	16
Number of Observations	
Number of Observations Read	16
Number of Observations Used	16
Number of Observations Not Used	0

The “Dimensions” table reveals that **X** is 16×4 and **Z** is 16×8 . Since there are no SUBJECT= effects, PROC MIXED considers the data effectively to be from one subject with 16 observations.

The Mixed Procedure					
Parameter Search					
CovP1	CovP2	CovP3	Variance	Res Log Like	-2 Res Log Like
17.0000	0.3000	1.0000	80.1400	-52.4699	104.9399

20.0000	0.3950	1.0000	77.5871	-52.4699	104.9399
20.0000	0.4000	1.0000	77.5148	-52.4703	104.9406

Only a portion of the “Parameter Search” table is shown because the full listing has 651 rows.

The Mixed Procedure				
Iteration History				
Iteration	Evaluations	-2 Res	Log Like	Criterion
1	2	104.93416367		0.00000000
Convergence criteria met.				

Convergence is quick because PROC MIXED starts from the best value from the grid search.

The Mixed Procedure				
Covariance Parameter Estimates				
Cov Parm	Estimate	Standard Error	Z Value	Pr > Z
b	1464.36	2098.01	0.70	0.2426
a*b	26.9581	59.6570	0.45	0.3257
Residual	78.8426	35.3512	2.23	0.0129

The preceding table lists the variance components estimates. Note that B is much more variable than A*B.

The Mixed Procedure				
Asymptotic Covariance Matrix of Estimates				
Row	Cov Parm	CovP1	CovP2	CovP3
1	b	4401640	1.2831	-273.32
2	a*b	1.2831	3558.96	-502.84
3	Residual	-273.32	-502.84	1249.71

The asymptotic covariance matrix also reflects the large variability of B relative to A*B.

The Mixed Procedure	
Fit Statistics	
-2 Res Log Likelihood	104.9
AIC (smaller is better)	110.9
AICC (smaller is better)	113.6
BIC (smaller is better)	107.0
PARMS Model Likelihood Ratio Test	
DF	Chi-Square
2	0.00
Pr > ChiSq	
	1.0000

The PARMS likelihood ratio test (LRT) compares the best model from the grid search with the final fitted model. Since these models are nearly the same, the LRT is not significant.

The Mixed Procedure										
Mixed Model Equations										
Row	Effect	a	b	Col1	Col2	Col3	Col4	Col5	Col6	Col7

10	2	2	145	142.330	4.70076	10	0.05	131.856	152.804	2.6703
11	2	2	141	142.330	4.70076	10	0.05	131.856	152.804	-1.3297
12	3	1	186	185.687	5.52589	10	0.05	173.374	197.999	0.3134
13	3	1	183	185.687	5.52589	10	0.05	173.374	197.999	-2.6866
14	3	2	142	133.542	4.72563	10	0.05	123.013	144.072	8.4578
15	3	2	125	133.542	4.72563	10	0.05	123.013	144.072	-8.5422
16	3	2	136	133.542	4.72563	10	0.05	123.013	144.072	2.4578

The preceding output lists the predicted values from the model. These values are the sum of the fixed effects estimates and the empirical best linear unbiased predictors (EBLUPs) of the random effects. It is often useful to plot predicted values and residuals to assess the adequacy of the model, using another SAS procedure to generate plots and diagnostic measures.

To plot the likelihood surface using the G3D procedure from SAS/GRAPH software, use the following source:

```
proc g3d data=parms;
  plot CovP1*CovP2 = ResLogLike
    / ctop=red cbottom=blue caxis=black;
run;
```

The results from this plot are shown in [Output 46.3.2](#). The peak of the surface is the REML estimates for the B and A*B variance components.

Output 46.3.2. Plot of Likelihood Surface

Example 46.4. Known G and R

This animal breeding example from Henderson (1984, p. 53) considers multiple traits. The data are artificial and consist of measurements of two traits on three animals, but the second trait of the third animal is missing. Assuming an additive genetic model, you can use PROC MIXED to predict the breeding value of both traits on all three animals and also to predict the second trait of the third animal. The data are as follows:

```
data h;
  input Trait Animal Y;
  datalines;
  1 1 6
  1 2 8
  1 3 7
  2 1 9
  2 2 5
  2 3 .
  ;
```

Both **G** and **R** are known.

$$\mathbf{G} = \begin{bmatrix} 2 & 1 & 1 & 2 & 1 & 1 \\ 1 & 2 & .5 & 1 & 2 & .5 \\ 1 & .5 & 2 & 1 & .5 & 2 \\ 2 & 1 & 1 & 3 & 1.5 & 1.5 \\ 1 & 2 & .5 & 1.5 & 3 & .75 \\ 1 & .5 & 2 & 1.5 & .75 & 3 \end{bmatrix}$$

$$\mathbf{R} = \begin{bmatrix} 4 & 0 & 0 & 1 & 0 & 0 \\ 0 & 4 & 0 & 0 & 1 & 0 \\ 0 & 0 & 4 & 0 & 0 & 1 \\ 1 & 0 & 0 & 5 & 0 & 0 \\ 0 & 1 & 0 & 0 & 5 & 0 \\ 0 & 0 & 1 & 0 & 0 & 5 \end{bmatrix}$$

In order to read **G** into PROC MIXED using the GDATA= option in the RANDOM statement, perform the following DATA step:

```
data g;
  input Row Col1-Col6;
  datalines;
1 2 1 1 2 1 1
2 1 2 .5 1 2 .5
3 1 .5 2 1 .5 2
4 2 1 1 3 1.5 1.5
5 1 2 .5 1.5 3 .75
6 1 .5 2 1.5 .75 3
;
```

The preceding data are in the dense representation for a GDATA= data set. You can also construct a data set with the sparse representation using Row, Col, and Value variables, although this would require 21 observations instead of 6 for this example.

The PROC MIXED code is as follows:

```
proc mixed data=h mmeq mmeqsol;
  class Trait Animal;
  model Y = Trait / noint s outp=predicted;
  random Trait*Animal / type=un gdata=g g gi s;
  repeated / type=un sub=Animal r ri;
  parms (4) (1) (5) / noiter;
run;

proc print data=predicted;
run;
```

The MMEQ and MMEQSOL options request the mixed model equations and their solution. The variables Trait and Animal are classification variables, and Trait defines

the entire \mathbf{X} matrix for the fixed-effects portion of the model, since the intercept is omitted with the NOINT option. The fixed-effects solution vector and predicted values are also requested using the S and OUTP= options, respectively.

The random effect Trait*Animal leads to a \mathbf{Z} matrix with six columns, the first five corresponding to the identity matrix and the last consisting of 0s. An unstructured \mathbf{G} matrix is specified using the TYPE=UN option, and it is read into PROC MIXED from a SAS data set using the GDATA=G specification. The G and GI options request the display of \mathbf{G} and \mathbf{G}^{-1} , respectively. The S option requests that the random-effects solution vector be displayed.

Note that the preceding \mathbf{R} matrix is block diagonal if the data are sorted by animals. The REPEATED statement exploits this fact by requesting \mathbf{R} to have unstructured 2×2 blocks corresponding to animals, which are the subjects. The R and RI options request that the estimated 2×2 blocks for the first animal and its inverse be displayed. The PARMs statement lists the parameters of this 2×2 matrix. Note that the parameters from \mathbf{G} are not specified in the PARMs statement because they have already been assigned using the GDATA= option in the RANDOM statement. The NOITER option prevents PROC MIXED from computing residual (restricted) maximum likelihood estimates; instead, the known values are used for inferences.

The results from this analysis are shown in [Output 46.4.1](#).

Output 46.4.1. Known G and R

The Mixed Procedure	
Model Information	
Data Set	WORK.H
Dependent Variable	Y
Covariance Structure	Unstructured
Subject Effect	Animal
Estimation Method	REML
Residual Variance Method	None
Fixed Effects SE Method	Model-Based
Degrees of Freedom Method	Containment

The “Unstructured” covariance structure applies to both \mathbf{G} and \mathbf{R} here.

The Mixed Procedure		
Class Level Information		
Class	Levels	Values
Trait	2	1 2
Animal	3	1 2 3

The levels of Trait and Animal have been specified correctly.

The Mixed Procedure	
Dimensions	
Covariance Parameters	3
Columns in X	2
Columns in Z	6
Subjects	1
Max Obs Per Subject	6
Number of Observations	
Number of Observations Read	6
Number of Observations Used	5
Number of Observations Not Used	1

The three covariance parameters indicated here correspond to those from the **R** matrix. Those from **G** are considered fixed and known because of the GDATA= option.

The Mixed Procedure				
Parameter Search				
CovP1	CovP2	CovP3	Res Log Like	-2 Res Log Like
4.0000	1.0000	5.0000	-7.3731	14.7463

The preceding table results from the PARMs statement.

The Mixed Procedure			
Estimated R Matrix for Subject 1			
Row	Col1	Col2	
1	4.0000	1.0000	
2	1.0000	5.0000	

The block of \mathbf{R} corresponding to the first animal is shown in the “Estimated R Matrix” table.

The Mixed Procedure		
Estimated Inv(R) Matrix for Subject 1		
Row	Col1	Col2
1	0.2632	-0.05263
2	-0.05263	0.2105

The inverse of the block of \mathbf{R} corresponding to the first animal is shown in the preceding table.

The Mixed Procedure							
Estimated G Matrix							
Row	Effect	Trait	Animal	Col1	Col2	Col3	Col4
1	Trait*Animal	1	1	2.0000	1.0000	1.0000	2.0000
2	Trait*Animal	1	2	1.0000	2.0000	0.5000	1.0000
3	Trait*Animal	1	3	1.0000	0.5000	2.0000	1.0000
4	Trait*Animal	2	1	2.0000	1.0000	1.0000	3.0000
5	Trait*Animal	2	2	1.0000	2.0000	0.5000	1.5000
6	Trait*Animal	2	3	1.0000	0.5000	2.0000	1.5000

Estimated G Matrix		
Row	Col15	Col16
1	1.0000	1.0000
2	2.0000	0.5000
3	0.5000	2.0000
4	1.5000	1.5000
5	3.0000	0.7500
6	0.7500	3.0000

The preceding table lists the \mathbf{G} matrix as specified in the GDATA= data set.

The Mixed Procedure							
Estimated Inv(G) Matrix							
Row	Effect	Trait	Animal	Col1	Col2	Col3	Col4
1	Trait*Animal	1	1	2.5000	-1.0000	-1.0000	-1.6667
2	Trait*Animal	1	2	-1.0000	2.0000		0.6667
3	Trait*Animal	1	3	-1.0000		2.0000	0.6667
4	Trait*Animal	2	1	-1.6667	0.6667	0.6667	1.6667
5	Trait*Animal	2	2	0.6667	-1.3333		-0.6667
6	Trait*Animal	2	3	0.6667		-1.3333	-0.6667

Estimated Inv(G) Matrix			
Row	Col5	Col6	
1	0.6667	0.6667	
2	-1.3333		
3		-1.3333	
4	-0.6667	-0.6667	
5	1.3333		
6		1.3333	

The preceding table lists G^{-1} . The blank values correspond to zeros.

The Mixed Procedure		
Covariance Parameter Estimates		
Cov Parm	Subject	Estimate
UN(1,1)	Animal	4.0000
UN(2,1)	Animal	1.0000
UN(2,2)	Animal	5.0000

The parameters from R are listed again.

The Mixed Procedure	
Fit Statistics	
-2 Res Log Likelihood	14.7
AIC (smaller is better)	14.7
AICC (smaller is better)	14.7
BIC (smaller is better)	14.7

You can use this model-fitting information to compare this model with others.

The Mixed Procedure							
Mixed Model Equations							
Row	Effect	Trait	Animal	Col1	Col2	Col3	Col4
1	Trait	1		0.7763	-0.1053	0.2632	0.2632
2	Trait	2		-0.1053	0.4211	-0.05263	-0.05263
3	Trait*Animal	1	1	0.2632	-0.05263	2.7632	-1.0000
4	Trait*Animal	1	2	0.2632	-0.05263	-1.0000	2.2632
5	Trait*Animal	1	3	0.2500		-1.0000	
6	Trait*Animal	2	1	-0.05263	0.2105	-1.7193	0.6667
7	Trait*Animal	2	2	-0.05263	0.2105	0.6667	-1.3860
8	Trait*Animal	2	3			0.6667	

Mixed Model Equations					
Row	Col5	Col6	Col7	Col8	Col9
1	0.2500	-0.05263	-0.05263		4.6974
2		0.2105	0.2105		2.2105
3	-1.0000	-1.7193	0.6667	0.6667	1.1053
4		0.6667	-1.3860		1.8421
5	2.2500	0.6667		-1.3333	1.7500
6	0.6667	1.8772	-0.6667	-0.6667	1.5789
7		-0.6667	1.5439		0.6316
8	-1.3333	-0.6667		1.3333	

The coefficients of the mixed model equations agree with Henderson (1984, p. 55).

The Mixed Procedure							
Mixed Model Equations Solution							
Row	Effect	Trait	Animal	Col1	Col2	Col3	Col4
1	Trait	1		2.5508	1.5685	-1.3047	-1.1775
2	Trait	2		1.5685	4.5539	-1.4112	-1.3534
3	Trait*Animal	1	1	-1.3047	-1.4112	1.8282	1.0652
4	Trait*Animal	1	2	-1.1775	-1.3534	1.0652	1.7589
5	Trait*Animal	1	3	-1.1701	-0.9410	1.0206	0.7085
6	Trait*Animal	2	1	-1.3002	-2.1592	1.8010	1.0900
7	Trait*Animal	2	2	-1.1821	-2.1055	1.0925	1.7341
8	Trait*Animal	2	3	-1.1678	-1.3149	1.0070	0.7209

Mixed Model Equations Solution					
Row	Col5	Col6	Col7	Col8	Col9
1	-1.1701	-1.3002	-1.1821	-1.1678	6.9909
2	-0.9410	-2.1592	-2.1055	-1.3149	6.9959
3	1.0206	1.8010	1.0925	1.0070	0.05450
4	0.7085	1.0900	1.7341	0.7209	-0.04955
5	1.7812	1.0095	0.7197	1.7756	0.02230
6	1.0095	2.7518	1.6392	1.4849	0.2651
7	0.7197	1.6392	2.6874	0.9930	-0.2601
8	1.7756	1.4849	0.9930	2.7645	0.1276

The solution to the mixed model equations also matches that given by Henderson (1984, p. 55).

The Mixed Procedure						
Solution for Fixed Effects						
Effect	Trait	Estimate	Standard Error	DF	t Value	Pr > t
Trait	1	6.9909	1.5971	3	4.38	0.0221
Trait	2	6.9959	2.1340	3	3.28	0.0465

The estimates for the two traits are nearly identical, but the standard error of the second one is larger because of the missing observation.

The Mixed Procedure							
Solution for Random Effects							
Effect	Trait	Animal	Estimate	Std Err Pred	DF	t Value	Pr > t
Trait*Animal	1	1	0.05450	1.3521	0	0.04	.
Trait*Animal	1	2	-0.04955	1.3262	0	-0.04	.
Trait*Animal	1	3	0.02230	1.3346	0	0.02	.
Trait*Animal	2	1	0.2651	1.6589	0	0.16	.
Trait*Animal	2	2	-0.2601	1.6393	0	-0.16	.
Trait*Animal	2	3	0.1276	1.6627	0	0.08	.

The Estimate column lists the best linear unbiased predictions (BLUPs) of the breeding values of both traits for all three animals. The *p*-values are missing because the default containment method for computing degrees of freedom results in zero degrees of freedom for the random effects parameter tests.

The Mixed Procedure				
Type 3 Tests of Fixed Effects				
Effect	Num DF	Den DF	F Value	Pr > F
Trait	2	3	10.59	0.0437

The two estimated traits are significantly different from zero at the 5% level.

Obs	Trait	Animal	Y	Pred	StdErr		DF	Alpha	Lower	Upper	Resid
					Pred						
1	1	1	6	7.04542	1.33027		0	0.05	.	.	-1.04542
2	1	2	8	6.94137	1.39806		0	0.05	.	.	1.05863
3	1	3	7	7.01321	1.41129		0	0.05	.	.	-0.01321
4	2	1	9	7.26094	1.72839		0	0.05	.	.	1.73906
5	2	2	5	6.73576	1.74077		0	0.05	.	.	-1.73576
6	2	3	.	7.12015	2.99088		0	0.05	.	.	.

The preceding table contains the predicted values of the observations based on the trait and breeding value estimates, that is, the fixed and random effects. The predicted values are not the predictions of future records in the sense that they do not contain a component corresponding to a new observational error. Refer to Henderson (1984) for information on predicting future records. The L95 and U95 columns usually contain confidence limits for the predicted values; they are missing here because the random-effects parameter degrees of freedom equals 0.

Example 46.5. Random Coefficients

This example comes from a pharmaceutical stability data simulation performed by Obenchain (1990). The observed responses are replicate assay results, expressed in percent of label claim, at various shelf ages, expressed in months. The desired mixed model involves three batches of product that differ randomly in intercept (initial potency) and slope (degradation rate). This type of model is also known as a hierarchical or multilevel model (Singer 1998; Sullivan, Dukes, and Losina 1999).

The SAS code is as follows:

```

data rc;
  input Batch Month @@;
  Monthc = Month;
  do i = 1 to 6;
    input Y @@;
    output;
  end;
  datalines;
1 0 101.2 103.3 103.3 102.1 104.4 102.4
1 1 98.8 99.4 99.7 99.5 . .
1 3 98.4 99.0 97.3 99.8 . .
1 6 101.5 100.2 101.7 102.7 . .
1 9 96.3 97.2 97.2 96.3 . .
1 12 97.3 97.9 96.8 97.7 97.7 96.7
2 0 102.6 102.7 102.4 102.1 102.9 102.6
2 1 99.1 99.0 99.9 100.6 . .
2 3 105.7 103.3 103.4 104.0 . .
2 6 101.3 101.5 100.9 101.4 . .
2 9 94.1 96.5 97.2 95.6 . .
2 12 93.1 92.8 95.4 92.2 92.2 93.0

```

```

3  0  105.1 103.9 106.1 104.1 103.7 104.6
3  1  102.2 102.0 100.8  99.8      .      .
3  3  101.2 101.8 100.8 102.6      .      .
3  6  101.1 102.0 100.1 100.2      .      .
3  9  100.9  99.5 102.2 100.8      .      .
3 12   97.8  98.3  96.9  98.4  96.9  96.5
;

proc mixed data=rc;
  class Batch;
  model Y = Month / s;
  random Int Month / type=un sub=Batch s;
run;

```

In the DATA step, `Monthc` is created as a duplicate of `Month` in order to enable both a continuous and classification version of the same variable. The variable `Monthc` is used in a subsequent [analysis](#) on page 2814.

In the PROC MIXED code, `Batch` is listed as the only classification variable. The fixed effect `Month` in the MODEL statement is not declared a classification variable; thus it models a linear trend in time. An intercept is included as a fixed effect by default, and the `S` option requests that the fixed-effects parameter estimates be produced.

The two RANDOM effects are `Int` and `Month`, modeling random intercepts and slopes, respectively. Note that `Intercept` and `Month` are used as both fixed and random effects. The `TYPE=UN` option in the RANDOM statement specifies an unstructured covariance matrix for the random intercept and slope effects. In mixed model notation, **G** is block diagonal with unstructured 2×2 blocks. Each block corresponds to a different level of `Batch`, which is the SUBJECT= effect. The unstructured type provides a mechanism for estimating the correlation between the random coefficients. The `S` option requests the production of the random-effects parameter estimates.

The results from this analysis are shown in [Output 46.5.1](#).

Output 46.5.1. Random Coefficients Analysis

The Mixed Procedure	
Model Information	
Data Set	WORK.RC
Dependent Variable	Y
Covariance Structure	Unstructured
Subject Effect	Batch
Estimation Method	REML
Residual Variance Method	Profile
Fixed Effects SE Method	Model-Based
Degrees of Freedom Method	Containment

The “Unstructured” covariance structure applies to **G** here.

The Mixed Procedure			
Class Level Information			
Class	Levels	Values	
Batch	3	1	2 3

Batch is the only classification variable in this analysis, and it has three levels.

The Mixed Procedure	
Dimensions	
Covariance Parameters	4
Columns in X	2
Columns in Z Per Subject	2
Subjects	3
Max Obs Per Subject	36
Number of Observations	
Number of Observations Read	108
Number of Observations Used	84
Number of Observations Not Used	24

The “Dimensions” table indicates that there are three subjects (corresponding to batches). The 24 observations not used correspond to the missing values of Y in the input data set.

The Mixed Procedure				
Iteration History				
Iteration	Evaluations	-2 Res	Log Like	Criterion
0	1	367.02768461		
1	1	350.32813577		0.00000000
Convergence criteria met.				

Only one iteration is required for convergence.

The Mixed Procedure		
Covariance Parameter Estimates		
Cov Parm	Subject	Estimate
UN(1,1)	Batch	0.9768
UN(2,1)	Batch	-0.1045
UN(2,2)	Batch	0.03717
Residual		3.2932

The estimated elements of the unstructured 2×2 matrix comprising the blocks of G are listed in the Estimate column. Note that the random coefficients are negatively correlated.

The Mixed Procedure		
Fit Statistics		
-2 Res Log Likelihood		350.3
AIC (smaller is better)		358.3
AICC (smaller is better)		358.8
BIC (smaller is better)		354.7
Null Model Likelihood Ratio Test		
DF	Chi-Square	Pr > ChiSq
3	16.70	0.0008

The null model likelihood ratio test indicates a significant improvement over the null model consisting of no random effects and a homogeneous residual error.

The Mixed Procedure					
Solution for Fixed Effects					
Effect	Estimate	Standard Error	DF	t Value	Pr > t
Intercept	102.70	0.6456	2	159.08	<.0001
Month	-0.5259	0.1194	2	-4.41	0.0478

The fixed effects estimates represent the estimated means for the random intercept and slope, respectively.

The Mixed Procedure						
Solution for Random Effects						
Effect	Batch	Estimate	Std Err Pred	DF	t Value	Pr > t
Intercept	1	-1.0010	0.6842	78	-1.46	0.1474
Month	1	0.1287	0.1245	78	1.03	0.3047
Intercept	2	0.3934	0.6842	78	0.58	0.5669
Month	2	-0.2060	0.1245	78	-1.65	0.1021
Intercept	3	0.6076	0.6842	78	0.89	0.3772
Month	3	0.07731	0.1245	78	0.62	0.5365

The random effects estimates represent the estimated deviation from the mean intercept and slope for each batch. Therefore, the intercept for the first batch is close to $102.7 - 1 = 101.7$, while the intercepts for the other two batches are greater than 102.7. The second batch has a slope less than the mean slope of -0.526 , while the other two batches have slopes larger than -0.526 .

The Mixed Procedure				
Type 3 Tests of Fixed Effects				
Effect	Num DF	Den DF	F Value	Pr > F
Month	1	2	19.41	0.0478

The F -statistic in the “Type 3 Tests of Fixed Effects” table is the square of the t -statistic used in the test of Month in the preceding “Solution for Fixed Effects” table. Both statistics test the null hypothesis that the slope assigned to Month equals 0, and this hypothesis can barely be rejected at the 5% level.

It is also possible to fit a random coefficients model with error terms that follow a nested structure (Fuller and Battese 1973). The following SAS code represents one way of doing this:

```
proc mixed data=rc;
  class Batch Monthc;
  model Y = Month / s;
  random Int Month Monthc / sub=Batch s;
run;
```

The variable Monthc is added to the CLASS and RANDOM statements, and it models the nested errors. Note that Month and Monthc are continuous and classification versions of the same variable. Also, the TYPE=UN option is dropped from the RANDOM statement, resulting in the default variance components model instead of correlated random coefficients.

The results from this analysis are shown in [Output 46.5.2](#).

Output 46.5.2. Random Coefficients with Nested Errors Analysis

The Mixed Procedure			
Model Information			
Data Set		WORK.RC	
Dependent Variable		Y	
Covariance Structure		Variance Components	
Subject Effect		Batch	
Estimation Method		REML	
Residual Variance Method		Profile

Number of Observations Not Used			24
Iteration History			
Iteration	Evaluations	-2 Res Log Like	Criterion
0	1	367.02768461	
1	4	277.51945360	.
2	1	276.97551718	0.00104208
3	1	276.90304909	0.00003174
4	1	276.90100316	0.00000004
5	1	276.90100092	0.00000000
Convergence criteria met.			
Covariance Parameter Estimates			
Cov Parm	Subject	Estimate	
Intercept	Batch	0	
Month	Batch	0.01243	
Monthc	Batch	3.7411	
Residual		0.7969	

For this analysis, the Newton-Raphson algorithm requires five iterations and nine likelihood evaluations to achieve convergence. The missing value in the Criterion column in iteration 1 indicates that a boundary constraint has been dropped.

The estimate for the **Intercept** variance component equals 0. This occurs frequently in practice and indicates that the restricted likelihood is maximized by setting this variance component equal to 0. Whenever a zero variance component estimate occurs, the following note appears in the SAS log:

NOTE: Estimated G matrix is not positive definite.

The remaining variance component estimates are positive, and the estimate corresponding to the nested errors (MONTHC) is much larger than the other two.

The Mixed Procedure	
Fit Statistics	
-2 Res Log Likelihood	276.9
AIC (smaller is better)	282.9
AICC (smaller is better)	283.2
BIC (smaller is better)	280.2

A comparison of AIC and BIC for this model with those of the previous model favors the nested error model. Strictly speaking, a likelihood ratio test cannot be carried out between the two models because one is not contained in the other; however, a cautious comparison of likelihoods can be informative.

The Mixed Procedure					
Solution for Fixed Effects					
Effect	Estimate	Standard Error	DF	t Value	Pr > t
Intercept	102.56	0.7287	2	140.74	<.0001
Month	-0.5003	0.1259	2	-3.97	0.0579

The better-fitting covariance model impacts the standard errors of the fixed effects parameter estimates more than the estimates themselves.

The Mixed Procedure							
Solution for Random Effects							
Effect	Batch	Monthc	Estimate	Std Err Pred	DF	t Value	Pr > t

Monthc	2	3	3.1063	0.6865	66	4.53	<.0001
Monthc	2	6	2.0649	0.7328	66	2.82	0.0064
Monthc	2	9	-1.4450	0.9300	66	-1.55	0.1250
Monthc	2	12	-2.4405	1.1992	66	-2.04	0.0459
Intercept	3		0
Month	3		0.07600	0.09268	66	0.82	0.4152
Monthc	3	0	1.9574	0.7896	66	2.48	0.0157
Monthc	3	1	-0.8850	0.7571	66	-1.17	0.2466
Monthc	3	3	0.3006	0.6865	66	0.44	0.6629
Monthc	3	6	0.7972	0.7328	66	1.09	0.2806
Monthc	3	9	2.0059	0.9300	66	2.16	0.0347
Monthc	3	12	0.002293	1.1992	66	0.00	0.9985

The random effects solution provides the empirical best linear unbiased predictions (EBLUPs) for the realizations of the random intercept, slope, and nested errors. You can use these values to compare batches and months.

The Mixed Procedure				
Type 3 Tests of Fixed Effects				
Effect	Num DF	Den DF	F Value	Pr > F
Month	1	2	15.78	0.0579

The test of Month is similar to that from the previous model, although it is no longer significant at the 5% level.

Example 46.6. Line-Source Sprinkler Irrigation

These data appear in Hanks et al. (1980), Johnson, Chaudhuri, and Kanemasu (1983), and Stroup (1989b). Three cultivars (Cult) of winter wheat are randomly assigned to rectangular plots within each of three blocks (Block). The nine plots are located side-by-side, and a line-source sprinkler is placed through the middle. Each plot is subdivided into twelve subplots, six to the north of the line-source, six to the south (Dir). The two plots closest to the line-source represent the maximum irrigation level

(Irrig=6), the two next-closest plots represent the next-highest level (Irrig=5), and so forth.

This example is a case where both **G** and **R** can be modeled. One of Stroup's models specifies a diagonal **G** containing the variance components for **Block**, **Block*Dir**, and **Block*Irrig**, and a Toeplitz **R** with four bands. The SAS code to fit this model and carry out some further analyses follows.

Caution: This analysis may require considerable CPU time.

```

data line;
  length Cult$ 8;
  input Block Cult$ @;
  row = _n_;
  do Sbplt=1 to 12;
    if Sbplt le 6 then do;
      Irrig = Sbplt;
      Dir = 'North';
    end;
    else do;
      Irrig = 13 - Sbplt;
      Dir = 'South';
    end;
    input Y @; output;

run;

```

The preceding code uses the bar operator (|) and the at sign (@) to specify all two-factor interactions between Cult, Dir, and Irrig as fixed effects.

The RANDOM statement sets up the **Z** and **G** matrices corresponding to the random effects Block, Block*Dir, and Block*Irrig.

In the REPEATED statement, the TYPE=TOEP(4) option sets up the blocks of the **R** matrix to be Toeplitz with four bands below and including the main diagonal. The subject effect is Block(Cult), and it produces nine 12×12 blocks. The R option requests that the first block of **R** be displayed.

Least-squares means (LSMEANS) are requested for Cult, Irrig, and Cult*Irrig, and a few ESTIMATE statements are specified to illustrate some linear combinations of the fixed effects.

The results from this analysis are shown in [Output 46.6.1](#).

Output 46.6.1. Line-Source Sprinkler Irrigation Analysis

The Mixed Procedure	
Model Information	
Data Set	WORK.LINE
Dependent Variable	Y
Covariance Structures	Variance Components, Toeplitz
Subject Effect	Block*Cult
Estimation Method	REML

12		-0.09253	0.001452	0.007986	0.2850

The first block of the estimated **R** matrix has the TOEP(4) structure, and the observations that are three plots apart exhibit a negative correlation.

The Mixed Procedure		
Covariance Parameter Estimates		
Cov Parm	Subject	Estimate
Block		0.2194
Block*Dir		0.01768
Block*Irrig		0.03539
TOEP(2)	Block*Cult	0.007986
TOEP(3)	Block*Cult	0.001452
TOEP(4)	Block*Cult	-0.09253
Residual		0.2850

The preceding table lists the estimated covariance parameters from both **G** and **R**. The first three are the variance components making up the diagonal **G**, and the final four make up the Toeplitz structure in the blocks of **R**. The Residual row corresponds to the variance of the Toeplitz structure, and it was the parameter profiled out during the optimization process.

The Mixed Procedure	
Fit Statistics	
-2 Res Log Likelihood	183.2
AIC (smaller is better)	197.2
AICC (smaller is better)	198.8
BIC (smaller is better)	190.9

The “-2 Res Log Likelihood” value is the same as the final value listed in the “Iteration History” table.

The Mixed Procedure				
Type 3 Tests of Fixed Effects				
Effect	Num DF	Den DF	F Value	Pr > F
Cult	2	68	7.98	0.0008
Dir	1	2	3.95	0.1852
Cult*Dir	2	68	3.44	0.0379
Irrig	5	10	102.60	<.0001
Cult*Irrig	10	68	1.91	0.0580
Dir*Irrig	5	68	6.12	<.0001

Every fixed effect except for Dir and Cult*Irrig is significant at the 5% level.

The Mixed Procedure					
Estimates					
Label	Estimate	Standard Error	DF	t Value	Pr > t
Bridger vs Luke	-0.03889	0.09524	68	-0.41	0.6843
Linear Irrig	30.6444	1.4412	10	21.26	<.0001
B vs L x Linear Irrig	-9.8667	2.7400	68	-3.60	0.0006

The “Estimates” table lists the results from the various linear combinations of fixed effects specified in the ESTIMATE statements. Bridger is not significantly different from Luke, and Irrig possesses a strong linear component. This strength appears to be influencing the significance of the interaction.

The Mixed Procedure							
Least Squares Means

Cult*Irrig	Nugaines	6	6.2167	0.3697	68	16.81	<.0001

The LS-means are useful in comparing the levels of the various fixed effects. For example, it appears that irrigation levels 5 and 6 have virtually the same effect.

An interesting exercise is to try fitting other variance-covariance models to these data and comparing them to this one using likelihood ratio tests, Akaike's Information Criterion, or Schwarz's Bayesian Information Criterion. In particular, some spatial models are worth investigating (Marx and Thompson 1987; Zimmerman and Harville 1991). The following is one example of spatial model code.

```
proc mixed;
  class Block Cult Dir Irrig;
  model Y = Cult|Dir|Irrig@2;
  repeated / type=sp(pow)(Row Sbplt)
    sub=intercept;
run;
```

The TYPE=SP(POW)(ROW SBPLT) option in the REPEATED statement requests the spatial power structure, with the two defining coordinate variables being ROW and Sbplt. The SUB=INTERCEPT option indicates that the entire data set is to be considered as one subject, thereby modeling \mathbf{R} as a dense 108×108 covariance matrix. Refer to Wolfinger (1993) for further discussion of this example and additional analyses.

Example 46.7. Influence in Heterogeneous Variance Model (Experimental)

In this example from Snedecor and Cochran (1976, p. 256) a one-way classification model with heterogeneous variances is fit. The data represent amounts of different types of fat absorbed by batches of doughnuts during cooking, measured in grams.

```
data absorb;
  input FatType Absorbed @@;
  datalines;
  1 164 1 172 1 168 1 177 1 156 1 195
  2 178 2 191 2 197 2 182 2 185 2 177
  3 175 3 193 3 178 3 171 3 163 3 176
  4 155 4 166 4 149 4 164 4 170 4 168
  ;
```

The statistical model for these data can be written as

$$\begin{aligned}
 Y_{ij} &= \mu + \tau_i + \epsilon_{ij} \\
 i &= 1, \dots, t = 4 \\
 j &= 1, \dots, r = 6 \\
 \epsilon_{ij} &= (0, \sigma_i^2)
 \end{aligned}$$

where Y_{ij} is the amount of fat absorbed by the j th batch of the i th fat type, and τ_i denotes the fat-type effects. A quick glance at the data suggests that observations 6, 9, 14, and 21 might be influential on the analysis, because these are extreme observations for the respective fat types.

The following SAS statements fit this model and request influence diagnostics for the fixed effects and covariance parameters. The experimental ODS GRAPHICS statement requests plots of the influence diagnostics in addition to the tabular output. The ESTIMATE suboption requests plots of “leave-one-out” estimates for the fixed effects and group variances.

```
ods html;
ods graphics on;

proc mixed data=absorb asycov;
  class FatType;
  model Absorbed = FatType / s
          influence(iter=10 estimates);
  repeated / group=FatType;
  ods output Influence=inf;
run;

ods graphics off;
ods html close;
```

The “Influence” table is output to the SAS data set inf so that parameter estimates can be printed subsequently. Results from this analysis are shown in [Output 46.7.1](#).

Output 46.7.1. Heterogeneous Variance Analysis

Covariance Parameter Estimates						
	Cov Parm	Group	Estimate			
	Residual	FatType 1	178.00			
	Residual	FatType 2	60.4000			
	Residual	FatType 3	97.6000			
	Residual	FatType 4	67.6000			
Solution for Fixed Effects						
Effect	Fat Type	Estimate	Standard Error	DF	t Value	Pr > t
Intercept		162.00	3.3566	20	48.26	<.0001
FatType	1	10.0000	6.3979	20	1.56	0.1337
FatType	2	23.0000	4.6188	20	4.98	<.0001
FatType	3	14.0000	5.2472	20	2.67	0.0148
FatType	4	0

The variances in the four groups are shown in the “Covariance Parameter Estimates” table. The estimated variance in the first group is two to three times larger than the variance in the other groups.

The fixed effects solutions correspond to estimates of the following parameters:

- Intercept : $\mu + \tau_4$
- FatType 1 : $\tau_1 - \tau_4$
- FatType 2 : $\tau_2 - \tau_4$
- FatType 3 : $\tau_3 - \tau_4$
- FatType 4 : 0

You can easily verify that these estimates are simple functions of the arithmetic means \bar{y}_i in the groups. For example, $\widehat{\mu + \tau_4} = \bar{y}_4 = 162.0$, $\widehat{\tau_1 - \tau_4} = \bar{y}_1 - \bar{y}_4 = 10.0$,

and so forth. The covariance parameter estimates are the sample variances in the groups and are uncorrelated.

The Mixed Procedure					
Asymptotic Covariance Matrix of Estimates					
Row	Cov Parm	CovP1	CovP2	CovP3	CovP4
1	Residual	12674			
2	Residual		1459.26		
3	Residual			3810.30	
4	Residual				1827.90

The following statements print the “leave-one-out” estimates for fixed effects and covariance parameters that were written to the inf data set with the ESTIMATES suboption.

```
proc print data=inf label;
  var parm1-parm5 covp1-covp4;
run;
```

Output 46.7.2. Leave-One-Out Estimates

Obs	Intercept	Fat				Residual	Residual	Residual	Residual

The estimate of the intercept is affected only when observations from the last group are removed. The estimate of the “FatType 1” effect reacts to removal of observations in the first and last group (Output 46.7.3).

While observations can impact one or more fixed effects solutions in this model, they can only affect one covariance parameter, the variance in their group (Output 46.7.4). Observations 6, 9, 14, and 21, which are extreme in their group, reduce the group variance considerably.

These graphical displays are requested by specifying the experimental ODS GRAPHICS statement. For general information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the MIXED procedure, see the “ODS Graphics” section on page 2757.

Output 46.7.3. Fixed Effects Delete Estimates (Experimental)

Output 46.7.4. Covariance Parameter Delete Estimates (Experimental)

Diagnostics related to residuals and predicted values are printed with the following statements.

```
proc print data=inf label;
  var observed predicted residual pressres
  student Rstudent;
run;
```

Observations 6, 9, 14, and 21 have large studentized residuals ([Output 46.7.5](#)). That the externally studentized residuals are much larger than the internally studentized residuals for these observations indicates that the variance estimate in the group shrinks when the observation is removed. Also important to note is that comparisons based on raw residuals in models with heterogeneous variance can be misleading. Observation 5, for example, has a larger residual but a smaller studentized residual than observation 21. The variance for the first fat type is much larger than the variance in the fourth group. A “large” residual is more “surprising” in the groups with small variance.

Output 46.7.5. Residual Diagnostics

Obs	Observed Value	Predicted Mean	Residual	PRESS Residual	Internally Studentized Residual	Externally Studentized Residual

Output 46.7.7. REML Distance and Fixed Effects Diagnostics (Experimental)

Scanning the restricted likelihood distances, observations 6, 9, 14, and 21 clearly displace the REML solution more than any other observations (Output 46.7.6, Output 46.7.7). These observations are also associated with large values for Cook's D and values of COVRATIO far less than one. The latter indicates that the fixed effects are estimated more precisely when these observations are removed from the analysis.

The same conclusions hold for the covariance parameter estimates.

```
proc print data=inf label;
  var iter CookDCP CovRatioCP;
run;
```

Observations 6, 9, 14, and 21 change the estimates and their precision considerably (Output 46.7.8, Output 46.7.9). All iterative updates converged within at most four iterations.

Output 46.7.8. Covariance Parameter Diagnostics

Obs	Iterations	Cook's D CovParms	COVRATIO CovParms

Output 46.7.9. Covariance Parameter Diagnostics (Experimental)

Example 46.8. Influence Analysis for Repeated Measures Data (Experimental)

This example revisits the repeated measures data analyzed in [Example 46.2](#). Recall that the data consist of growth measurements at ages 8, 10, 12, and 14 for 11 girls and 16 boys. The model being fit contains fixed effects for **Gender**, **Age** and their interaction.

The earlier analysis of these data indicated some unusual observations in this data set. Because of the clustered data structure it is of interest to study the influence of clusters (children) on the analysis rather than the influence of individual observations. A cluster comprises the repeated measurements for each child.

The repeated measures are first modeled with an unstructured within-child variance-covariance matrix. A residual variance is not profiled in this model. A noniterative influence analysis will update the fixed effects only. The statements

```
proc mixed data=pr method=ml;
  class person gender;
  model y = gender age gender*age /
          influence(effect=person);
  repeated / type=un subject=person;
  ods select influence;
run;
```

request this noniterative maximum likelihood analysis and produce [Output 46.8.1](#). Each observation in the “Influence Diagnostics” table represents the removal of four

observations. The subjects 10, 15, and 24 have the greatest impact on the fixed effects (Cook's D), and subject 10 and 21 have large PRESS statistics. The twenty-first child has a large PRESS statistic, and its D statistic is not that extreme. This is an indication that the model fits rather poorly for this child, whether it is part of the data or not.

Output 46.8.1. Default Influence Statistics in Noniterative Analysis

The Mixed Procedure			
Influence Diagnostics for Levels of Person			
Person	Number of Observations in Level	PRESS Statistic	Cook's D

23	4	4.9656	0.01245
24	4	37.2494	0.15094
25	4	4.3756	0.03375
26	4	8.1448	0.03470
27	4	20.2913	0.02523

The previous analysis does not take into account the effect on the covariance parameters when a subject is removed from the analysis. If you also update the covariance parameters, the impact of observations on these can amplify or allay their effect on the fixed effects. To assess the overall influence of subjects on the analysis and to compute separate statistics for the fixed effects and covariance parameters, an iterative analysis is obtained by adding the INFLUENCE suboption ITER=.

```
ods html;
ods graphics on;

proc mixed data=pr method=ml;
  class person gender;
  model y = gender age gender*age /
          influence(effect=person iter=5);
  repeated / type=un subject=person;
run;

ods graphics off;
ods html close;
```

The number of additional iterations following removal of the observations for a particular subject is limited to five. Graphical displays of influence diagnostics are requested by specifying the experimental ODS GRAPHICS statement. The MIXED procedure produces a plot of influence statistics that pertain to overall influence and the fixed effects (Output 46.8.2) and a second panel that shows the influence on the covariance parameters (Output 46.8.3). For general information about ODS graphics, see Chapter 15, “Statistical Graphics Using ODS.” For specific information about the graphics available in the MIXED procedure, see the “ODS Graphics” section on page 2757.

Output 46.8.2. Overall and Fixed Effects Diagnostics (Experimental)

As judged by the restricted likelihood distance in Output 46.8.2, subjects 20 and 24 clearly have the most influence on the overall analysis. The reference line in this plot is the 75th percentile of a chi-square distribution with degrees of freedom equal to the number of parameters being updated (14). Comparing the D statistics for fixed

effects and covariance parameters, subject 20 has a dramatic effect on the estimates of variances and covariances. This subject also affects the precision of the covariance parameter estimates more than any other subject in [Output 46.8.3](#) (COVRATIO near 0, large COVTRACE, MDFFITS large compared to Cook's D).

Output 46.8.3. Covariance Parameter Diagnostics (Experimental)

The child who exerts the greatest influence on the fixed effects is subject 24. Maybe surprisingly, this subject impacts the variance-covariance matrix of the fixed effects more than subject 20 (small COVRATIO in [Output 46.8.3](#)).

The final model investigated for these data is a random coefficient model as in Stram and Lee (1994) with random effects for the intercept and age effect. The following statements examine the estimates for fixed effects and the entries of the unstructured 2×2 variance matrix of the random coefficients graphically.

```
ods html;
ods graphics on;

proc mixed data=pr method=ml;
  class person gender;
  model y = gender age gender*age /
    influence(iter=5 effect=person est);
  random intercept age / type=un subject=person;
  ods select InfluenceEstParmPanel1
    InfluenceEstCovPPanel1;
run;

ods graphics off;
ods html close;
```

In [Output 46.8.4](#) the graphs on the left-hand side of the panel represent the intercept and slope estimate for boys; the graphs on the right-hand side represent the difference in intercept and slope between boys and girls. Removing any one of the first eleven children, who are girls, does not alter the intercept or slope in the group of boys. The difference in these parameters between boys and girls is altered by the removal of any child. Subject 24 changes the fixed effects considerably, subject 20 much less so. This is consistent with findings based on the unstructured variance-covariance model ([Output 46.8.2](#)).

Output 46.8.4. Fixed Effects Delete Estimates (Experimental)

The covariance parameter estimates in [Output 46.8.5](#) show several important features.

- The panels do not contain information on subject 24. Estimation of the \mathbf{G} matrix following removal of that child did not yield a positive definite matrix. As a consequence, covariance parameter diagnostics are not produced for this subject.
- Subject 20 has great impact on the four covariance parameters. Removing this child from the analysis increases the variance of the random intercept and random slope and reduces the residual variance by almost 80%. The repeated measurements of this child exhibit an up-and-down behavior.
- The variance of the random intercept and slope are reduced when child 15 is removed from the analysis. This child's growth measurements oscillate about 27.0 from age 10 on.

Output 46.8.5. Covariance Parameter Delete Estimates (Experimental)

Examining observed and residual values by levels of classification variables is also a useful tool to diagnose the adequacy of the model and unusual observations. Box plots for effects in the model that comprise a single classification variable are requested with the experimental ODS GRAPHICS statement and the experimental BOXPLOT option of the PROC MIXED statement. Since this includes SUBJECT= and GROUP= effects, the statements

```
ods html;
ods graphics on;

proc mixed data=pr method=ml boxplot;
  class person gender;
  model y = gender age gender*age;
  random intercept age / type=un subject=person;
run;

ods graphics off;
ods html close;
```

produce six box plots in the following order: Y by Gender, residual by Gender, Y by Person, residual by Person, and conditional residuals by Gender and Person. The plots for the Person effect are shown in [Output 46.8.6](#)–[Output 46.8.8](#).

Box plots of the observed values show the variation within and between children clearly. The group of girls (subjects 1–11) is distinguishable from the group of boys by somewhat lesser average growth and lesser within-child variation ([Output 46.8.6](#)). After adjusting for overall (population-averaged) gender and age effects, the residual within-child variation is reduced but substantial differences in the means remain

(Output 46.8.7). If child-specific inferences are desired, a model accounting for only Gender, Age, and Gender*Age effects is not adequate for these data.

Output 46.8.6. Distribution of Observed Values (Experimental)

Output 46.8.7. Distribution of Marginal Residuals (Experimental)

The conditional residuals incorporate the EBLUPs for each child and enable you to examine whether the subject-specific model is adequate ([Output 46.8.8](#)). By using each child “as its own control” the residuals are now centered near zero. Subjects 20 and 24 stand out as unusual in all three sets of box plots.

Output 46.8.8. Distribution of Conditional Residuals (Experimental)

Example 46.9. Examining Individual Test Components

The LCOMPONENTS option of the MODEL statement enables you to perform single degree of freedom tests for individual rows of the **L** matrix. Such tests are useful to identify interaction patterns. In a balanced layout, Type 3 components of **L** associated with **A*B** interactions correspond to simple contrasts of cell mean differences.

The first example revisits the data from the split-plot design by Stroup (1989a) that was analyzed in [Example 46.1](#) on page 2777. Recall that variables **A** and **B** represent the whole-plot and subplot factors, respectively.

```
proc mixed data=sp;
  class a b block ;
  model y = a b a*b / LComponents e3;
  random block a*block;
run;
```

The MIXED procedure constructs a separate **L** matrix for each of the three fixed effects components. The matrices are displayed in [Output 46.9.1](#). The test for fixed effects are shown in [Output 46.9.2](#).

Output 46.9.1. Coefficients of Type 3 Estimable Functions

The Mixed Procedure				
Type 3 Coefficients for A				
Effect	A	B	Row1	Row2
Intercept				
A	1		1	
A	2			1
A	3		-1	-1
B		1		
B		2		
A*B	1	1	0.5	
A*B	1	2	0.5	
A*B	2	1		0.5
A*B	2	2		0.5
A*B	3	1	-0.5	-0.5
A*B	3	2	-0.5	-0.5
Type 3 Coefficients for B				
Effect	A	B	Row1	
Intercept				
A	1			
A	2			
A	3			
B		1		1
B		2		-1
A*B	1	1	0.3333	
A*B	1	2	-0.333	
A*B	2	1	0.3333	
A*B	2	2	-0.333	
A*B	3	1	0.3333	
A*B	3	2	-0.333	
Type 3 Coefficients for A*B				
Effect	A	B	Row1	Row2
Intercept				
A	1			
A	2			
A	3			
B		1		
B		2		
A*B	1	1	1	
A*B	1	2	-1	
A*B	2	1		1
A*B	2	2		-1
A*B	3	1	-1	-1
A*B	3	2	1	1

Output 46.9.2. Type 3 Tests in Split-Plot Example

The Mixed Procedure				
Type 3 Tests of Fixed Effects				
Effect	Num DF	Den DF	F Value	Pr > F
A	2	6	4.07	0.0764
B	1	9	19.39	0.0017
A*B	2	9	4.02	0.0566

If $\mu_{i.}$ denotes a whole-plot main effect mean, $\mu_{.j}$ denotes a subplot main effect mean, and μ_{ij} denotes a cell mean, the five components shown in [Output 46.9.3](#) correspond to tests of

- $H_0 : \mu_{1.} = \mu_{2.}$
- $H_0 : \mu_{2.} = \mu_{3.}$
- $H_0 : \mu_{.1} = \mu_{.2}$
- $H_0 : \mu_{11} - \mu_{12} = \mu_{31} - \mu_{32}$
- $H_0 : \mu_{21} - \mu_{22} = \mu_{31} - \mu_{32}$

Output 46.9.3. Type 3 LComponents Table

The Mixed Procedure						
L Components of Type 3 Tests of Fixed Effects						
Effect	L Index	Estimate	Standard Error	DF	t Value	Pr > t
A	1	7.1250	3.1672	6	2.25	0.0655
A	2	8.3750	3.1672	6	2.64	0.0383
B	1	5.5000	1.2491	9	4.40	0.0017
A*B	1	7.7500	3.0596	9	2.53	0.0321
A*B	2	7.2500	3.0596	9	2.37	0.0419

The first three components are comparisons of marginal means. The fourth component compares the effect of factor **B** at the first whole-plot level against the effect of **B** at the third whole-plot level. Finally, the last component tests whether the factor **B** effect changes between the second and third whole-plot level.

The Type 3 component tests can also be produced with corresponding ESTIMATE statements.

```
proc mixed data=sp;
  class a b block ;
  model y = a b a*b;
  random block a*block;
  estimate 'a 1' a 1 0 -1;
  estimate 'a 2' a 0 1 -1;
  estimate 'b 1' b 1 -1;
  estimate 'a*b 1' a*b 1 -1 0 0 -1 1;
  estimate 'a*b 2' a*b 0 0 1 -1 -1 1;
  ods select estimates;
run;
```

The Mixed Procedure						
Estimates						
Label	Estimate	Standard Error	DF	t Value	Pr > t	
a 1	7.1250	3.1672	6	2.25	0.0655	
a 2	8.3750	3.1672	6	2.64	0.0383	
b 1	5.5000	1.2491	9	4.40	0.0017	
a*b 1	7.7500	3.0596	9	2.53	0.0321	
a*b 2	7.2500	3.0596	9	2.37	0.0419	

A second useful application of the LCOMPONENT option is in polynomial models where Type 1 tests are often used to test the entry of model terms sequentially. The SOLUTION option of the MODEL statement displays the regression coefficients that correspond to a Type 3 analysis, that is,

- the coefficients represent the partial coefficients you would get by adding the regressor variable last in a model containing all other effects
- the tests are identical to those in the “Type 3 Tests of Fixed Effects” table

Consider the following data set and the fit of a third order polynomial regression model.

```
data polynomial;
  do x=1 to 20; input y@@; output; end;
  datalines;
1.092 1.758 1.997 3.154 3.880
3.810 4.921 4.573 6.029 6.032
6.291 7.151 7.154 6.469 7.137
6.374 5.860 4.866 4.155 2.711
;

proc mixed data=polynomial;
  model y = x x*x x*x*x / s lcomponents htype=1;
run;
```

The t -tests displayed in the “Solution for Fixed Effects” table are Type 3 tests, sometimes referred to as partial tests. They measure the contribution of a regressor in the presence of all other regressor variables in the model.

The Mixed Procedure					
Solution for Fixed Effects					
Effect	Estimate	Standard Error	DF	t Value	Pr > t
Intercept	0.7837	0.3545	16	2.21	0.0420
x	0.3726	0.1426	16	2.61	0.0189
x*x	0.04756	0.01558	16	3.05	0.0076
x*x*x	-0.00306	0.000489	16	-6.27	<.0001

The Type 3 L components are identical to the tests in the “Solutions for Fixed Effects” table. The Type 1 table yields

- sequential (Type 1) tests of regression variables which test the significance of a regressor given all other variables preceding it in the model list
- the regression coefficients for sequential submodels

The Mixed Procedure						
L Components of Type 1 Tests of Fixed Effects						
Effect	L Index	Estimate	Standard Error	DF	t Value	Pr > t
x	1	0.1763	0.01259	16	14.01	<.0001
x*x	1	-0.04886	0.002449	16	-19.95	<.0001
x*x*x	1	-0.00306	0.000489	16	-6.27	<.0001

L Components of Type 3 Tests of Fixed Effects						
Effect	L Index	Estimate	Standard Error	DF	t Value	Pr > t
x	1	0.3726	0.1426	16	2.61	0.0189
x*x	1	0.04756	0.01558	16	3.05	0.0076
x*x*x	1	-0.00306	0.000489	16	-6.27	<.0001

The estimate of 0.1763 is the regression coefficient in a simple linear regression of Y on X. The estimate of -0.04886 is the partial coefficient for the quadratic term when it is added to a model containing only a linear component. Similarly, the value -0.00306 is the partial coefficient for the cubic term when it is added to a model containing a linear and quadratic component. The last Type 1 component is always identical to the corresponding Type 3 component.

Chapter 47

The MODECLUS Procedure

Overview

The MODECLUS procedure clusters observations in a SAS data set using any of several algorithms based on nonparametric density estimates. The data can be numeric coordinates or distances. PROC MODECLUS can perform approximate significance tests for the number of clusters and can hierarchically join nonsignificant clusters. The significance tests are empirically validated by simulations with sample sizes ranging from 20 to 2000.

PROC MODECLUS produces output data sets containing density estimates and cluster membership, various cluster statistics including approximate p -values, and a summary of the number of clusters generated by various algorithms, smoothing parameters, and significance levels.

Most clustering methods are biased toward finding clusters possessing certain characteristics related to size (number of members), shape, or dispersion. Methods based on the least-squares criterion (Sarle 1982), such as k -means and Ward's minimum variance method, tend to find clusters with roughly the same number of observations in each cluster. Average linkage (see [Chapter 23, "The CLUSTER Procedure,"](#)) is somewhat biased toward finding clusters of equal variance. Many clustering methods tend to produce compact, roughly hyperspherical clusters and are incapable of detecting clusters with highly elongated or irregular shapes. The methods with the least bias are those based on nonparametric density estimation (Silverman 1986, pp. 130–146; Scott 1992, pp. 125–190) such as density linkage (see [Chapter 23, "The CLUSTER Procedure,"](#) Wong and Lane 1983, and Wong and Schaack 1982). The biases of many commonly used clustering methods are discussed in [Chapter 7, "Introduction to Clustering Procedures."](#)

PROC MODECLUS implements several clustering methods using nonparametric density estimation. Such clustering methods are referred to hereafter as *nonparametric clustering methods*. The methods in PROC MODECLUS are related to, but not identical to, methods developed by Gitman (1973), Huizinga (1978), Koontz and Fukunaga (1972a, 1972b), Koontz, Narendra, and Fukunaga (1976), Mizoguchi and Shimura (1980), and Wong and Lane (1983). Details of the algorithms are provided in the section ["Clustering Methods"](#) on page 2874.

For nonparametric clustering methods, a cluster is loosely defined as a region surrounding a local maximum of the probability density function (see the section ["Significance Tests"](#) on page 2876 for a more rigorous definition). Given a sufficiently large sample, nonparametric clustering methods are capable of detecting clusters of unequal size and dispersion and with highly irregular shapes. Nonparametric methods can also obtain good results for compact clusters of equal size and disper-

sion, but they naturally require larger sample sizes for good recovery than clustering methods that are biased toward finding such “nice” clusters.

For coordinate data, nonparametric clustering methods are less sensitive to changes in scale of the variables or to affine transformations of the variables than are most other commonly used clustering methods. Nevertheless, it is necessary to consider questions of scaling and transformation, since variables with large variances tend to have more effect on the resulting clusters than those with small variances. If two or more variables are not measured in comparable units, some type of standardization or scaling is necessary; otherwise, the distances used by the procedure may be based on inappropriate apples-and-oranges computations. For variables with comparable units of measurement, standardization or scaling may still be desirable if the scale estimates of the variables are not related to their expected importance for defining clusters. If you want two variables to have equal importance in the analysis, they should have roughly equal scale estimates. If you want one variable to have more effect than another, the former should be scaled to have a greater scale estimate than the latter. The STD option in the PROC MODECLUS statement scales all variables to equal variance. However, the variance is not necessarily the most appropriate scale estimate for cluster analysis. In particular, outliers should be removed before using PROC MODECLUS with the STD option. A variety of scale estimators including robust estimators are provided in the STDIZE procedure (for detailed information, see Chapter 66, “The STDIZE Procedure,”). Additionally, the ACECLUS procedure provides another way to transform the variables to try to improve the separation of clusters.

Since clusters are defined in terms of local maxima of the probability density function, nonlinear transformations of the data may change the number of population clusters. The variables should be transformed so that equal differences are of equal practical importance. An interval scale of measurement is required. Ordinal or ranked data are generally inappropriate, since monotone transformations can produce any arbitrary number of modes.

Unlike the methods in the CLUSTER procedure, the methods in the MODECLUS procedure are not inherently hierarchical. However, PROC MODECLUS can do approximate nonparametric significance tests for the number of clusters by obtaining an approximate p -value for each cluster, and it can hierarchically join nonsignificant clusters.

Another important difference between the MODECLUS procedure and many other clustering methods is that you do not tell PROC MODECLUS how many clusters you want. Instead, you specify a *smoothing parameter* (see the section “Density Estimation” on page 2870) and, optionally, a significance level, and PROC MODECLUS determines the number of clusters. You can specify a list of smoothing parameters, and PROC MODECLUS performs a separate cluster analysis for each value in the list.

Getting Started

This section illustrates how PROC MODECLUS can be used to examine the clusters of data in the following artificial data set.

```
data example;
  input x y @@;
  datalines;
18 18 20 22 21 20 12 23 17 12 23 25 25 20 16 27
20 13 28 22 80 20 75 19 77 23 81 26 55 21 64 24
72 26 70 35 75 30 78 42 18 52 27 57 41 61 48 64
59 72 69 72 80 80 31 53 51 69 72 81
;
```

It is a good practice to plot the data to check for obvious clusters or pathologies prior to the analysis. The interactive graphics of the SAS/INSIGHT product are effective for visualizing clusters. In this example, with only two variables and a small sample size, the GPLOT procedure is adequate. The following statements produce [Figure 47.1](#):

```
axis1 label=(angle=90 rotate=0) minor=none
      order=(0 to 80 by 20);
axis2 minor=none;
proc gplot;
  plot y*x /frame cframe=ligr vaxis=axis1 haxis=axis2;
run;
```

The plot suggests three clusters. Of these clusters, the one in the lower left corner is the most compact, while the lower right cluster is more dispersed.

The upper cluster is elongated and would be difficult for most clustering algorithms to identify as a single cluster. The plot also suggests that a Euclidean distance of 10 or 20 is a good initial guess for the neighborhood size in density estimation and clustering.

Figure 47.1. Scatter Plot of Data

To obtain a cluster analysis, you must specify the `METHOD=` option; for most purposes, `METHOD=1` is recommended. The cluster analysis can be performed with a list of radii (`R=10 15 35`), as illustrated in the following PROC MODECLUS step. An output data set containing the cluster membership is created with the `OUT=` option and then used by PROC GPLOT to display the membership. The following statements produce Figure 47.2 through Figure 47.5:

```
proc modeclus data=example method=1 r=10 15 35 out=out;
run;
```

For each cluster solution, PROC MODECLUS produces a table of cluster statistics including the cluster number, the number of observations in the cluster, the maximum estimated density within the cluster, the number of observations in the cluster having a neighbor that belongs to a different cluster, and the estimated saddle density of the cluster. The results are displayed in Figure 47.2, Figure 47.3, and Figure 47.4 for three different radii. A smaller radius (`R=10`) yields a larger number of clusters (6), as displayed in Figure 47.1; a larger radius (`R=35`) includes all observations in a single cluster, as displayed in Figure 47.5. Note that all clusters in these three figures are “isolated” since their corresponding boundary frequencies are all 0s. Therefore, all the estimated saddle densities are missing.

```

The MODECLUS Procedure
R=10 METHOD=1

Cluster Statistics
Maximum
Estimated      Boundary      Estimated
Cluster      Frequency      Density      Frequency      Saddle
-----
1              10      0.00106103      0              .

```

Figure 47.4. Results from PROC MODECLUS for METHOD=1 and R=35

A table summarizing each cluster solution is then produced, as displayed in [Figure 47.5](#).

The MODECLUS Procedure		
Cluster Summary		
R	Number of Clusters	Frequency of Unclassified Objects
10	6	0
15	3	0
35	1	0

Figure 47.5. Summary Table

The OUT= data set contains a complete copy of the input data set for each cluster solution. Using a BY statement in the following PROC GPLOT step, you can examine the differences in cluster memberships for each radius. The following statements produce [Figure 47.6](#) through [Figure 47.8](#):

```
symbol1 v='1' font=swiss c=white; symbol2 v='2' font=swiss c=yellow;
symbol3 v='3' font=swiss c=cyan; symbol4 v='4' font=swiss c=green;
symbol5 v='5' font=swiss c=orange; symbol6 v='6' font=swiss c=blue;
symbol7 v='7' font=swiss c=black;
proc gplot data=out;
  plot y*x=cluster /frame cframe=ligr nolegend vaxis=axis1
      haxis=axis2;
by _r_;
run;
```

Figure 47.6. Scatter Plots of Cluster Memberships with `_R_=10`

Figure 47.7. Scatter Plots of Cluster Memberships with `_R_=15`

Figure 47.8. Scatter Plots of Cluster Memberships with `_R_=35`

Syntax

The following statements invoke the MODECLUS procedure:

```
PROC MODECLUS < options > ;
  BY variables ;
  FREQ | FREQUENCY variable ;
  ID variable ;
  VAR | VARIABLES variables ;
```

The PROC MODECLUS statement is required. All other statements are optional.

PROC MODECLUS Statement

```
PROC MODECLUS < options > ;
```

The PROC MODECLUS statement invokes the procedure.

Options available in the PROC MODECLUS statement are classified by function in [Table 47.1](#). The corresponding default value for each option, if applicable, is also listed in this table.

Table 47.1. Functional Summary

Description	Option	Default Value
Data Sets		
specify input data set name	DATA=	_LAST_
specify output data set name for observations	OUT=	
specify output data set name for clusters	OUTC=	
specify output data set name for cluster solutions	OUTS=	
Variables in Output Data Sets		
specify variable in the OUT= and OUTCLUS= data sets identifying clusters	CLUSTER=	CLUSTER
specify variable in the OUT= data set containing density estimates	DENSITY=	DENSITY
specify length of variables in the output data sets	OUTLENGTH=	8
Results and Data Processing before Clustering *		
request simple statistics	SIMPLE	
standardize the variables to mean 0 and standard deviation 1	STANDARD	
Smoothing Parameters		
specify number of neighbors to use for k th-nearest-neighbor density estimation	DK=	

*for coordinate data only

Table 47.1. (continued)

Description	Option	Default Value
specify number of neighbors to use for clustering	CK=	
specify number of neighbors to use for k th-nearest-neighbor density estimation and clustering	K=	
specify radius of the sphere of support for uniform-kernel density estimation	DR=	
specify radius of the neighborhood for clustering	CR=	
specify radius of the sphere of support for uniform-kernel density estimation and the neighborhood clustering	R=	
Density Estimation Options		
specify number of times the density estimates are to be cascaded	CASCADE=	0
compute the likelihood cross-validation criterion	CROSS or CROSSLIST	
specify dimensionality to be used when computing density estimates	DIMENSION=	nvar* or 1 [†]
use arithmetic means for cascading density estimates	AM	
use harmonic means for cascading density estimates	HM	
use sums for cascading density estimates	SUM	
Clustering Methods Options		
dissolve clusters with n or fewer members	DOCK	
stop the analysis after obtaining a solution with either no cluster or a single cluster	EARLY	
request that nonsignificant clusters be hierarchically joined.	JOIN(=)	
specify maximum number of clusters to be obtained with METHOD=6	MAXCLUSTERS=	no limit
specify clustering method to use	METHOD=	
specify minimum members for either cluster to be designated a modal cluster when two clusters are joined using METHOD=5	MODE=	the value of K [‡] or 2 [§]
specify power of the density used with METHOD=6	POWER=	2
specify approximate significance tests for the number of clusters	TEST	

* number of variables, for coordinate data

† for distance data

‡ when K= is specified

§ when K= is not specified

Table 47.1. (continued)

Description	Option	Default Value
specify assignment threshold used with METHOD=6	THRESHOLD=	0.5
Miscellaneous Options		
produce all optional output	ALL	
display the density and cluster membership of observations with neighbors belonging to a different cluster	BOUNDARY	
retain the neighbor lists for each observation in memory	CORE	
display the estimated cross-validated log density of each observation	CROSSLIST	
display the estimated density and cluster membership of each observation	LIST	
display estimates of local dimensionality and write them to the OUT=data set	LOCAL	
display the neighbors of each observation	NEIGHBOR	
suppress the display of the output	NOPRINT	
suppress the display of the summary of the number of clusters, number of unassigned observations, and maximum p -value for each analysis	NOSUMMARY	
suppress the display of statistics for each cluster	SHORT	
trace the cluster assignments for the METHOD=6 algorithm	TRACE	

You can specify at least one of the following options for smoothing parameters for density estimation: DK=, K=, DR=, or R=. To obtain a cluster analysis, you can specify the METHOD= option and at least one of the following smoothing parameters for clustering: CK=, K=, CR=, or R=. If you want significance tests for the number of clusters, you should specify either the DR= or R= option. If none of the smoothing parameters is specified, the MODECLUS procedure provides a default value for the R= option. See the section “[Density Estimation](#)” on page 2870 for the formula of a reasonable first guess for R= and a discussion of smoothing parameters.

You can specify lists of values for the DK=, CK=, K=, DR=, CR=, and R= options. Numbers in the lists can be separated by blanks or commas. You can include in the lists one or more items of the form *start TO stop BY increment*. Each list can contain either one value or the same number of values as in every other list that contains more than one value. If a list has only one value, that value is used in combination with all the values in longer lists. If two or more lists have more than one value, then one analysis is done using the first value in each list, another analysis is done using the second value in each list, and so on.

You can specify the following options in the PROC MODECLUS statement.

ALL

produces all optional output.

AM

specifies arithmetic means for cascading density estimates. See the description of the `CASCADE=` option.

BOUNDARY

displays the density and cluster membership of observations with neighbors belonging to a different cluster.

CASCADE=*n***CASC=*n***

specifies the number of times the density estimates are to be cascaded (see the section “[Density Estimation](#)” on page 2870). The default value 0 performs no cascading.

You can specify a list of values for the `CASCADE=` option. Each value in the list is combined with each combination of smoothing parameters to produce a separate analysis.

CK=*n*

specifies the number of neighbors to use for clustering. The number of neighbors should be at least 2 but less than the number of observations. See the section “[Density Estimation](#)” on page 2870.

CLUSTER=*name*

provides a name for the variable in the `OUT=` and `OUTCLUS=` data sets identifying clusters. The default name is `CLUSTER`.

CORE

keeps the neighbor lists for each observation in the computer memory to make small problems run faster.

CR=*n*

specifies the radius of the neighborhood for clustering. See the section “[Density Estimation](#)” on page 2870.

CROSS

computes the likelihood cross-validation criterion (Silverman 1986, pp. 52–55). This option appears to be of limited usefulness (see the section “[Density Estimation](#)” on page 2870).

CROSSLIST

displays the cross-validated log density of each observation.

DATA=*SAS-data-set*

specifies the input data set containing observations to be clustered. If you omit the `DATA=` option, the most recently created SAS data set is used.

If the data set is `TYPE=DISTANCE`, the data are interpreted as a distance matrix. The number of variables must equal the number of observations in the data set or in each `BY` group. The distances are assumed to be Euclidean, but the procedure accepts other types of distances or dissimilarities. Unlike the `CLUSTER` procedure,

PROC MODECLUS uses the entire distance matrix, not just the lower triangle; the distances are not required to be symmetric. The neighbors of a given observation are determined solely from the distances in that observation. Missing values are considered infinite. Various distance measures can be computed from coordinate data using the DISTANCE procedure (for detailed information, see [Chapter 26, “The DISTANCE Procedure,”](#)).

If the data set is not TYPE=DISTANCE, the data are interpreted as coordinates in a Euclidean space, and Euclidean distances are computed. The variables can be discrete or continuous and should be at the interval level of measurement.

DENSITY=*name*

provides a name for the variable in the OUT= data set containing density estimates. The default name is DENSITY.

DIMENSION=*n***DIM=***n*

specifies the dimensionality to be used when computing density estimates. The default is the number of variables if the data are coordinates; the default is 1 if the data are distances.

DK=*n*

specifies the number of neighbors to use for *k*th-nearest-neighbor density estimation. The number of neighbors should be at least 2 but less than the number of observations. See the section [“Density Estimation”](#) on page 2870.

DOCK=*n*

dissolves clusters with *n* or fewer members by making the members unassigned.

DR=*n*

specifies the radius of the sphere of support for uniform-kernel density estimation. See the section [“Density Estimation”](#) on page 2870.

EARLY

stops the cluster analysis after obtaining either a solution with no cluster or a solution with one cluster to which all observations are assigned. The smoothing parameters should be specified in increasing order. This can reduce the computer time required for the analysis but may occasionally miss some multiple-cluster solutions.

HM

uses harmonic means for cascading density estimates. See the description of the CASCADE= option.

JOIN<=*p*>

requests that nonsignificant clusters be hierarchically joined. The JOIN option implies the TEST option. After each solution is obtained, the cluster with the largest approximate *p*-value is either joined to a neighboring cluster or, if there is no neighboring cluster, dissolved by making all of its members unassigned. After two clusters are joined, an analysis of the remaining clusters is displayed.

If you do not specify a *p*-value with the JOIN= option, joining continues until only one cluster remains, and the results are written to the output data sets after each

analysis. If you specify a p -value with the JOIN= option, joining continues until the greatest approximate p -value is less than the value given in the JOIN= option, and only if there is more than one cluster are the results for that analysis written to the output data sets.

Any value of p less than $1E-8$ is set to $1E-8$.

K= n

specifies the number of neighbors to use for k th-nearest-neighbor density estimation and clustering. The number of neighbors should be at least 2 but less than the number of observations. Specifying K= n is equivalent to specifying both DK= n and CK= n . See the section “[Density Estimation](#)” on page 2870.

LIST

displays the estimated density and cluster membership of each observation.

LOCAL

requests estimates of local dimensionality (Tukey and Tukey 1981, pp. 236–237).

MAXCLUSTERS= n **MAXC= n**

specifies the maximum number of clusters to be obtained with the METHOD=6 option. By default, there is no fixed limit.

METHOD= n **MET= n** **M= n**

specifies what clustering method to use. Since these methods do not have widely recognized names, the methods are indicated by numbers from 0 to 6. The methods are described in the section “[Clustering Methods](#)” on page 2874. For most purposes, METHOD=1 is recommended, although METHOD=6 may occasionally produce better results in return for considerably greater computer time and space requirements. METHOD=1 is not good for discrete coordinate data with only a few equally spaced values. In this case, METHOD=6 or METHOD=3 works better. METHOD=4 or METHOD=5 is less desirable than other methods when there are ties, since a general characteristic of agglomerative hierarchical clustering methods is that the results are indeterminate in the presence of ties.

You must specify the METHOD= option to obtain a cluster analysis.

You can specify a list of values for the METHOD= option. Each value in the list is combined with each combination of smoothing and cascading parameters to produce a separate cluster analysis.

MODE= n

specifies that when two clusters are joined using the METHOD=5 option (no other methods are affected by the MODE= option), each must have at least n members for either cluster to be designated a modal cluster. In any case, each cluster must also have a maximum density greater than the fusion density for either cluster to be designated a modal cluster. If you specify the K= option, the default value of the MODE= option is the same as the value of the K= option because the use of k th-nearest-neighbor density estimation limits the resolution that can be obtained for

clusters with fewer than k members. If you do not specify the `K=` option, the default is `MODE=2`. If you specify `MODE=0`, the default value is used instead of 0. If you specify a `FREQ` statement, the `MODE=` value is compared to the number of observations in each cluster, not to the sum of the frequencies.

NEIGHBOR

displays the neighbors of each observation in a table called “Nearest Neighbor List.”

NOPRINT

suppresses the display of the output. Note that this option temporarily disables the Output Delivery System (ODS). For more information, see [Chapter 14, “Using the Output Delivery System.”](#)

NOSUMMARY

suppresses the display of the summary of the number of clusters, number of unassigned observations, and maximum p -value for each analysis.

OUT=SAS-data-set

specifies the output data set containing the input data plus density estimates, cluster membership, and variables identifying the type of solution. There is an output observation corresponding to each input observation for each solution. Therefore, the `OUT=` data set can be very large.

OUTCLUS=SAS-data-set**OUTC=SAS-data-set**

specifies the output data set containing an observation corresponding to each cluster in each solution. The variables identify the solution and contain statistics describing the clusters.

OUTSUM=SAS-data-set**OUTS=SAS-data-set**

specifies the output data set containing an observation corresponding to each cluster solution giving the number of clusters and the number of unclassified observations for that solution.

OUTLENGTH= n **OUTL= n**

specifies the length of those output variables that are not copied from the input data set but are created by PROC MODECLUS.

The `OUTLENGTH=` option applies only to the following variables that appear in all of the output data sets: `_K_`, `_DK_`, `_CK_`, `_R_`, `_DR_`, `_CR_`, `_CASCAD_`, `_METHOD_`, `_NJOIN_`, and `_LOCAL_`.

The minimum value is 2 or 3, depending on the operating system. The maximum value is 8. The default value is 8.

POWER= n **POW= n**

specifies the power of the density used with the `METHOD=6` option. The default value is 2.

R=*n*

specifies the radius of the sphere of support for uniform-kernel density estimation and the neighborhood for clustering. Specifying $R=n$ is equivalent to specifying both $DR=n$ and $CR=n$. See the section “[Density Estimation](#)” on page 2870.

SHORT

suppresses the display of statistics for each cluster.

SIMPLE**S**

displays means, standard deviations, skewness, kurtosis, and a coefficient of bimodality. The SIMPLE option applies only to coordinate data.

STANDARD**STD**

standardizes the variables to mean 0 and standard deviation 1. The STANDARD option applies only to coordinate data.

SUM

uses sums for cascading density estimates. See the description of the [CASCADE=option](#) on page 2865.

TEST

performs approximate significance tests for the number of clusters. The $R=$ or $DR=$ option must also be specified with a nonzero value to obtain significance tests.

The significance tests performed by PROC MODECLUS are valid only for simple random samples, and they require at least 20 observations per cluster to have enough power to be of any use. See the section “[Significance Tests](#)” on page 2876.

THRESHOLD=*n***THR=*n***

specifies the assignment threshold used with the $METHOD=6$ option. The default is 0.5.

TRACE

traces the cluster assignments for the $METHOD=6$ algorithm.

BY Statement

BY variables ;

You can specify a BY statement with PROC MODECLUS to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.

- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the MODECLUS procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure.

For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

FREQ Statement

FREQ | FREQUENCY *variable* ;

If one variable in the input data set represents the frequency of occurrence for other values in the observation, specify the variable's name in a FREQ statement. PROC MODECLUS then treats the data set as if each observation appeared n times, where n is the value of the FREQ variable for the observation. Nonintegral values of the FREQ variable are truncated to the largest integer less than the FREQ value.

ID Statement

ID *variable* ;

The values of the ID variable identify observations in the displayed results and in the OUT= data set. If you omit the ID statement, each observation is identified by its observation number, and a variable called `_OBS_` is written to the OUT= data set containing the original observation numbers.

VAR Statement

VAR | VARIABLES *variables* ;

The VAR statement specifies numeric variables to be used in the cluster analysis. If you omit the VAR statement, all numeric variables not specified in other statements are used.

Details

Density Estimation

Refer to Silverman (1986) or Scott (1992) for an introduction to nonparametric density estimation.

PROC MODECLUS uses (hyper)spherical uniform kernels of fixed or variable radius. The density estimate at a point is computed by dividing the number of observations within a sphere centered at the point by the product of the sample size and the volume of the sphere. The size of the sphere is determined by the smoothing parameters that you are required to specify.

For fixed-radius kernels, specify the radius as a Euclidean distance with either the DR= or R= option. For variable-radius kernels, specify the number of neighbors desired within the sphere with either the DK= or K= option; the radius is then the smallest radius that contains at least the specified number of observations including the observation at which the density is being estimated. If you specify both the DR= or R= option and the DK= or K= option, the radius used is the maximum of the two indicated radii; this is useful for dealing with outliers.

It is convenient to refer to the sphere of support of the kernel at observation x_i as the *neighborhood* of x_i . The observations within the neighborhood of x_i are the *neighbors* of x_i . In some contexts, x_i is considered a neighbor of itself, but in other contexts it is not. The following notation is used in this chapter.

x_i	the i th observation
$d(x,y)$	the distance between points x and y
n	the total number of observations in the sample
n_i	the number of observations within the neighborhood of x_i including x_i itself
n_i^-	the number of observations within the neighborhood of x_i not including x_i itself
N_i	the set of indices of neighbors of x_i including i
N_i^-	the set of indices of neighbors of x_i not including i
v_i	the volume of the neighborhood of x_i
\hat{f}_i	the estimated density at x_i
\hat{f}_i^-	the cross-validated density estimate at x_i
C_k	the set of indices of observations assigned to cluster k
v	the number of variables or the dimensionality
s_l	standard deviation of the l th variable

The estimated density at x_i is

$$\hat{f}_i = \frac{n_i}{nv_i}$$

that is, the number of neighbors of x_i divided by the product of the sample size and the volume of the neighborhood at x_i .

The density estimates provided by uniform kernels are not quite as good as those provided by some other types of kernels, but they are quite satisfactory for clustering. The significance tests for the number of clusters require the use of fixed-size uniform kernels.

There is no simple answer to the question of which smoothing parameter to use (Silverman 1986, pp. 43–61, 84–88, 98–99). It is usually necessary to try several different smoothing parameters. A reasonable first guess for the K= option is in the

range of 0.1 to 1 times $n^{4/(v+4)}$, smaller values being suitable for higher dimensionalities. A reasonable first guess for the R= option in many coordinate data sets is given by

$$\left[\frac{2^{v+2}(v+2)\Gamma(.5v+1)}{nv^2} \right]^{1/(v+4)} \sqrt{\sum_{l=1}^v s_l^2}$$

which can be computed in a DATA step using the GAMMA function for Γ . The MODECLUS procedure also provides this first guess as a default smoothing parameter if none of the options (DR=, CR=, R=, DK=, CK=, and K=) is specified. This formula is derived under the assumption that the data are sampled from a multivariate normal distribution and, therefore, tend to be too large (oversmooth) if the true distribution is multimodal. Robust estimates of the standard deviations may be preferable if there are outliers. If the data are distances, the factor $\sqrt{\sum s_l^2}$ can be replaced by an average root-mean-square Euclidean distance divided by $\sqrt{2}$. To prevent outliers from appearing as separate clusters, you can also specify K=2 or CK=2 or, more generally, K=m or CK=m, $m \geq 2$, which in most cases forces clusters to have at least m members.

If the variables all have unit variance (for example, if you specify the STD option), you can use Table 47.2 to obtain an initial guess for the R= option.

Table 47.2. Reasonable First Guess for R= for Standardized Data

Number of Obs	Number of Variables									
	1	2	3	4	5	6	7	8	9	10
20	1.01	1.36	1.77	2.23	2.73	3.25	3.81	4.38	4.98	5.60
35	0.91	1.24	1.64	2.08	2.56	3.08	3.62	4.18	4.77	5.38
50	0.84	1.17	1.56	1.99	2.46	2.97	3.50	4.06	4.64	5.24
75	0.78	1.09	1.47	1.89	2.35	2.85	3.38	3.93	4.50	5.09
100	0.73	1.04	1.41	1.82	2.28	2.77	3.29	3.83	4.40	4.99
150	0.68	0.97	1.33	1.73	2.18	2.66	3.17	3.71	4.27	4.85
200	0.64	0.93	1.28	1.67	2.11	2.58	3.09	3.62	4.17	4.75
350	0.57	0.85	1.18	1.56	1.98	2.44	2.93	3.45	4.00	4.56
500	0.53	0.80	1.12	1.49	1.91	2.36	2.84	3.35	3.89	4.45
750	0.49	0.74	1.06	1.42	1.82	2.26	2.74	3.24	3.77	4.32
1000	0.46	0.71	1.01	1.37	1.77	2.20	2.67	3.16	3.69	4.23
1500	0.43	0.66	0.96	1.30	1.69	2.11	2.57	3.06	3.57	4.11
2000	0.40	0.63	0.92	1.25	1.63	2.05	2.50	2.99	3.49	4.03

One data-based method for choosing the smoothing parameter is likelihood cross validation (Silverman 1986, pp. 52–55). The cross-validated density estimate at an observation is obtained by omitting the observation from the computations.

$$\hat{f}_i^- = \frac{n_i^-}{nv_i}$$

The (log) likelihood cross-validation criterion is then computed as

$$\sum_{i=1}^n \log \hat{f}_i^-$$

The suggested smoothing parameter is the one that maximizes this criterion. With fixed-radius kernels, likelihood cross validation oversmooths long-tailed distributions; for purposes of clustering, it tends to undersmooth short-tailed distributions. With k -nearest-neighbor density estimation, likelihood cross validation is useless because it almost always indicates $k=2$.

Cascaded density estimates are obtained by computing initial kernel density estimates and then, at each observation, taking the arithmetic mean, harmonic mean, or sum of the initial density estimates of the observations within the neighborhood. The cascaded density estimates can, in turn, be cascaded, and so on. Let ${}_k\hat{f}_i$ be the density estimate at x_i cascaded k times. For all types of cascading, ${}_0\hat{f}_i = \hat{f}_i$. If the cascading is done by arithmetic means, then, for $k \geq 0$,

$${}_{k+1}\hat{f}_i = \sum_{j \in N_i} {}_k\hat{f}_j / n_i$$

For harmonic means,

$${}_{k+1}\hat{f}_i = \left(\sum_{j \in N_i} {}_k\hat{f}_j^{-1} / n_i \right)^{-1}$$

and for sums,

$${}_{k+1}\hat{f}_i = \left(\sum_{j \in N_i} {}_k\hat{f}_j^{k+1} \right)^{\frac{1}{k+2}}$$

To avoid cluttering formulas, the symbol \hat{f}_i is used from now on to denote the density estimate at x_i whether cascaded or not, since the clustering methods and significance tests do not depend on the degree of cascading.

Cascading increases the smoothness of the estimates with less computation than would be required by increasing the smoothing parameters to yield a comparable degree of smoothness. For population densities with bounded support and discontinuities at the boundaries, cascading improves estimates near the boundaries. Cascaded estimates, especially using sums, may be more sensitive to the local covariance structure of the distribution than are the uncascaded kernel estimates. Cascading seems to be useful for detecting very nonspherical clusters. Cascading was suggested by Tukey and Tukey (1981, p. 237). Additional research into the properties of cascaded density estimates is needed.

Clustering Methods

The number of clusters is a function of the smoothing parameters. The number of clusters tends to decrease as the smoothing parameters increase, but the relationship is not strictly monotonic. Generally, you should specify several different values of the smoothing parameters to see how the number of clusters varies.

The clustering methods used by PROC MODECLUS use spherical clustering neighborhoods of fixed or variable radius that are similar to the spherical kernels used for density estimation. For fixed-radius neighborhoods, specify the radius as a Euclidean distance with either the CR= or R= option. For variable-radius neighborhoods, specify the number of neighbors desired within the sphere with either the CK= or K= option; the radius is then the smallest radius that contains at least the specified number of observations including the observation for which the neighborhood is being determined. However, in the following descriptions of clustering methods, an observation is not considered to be one of its own neighbors. If you specify both the CR= or R= option and the CK= or K= option, the radius used is the maximum of the two indicated radii; this is useful for dealing with outliers. In this section, the symbols N_i , N_i^- , n_i , and n_i^- refer to clustering neighborhoods, not density estimation neighborhoods.

METHOD=0

Begin with each observation in a separate cluster. For each observation and each of its neighbors, join the cluster to which the observation belongs with the cluster to which the neighbor belongs. This method does not use density estimates. With a fixed clustering radius, the clusters are those obtained by cutting the single linkage tree at the specified radius (see Chapter 23, “The CLUSTER Procedure,”).

METHOD=1

Begin with each observation in a separate cluster. For each observation, find the nearest neighbor with a greater estimated density. If such a neighbor exists, join the cluster to which the observation belongs with the cluster to which the specified neighbor belongs.

Next, consider each observation with density estimates equal to that of one or more neighbors but not less than the estimate at any neighbor. Join the cluster containing the observation with (1) each cluster containing a neighbor of the observation such that the maximum density estimate in the cluster equals the density estimate at the observation and (2) the cluster containing the nearest neighbor of the observation such that the maximum density estimate in the cluster exceeds the density estimate at the observation.

This method is similar to the classification or assignment stage of algorithms described by Gitman (1973) and Huizinga (1978).

METHOD=2

Begin with each observation in a separate cluster. For each observation, find the neighbor with the greatest estimated density exceeding the estimated density of the observation. If such a neighbor exists, join the cluster to which the observation belongs with the cluster to which the specified neighbor belongs.

Observations with density estimates equal to that of one or more neighbors but not less than the estimate at any neighbor are treated the same way as they are in METHOD=1.

This method is similar to the first stage of an algorithm proposed by Mizoguchi and Shimura (1980).

METHOD=3

Begin with each observation in a separate cluster. For each observation, find the neighbor with greater estimated density such that the slope of the line connecting the point on the estimated density surface at the observation with the point on the estimated density surface at the neighbor is a maximum. That is, for observation x_i , find a neighbor x_j such that $(\hat{f}_j - \hat{f}_i)/d(x_j, x_i)$ is a maximum. If this slope is positive, join the cluster to which observation x_i belongs with the cluster to which the specified neighbor x_j belongs. This method was invented by Koontz, Narendra, and Fukunaga (1976).

Observations with density estimates equal to that of one or more neighbors but not less than the estimate at any neighbor are treated the same way as they are in METHOD=1. The algorithm suggested for this situation by Koontz, Narendra, and

Fukunaga (1976) may fail for flat areas in the estimated density that contain four or more observations.

METHOD=4

This method is equivalent to the first stage of two-stage density linkage (see Chapter 23, “The CLUSTER Procedure,”) without the use of the MODE=option.

METHOD=5

This method is equivalent to the first stage of two-stage density linkage (see Chapter 23, “The CLUSTER Procedure,”) with the use of the MODE=option.

METHOD=6

Begin with all observations unassigned.

Step 1: Form a list of seeds, each seed being a single observation such that the estimated density of the observation is not less than the estimated density of any of its neighbors. If you specify the MAXCLUSTERS= n option, retain only the n seeds with the greatest estimated densities.

Step 2: Consider each seed in decreasing order of estimated density.

1. If the current seed has already been assigned, proceed to the next seed. Otherwise, form a new cluster consisting of the current seed.
2. Add to the cluster any unassigned seed that is a neighbor of a member of the cluster or that shares a neighbor with a member of the cluster; repeat until no unassigned seed satisfies these conditions.
3. Add to the cluster all neighbors of seeds that belong to the cluster.
4. Consider each unassigned observation. Compute the ratio of the sum of the $p-1$ powers of the estimated density of the neighbors that belong to the current cluster to the sum of the $p-1$ powers of the estimated density of all of its neighbors, where p is specified by the POWER= option and is 2 by default. Let x_i be the current observation, and let k be the index of the current cluster. Then this ratio is

$$r_{ik} = \frac{\sum_{j \in N_i \cap C_k} \hat{f}_j^{p-1}}{\sum_{j \in N_i} \hat{f}_j^{p-1}}$$

(The sum of the $p-1$ powers of the estimated density of the neighbors of an observation is an estimate of the integral of the p th power of the density over the neighborhood.) If r_{ik} exceeds the maximum of 0.5 and the value of the THRESHOLD= option, add the observation x_i to the current cluster k . Repeat until no more observations can be added to the current cluster.

Step 3: (This step is performed only if the value of the THRESHOLD= option is less than 0.5.) Form a list of unassigned observations in decreasing order of estimated density. Repeat the following actions until the list is empty.

1. Remove the first observation from the list, for example, observation x_i .
2. For each cluster k , compute r_{ik} .
3. If the maximum over clusters of r_{ik} exceeds the value of the THRESHOLD= option, assign observation x_i to the corresponding cluster and insert all observations of which the current observation is a neighbor into the list, keeping the list in decreasing order of estimated density.

METHOD=6 is related to a method invented by Koontz and Fukunaga (1972a) and discussed by Koontz and Fukunaga (1972b).

Significance Tests

Significance tests require that a fixed-radius kernel be specified for density estimation via the DR= or R= option. You can also specify the DK= or K= option, but only the fixed radius is used for the significance tests.

The purpose of the significance tests is as follows: given a simple random sample of objects from a population, obtain an estimate of the number of clusters in the population such that the probability in repeated sampling that the estimate exceeds

the true number of clusters is not much greater than α , $1\% \leq \alpha \leq 10\%$. In other words, a sequence of null hypotheses of the form

$H_0^{(i)}$: The number of population clusters is i or less

where $i = 1, 2, \dots, n$, is tested against the alternatives such as

$H_a^{(i)}$: The number of population clusters exceeds i

with a maximum experimentwise error rate of approximately α . The tests protect you from overestimating the number of population clusters. It is impossible to protect against underestimating the number of population clusters without introducing much stronger assumptions than are used here, since the number of population clusters could conceivably exceed the sample size.

The method for conducting significance tests is as follows:

1. Estimate densities using fixed-radius uniform kernels.
2. Obtain preliminary clusters by a “valley-seeking” method. Other clustering methods could be used but would yield less power.
3. Compute an approximate p -value for each cluster by comparing the estimated maximum density in the cluster with the estimated maximum density on the cluster boundary.
4. Repeatedly join the least significant cluster with a neighboring cluster until all remaining clusters are significant.
5. Estimate the number of population clusters as the number of significant sample clusters.
6. The preceding steps can be repeated for any number of different radii, and the estimate of the number of population clusters can be taken to be the maximum number of significant sample clusters for any radius.

This method has the following useful features:

- No distributional assumptions are required.
- The choice of smoothing parameter is not critical since you can try any number of different values.
- The data can be coordinates or distances.
- Time and space requirements for the significance tests are no worse than those for obtaining the clusters.
- The power is high enough to be useful for practical purposes.

The method for computing the p -values is based on a series of plausible approximations. There are as yet no rigorous proofs that the method is infallible. Neither are there any asymptotic results. However, simulations for sample sizes ranging from 20 to 2000 indicate that the p -values are almost always conservative. The only case discovered so far in which the p -values are liberal is a uniform distribution in one dimension for which the simulated error rates exceed the nominal significance level only slightly for a limited range of sample sizes.

To make inferences regarding population clusters, it is first necessary to define what is meant by a cluster. For clustering methods using nonparametric density estimation, a cluster is usually loosely defined as a region surrounding a local maximum of the probability density function or a maximal connected set of local maxima. This definition may not be satisfactory for very rough densities with many local maxima. It is not applicable at all to discrete distributions for which the density does not exist. As another example in which this definition is not intuitively reasonable, consider a uniform distribution in two dimensions with support in the shape of a figure eight (including the interior). This density might be considered to contain two clusters even though it does not have two distinct modes.

These difficulties can be avoided by defining clusters in terms of the local maxima of a smoothed probability density or mass function. For example, define the neighborhood distribution function (NDF) with radius r at a point x as the probability that a randomly selected point will lie within a radius r of x , that is, the probability integral over a hypersphere of radius r centered at x :

$$s(x) = P(d(x, X) \leq r)$$

where X is the random variable being sampled, r is a user-specified radius, and $d(x, y)$ is the distance between points x and y .

The NDF exists for all probability distributions. You can select the radius according to the degree of resolution required. The minimum-variance unbiased estimate of the NDF at a point x is proportional to the uniform-kernel density estimate with corresponding support.

You can define a *modal region* as a maximal connected set of local maxima of the NDF. A cluster is a connected set containing exactly one modal region. This definition seems to give intuitively reasonable results in most cases. An exception is a uniform density on the perimeter of a square. The NDF has four local maxima. There are eight local maxima along the perimeter, but running PROC MODECLUS with the R= option would yield four clusters since the two local maxima at each corner are separated by a distance equal to the radius. While this density does indeed have four distinctive features (the corners), it is not obvious that each corner should be considered a cluster.

The number of population clusters depends on the radius of the NDF. The significance tests in PROC MODECLUS protect against overestimating the number of clusters at any specified radius. It is often useful to look at the clustering results across a range of radii. A plot of the number of sample clusters as a function of the radius is a useful descriptive display, especially for high-dimensional data (Wong and Schaack 1982).

If a population has two clusters, it must have two modal regions. If there are two modal regions, there must be a “valley” between them. It seems intuitively desirable that the boundary between the two clusters should follow the bottom of this valley. All the clustering methods in PROC MODECLUS are designed to locate the estimated cluster boundaries in this way, although methods 1 and 6 seem to be much more successful at this than the others. Regardless of the precise location of the cluster boundary, it is clear that the maximum of the NDF along the boundary between two clusters must be strictly less than the value of the NDF in either modal region; otherwise, there would be only a single modal region; according to Hartigan and Hartigan (1985), there must be a “dip” between the two modes. PROC MODECLUS assesses the significance of a sample cluster by comparing the NDF in the modal region with the maximum of the NDF along the cluster boundary. If the NDF has second-order derivatives in the region of interest and if the boundary between the two clusters is indeed at the bottom of the valley, then the maximum value of the NDF along the boundary occurs at a saddle point. Hence, this test is called a *saddle test*. This term is intended to describe any test for clusters that compares modal densities with saddle densities, not just the test currently implemented in the MODECLUS procedure.

The obvious estimate of the maximum NDF in a sample cluster is the maximum estimated NDF at an observation in the cluster. Let $m(k)$ be the index of the observation for which the maximum is attained in cluster k .

Estimating the maximum NDF on the cluster boundary is more complicated. One approach is to take the maximum NDF estimate at an observation in the cluster that has a neighbor belonging to another cluster. This method yields excessively large estimates when the neighborhood is large. Another approach is to try to choose an object closer to the boundary by taking the observation with the maximum sum of estimated densities of neighbors belonging to a different cluster. After some experimentation, it is found that a combination of these two methods works well. Let B_k be the set of indices of observations in cluster k that have neighbors belonging to a different cluster, and compute

$$\max_{i \in B_k} \left(0.2 \hat{f}_i n_i + \sum_{j \in N_i - C_k} \hat{f}_j \right)$$

Let $s(k)$ be the index of the observation for which the maximum is attained.

Using the notation $\#(S)$ for the cardinality of set S , let

$$\begin{aligned} n_{ij}^- &= \#(N_i^- \cap N_j^-) \\ c_m(k) &= n_{m(k)}^- - n_{m(k)s(k)}^- \\ c_s(k) &= n_{s(k)}^- - n_{m(k)s(k)}^- \text{ if } B_k \neq \emptyset, \\ &= 0 \text{ otherwise} \\ q_k &= 1/2 \text{ if } B_k \neq \emptyset, \\ &= 2/3 \text{ otherwise} \\ z_k &= \frac{c_m(k) - q_k(c_m(k) + c_s(k)) - 1/2}{\sqrt{q_k(1 - q_k)(c_m(k) + c_s(k))}} \end{aligned}$$

$$u = \left[(.2 + .05\sqrt{n}) \sum_{i:n_i>1} \frac{1}{n_i + 1} \right]$$

Let $R(u)$ be a random variable distributed as the range of a random sample of u observations from a standard normal distribution. Then the approximate p -value p_k for cluster k is

$$p_k = Pr(z_k > R(u)/\sqrt{2})$$

If points $m(k)$ and $s(k)$ are fixed a priori, z_k would be the usual approximately normal test statistic for comparing two binomial random variables. In fact, $m(k)$ and $s(k)$ are selected in such a way that $c_m(k)$ tends to be large and $c_s(k)$ tends to be small. For this reason, and because there may be a large number of clusters, each with its own z_k to be tested, each z_k is referred to the distribution of $R(u)$ instead of a standard normal distribution. If the tests are conducted for only one radius and if u is chosen equal to n , then the p -values are very conservative because (1) you are not making all possible pairwise comparisons of observations in the sample and (2) n_i^- and n_j^- are positively correlated if the neighborhoods overlap. In the formula for u , the summation overcorrects somewhat for the conservativeness due to correlated n_i^- 's. The factor $.2 + .05\sqrt{n}$ is empirically estimated from simulation results to adjust for the use of more than one radius.

If the JOIN option is specified, the least significant cluster (the cluster with the smallest z_k) is either dissolved or joined with a neighboring cluster. If no members of the cluster have neighbors belonging to a different cluster, all members of the cluster are unassigned. Otherwise, the cluster is joined to the neighboring cluster such that the sum of density estimates of neighbors of the estimated saddle point belonging to it is a maximum. Joining clusters increases the power of the saddle test. For example, consider a population with two well-separated clusters. Suppose that, for a certain radius, each population cluster is divided into two sample clusters. None of the four sample clusters is likely to be significant, but after the two sample clusters corresponding to each population cluster are joined, the remaining two clusters may be highly significant.

The saddle test implemented in PROC MODECLUS has been evaluated by simulation from known distributions. Some results are given in the following three tables. In [Table 47.3](#), samples of 20 to 2000 observations are generated from a one-dimensional uniform distribution. For sample sizes of 1000 or less, 2000 samples are generated and analyzed by PROC MODECLUS. For a sample size of 2000, only 1000 samples are generated. The analysis is done with at least 20 different values of the R= option spread across the range of radii most likely to yield significant results. The six central columns of the table give the observed error rates at the nominal error rates (α) at the head of each column. The standard errors of the observed error rates are given at the bottom of the table. The observed error rates are conservative for $\alpha \leq 5\%$, but they increase with α and become slightly liberal for sample sizes in the middle of the range tested.

Table 47.3. Observed Error Rates (%) for Uniform Distribution

Sample Size	Nominal Type 1 Error Rate						Number of Simulations
	1	2	5	10	15	20	
20	0.00	0.00	0.00	0.60	11.65	27.05	2000
50	0.35	0.70	4.50	10.95	20.55	29.80	2000
100	0.35	0.85	3.90	11.05	18.95	28.05	2000
200	0.30	1.35	4.00	10.50	18.60	27.05	2000
500	0.45	1.05	4.35	9.80	16.55	23.55	2000
1000	0.70	1.30	4.65	9.55	15.45	19.95	2000
2000	0.40	1.10	3.00	7.40	11.50	16.70	1000
Standard Error	0.22	0.31	0.49	0.67	0.80	0.89	2000
	0.31	0.44	0.69	0.95	1.13	1.26	1000

All unimodal distributions other than the uniform that have been tested, including normal, Cauchy, and exponential distributions and uniform mixtures, have produced much more conservative results. Table 47.4 displays results from a unimodal mixture of two normal distributions with equal variances and equal sampling probabilities and with means separated by two standard deviations. Any greater separation would produce a bimodal distribution. The observed error rates are quite conservative.

Table 47.4. Observed Error Rates (%) for Normal Mixture with 2σ Separation

Sample Size	Nominal Type 1 Error Rate						Number of Simulations
	1	2	5	10	15	20	
100	0.0	0.0	0.0	1.0	2.0	4.0	200
200	0.0	0.0	0.0	2.0	3.0	3.0	200
500	0.0	0.0	0.5	0.5	0.5	0.5	200

All distributions in two or more dimensions that have been tested yield extremely conservative results. For example, a uniform distribution on a circle yields observed error rates that are never more than one-tenth of the nominal error rates for sample sizes up to 1000. This conservatism is due to the fact that, as the dimensionality increases, more and more of the probability lies in the tails of the distribution (Silverman 1986, p. 92), and the saddle test used by PROC MODECLUS is more conservative for distributions with pronounced tails. This applies even to a uniform distribution on a hypersphere because, although the density has no tails, the NDF does.

Since the formulas for the significance tests do not involve the dimensionality, no problems are created when the data are linearly dependent. Simulations of data in nonlinear subspaces (the circumference of a circle or surface of a sphere) have also yielded conservative results.

Table 47.5 displays results in terms of power for identifying two clusters in samples from a bimodal mixture of two normal distributions with equal variances and equal sampling probabilities separated by four standard deviations. In this simulation, PROC MODECLUS never indicated more than two significant clusters.

Table 47.5. Power (%) for Normal Mixture with 4σ Separation

Sample Size	Nominal Type 1 Error Rate						Number of Simulations
	1	2	5	10	15	20	
20	0.0	0.0	0.0	2.0	37.5	68.5	200
35	0.0	13.5	38.5	48.5	64.0	75.5	200
50	17.5	26.0	51.5	67.0	78.5	84.0	200
75	25.5	36.0	58.5	77.5	85.5	89.5	200
100	40.0	54.5	72.5	84.5	91.5	92.5	200
150	70.5	80.0	92.0	97.0	100.0	100.0	200
200	89.0	96.0	99.5	100.0	100.0	100.0	200

The saddle test is not as efficient as excess-mass tests for multimodality (Müller and Sawitzki 1991, Polonik 1993). However, there is not yet a general approximation for the distribution of excess-mass statistics to circumvent the need for simulations to do significance tests. Refer to Minnotte (1992) for a review of tests for multimodality.

Computational Resources

The MODECLUS procedure stores coordinate data in memory if there is enough space. For distance data, only one observation at a time is in memory.

PROC MODECLUS constructs lists of the neighbors of each observation. The total space required is $12 \sum n_i$ bytes, where n_i is based on the largest neighborhood required by any analysis. The lists are stored in a SAS utility data set unless you specify the CORE option. You may get an error message from the SAS System or from the operating system if there is not enough disk space for the utility data set. Clustering method 6 requires a second list that is always stored in memory.

For coordinate data, the time required to construct the neighbor lists is roughly proportional to $v(\log n)(\sum n_i) \log(\sum n_i/n)$. For distance data, the time is roughly proportional to $n^2 \log(\sum n_i/n)$.

The time required for density estimation is proportional to $\sum n_i$ and is usually small compared to the time required for constructing the neighbor lists.

Clustering methods 0 through 3 are quite efficient, requiring time proportional to $\sum n_i$. Methods 4 and 5 are slower, requiring time roughly proportional to $(\sum n_i) \log(\sum n_i)$. Method 6 can also be slow, but the time requirements depend very much on the data and the particular options specified. Methods 4, 5, and 6 also require more memory than the other methods.

The time required for significance tests is roughly proportional to $g \sum n_i$, where g is the number of clusters.

PROC MODECLUS can process data sets of several thousand observations if you specify reasonable smoothing parameters. Very small smoothing values produce many clusters, whereas very large values produce many neighbors; either case can require excessive time or space.

Missing Values

If the data are coordinates, observations with missing values are excluded from the analysis.

If the data are distances, missing values are treated as infinite. The neighbors of each observation are determined solely by the distances in that observation. The distances are not required to be symmetric, and there is no check for symmetry; the neighbors of each observation are determined only from the distances in that observation. This treatment of missing values is quite different from that of the CLUSTER procedure, which ignores the upper triangle of the distance matrix.

Output Data Sets

The OUT= data set contains one complete copy of the input data set for each cluster solution. There are additional variables identifying each solution and giving information about individual observations. Solutions with only one remaining cluster when JOIN=*p* is specified are omitted from the OUT= data set (see the description of the JOIN= option on page 2866). The OUT= data set can be extremely large, so it may be advisable to specify the DROP= data set option to exclude unnecessary variables.

The OUTCLUS= or OUTC= data set contains one observation for each cluster in each cluster solution. The variables identify the solution and provide statistics describing the cluster.

The OUTSUM= or OUTS= data set contains one observation for each cluster solution. The variables identify the solution and provide information about the solution as a whole.

The following variables can appear in all of the output data sets:

- `_K_`, which is the value of the K= option for the current solution. This variable appears only if you specify the K= option.
- `_DK_`, which is the value of the DK= option for the current solution. This variable appears only if you specify the DK= option.
- `_CK_`, which is the value of the CK= option for the current solution. This variable appears only if you specify the CK= option.
- `_R_`, which is the value of the R= option for the current solution. This variable appears only if you specify the R= option.
- `_DR_`, which is the value of the DR= option for the current solution. This variable appears only if you specify the DR= option.
- `_CR_`, which is the value of the CR= option for the current solution. This variable appears only if you specify the CR= option.
- `_CASCAD_`, which is the number of times the density estimates have been cascaded for the current solution. This variable appears only if you specify the CASCADE= option.
- `_METHOD_`, which is the value of the METHOD= option for the current solution. This variable appears only if you specify the METHOD= option.

- `_NJOIN_`, which is the number of clusters that are joined or dissolved in the current solution. This variable appears only if you specify the JOIN option.
- `_LOCAL_`, which is the local dimensionality estimate of the observation. This variable appears only if you specify the LOCAL option.

The OUT= data set contains the following variables:

- the variables from the input data set
- `_OBS_`, which is the observation number from the input data set. This variable appears only if you omit the ID statement.
- `DENSITY`, which is the estimated density at the observation. This variable can be renamed by the DENSITY= option.
- `CLUSTER`, which is the number of the cluster to which the observation is assigned. This variable can be renamed by the CLUSTER= option.

The OUTC= data set contains the following variables:

- the BY variables, if any
- `_NCLUS_`, which is the number of clusters in the solution
- `CLUSTER`, which is the number of the current cluster
- `_FREQ_`, which is the number of observations in the cluster
- `_MODE_`, which is the maximum estimated density in the cluster
- `_BFREQ_`, which is the number of observations in the cluster with neighbors belonging to a different cluster
- `_SADDLE_`, which is the estimated saddle density for the cluster
- `_MC_`, which is the number of observations within the fixed-radius density-estimation neighborhood of the modal observation. This variable appears only if you specify the TEST or JOIN option.
- `_SC_`, which is the number of observations within the fixed-radius density-estimation neighborhood of the saddle observation. This variable appears only if you specify the TEST or JOIN option.
- `_OC_`, which is the number of observations within the overlap of the two previous neighborhoods. This variable appears only if you specify the TEST or JOIN option.
- `_Z_`, which is the approximate z statistic for the cluster. This variable appears only if you specify the TEST or JOIN option.
- `_P_`, which is the approximate p -value for the cluster. This variable appears only if you specify the TEST or JOIN option.

The OUTS= data set contains the following variables:

- the BY variables, if any
- `_NCLUS_`, which is the number of clusters in the solution
- `_UNCL_`, which is the number of unclassified observations
- `_CROSS_`, which is the likelihood cross-validation criterion if you specify the `CROSS` or `CROSSLIST` option

Displayed Output

If you specify the `SIMPLE` option and the data are coordinates, `PROC MODECLUS` displays the following simple descriptive statistics for each variable:

- the MEAN
- the standard deviation, `STD DEV`
- the `SKEWNESS`
- the `KURTOSIS`
- a coefficient of `BIMODALITY` (see Chapter 23, “The `CLUSTER` Procedure,”)

If you specify the `NEIGHBOR` option, `PROC MODECLUS` displays a list of the neighbors of each observation. The table contains

- the observation number or ID value of the observation
- the observation number or ID value of each of its neighbors
- the distance to each neighbor

If you specify the `CROSSLIST` option, `PROC MODECLUS` produces a table of information regarding cross validation of the density estimates. Each table has a row for each observation. For each observation, the following are displayed:

- the observation number or ID value of the observation
- the radius of the neighborhood
- the number of neighbors
- the estimated log density
- the estimated cross-validated log density

If you specify the `LOCAL` option, `PROC MODECLUS` produces a table of information regarding estimates of local dimensionality. Each table has a row for each observation. For each observation, the following are displayed:

- the observation number or ID value of the observation
- the radius of the neighborhood
- the estimated local dimensionality

If you specify the LIST option, PROC MODECLUS produces a table listing the observations within each cluster. The table can include

- the cluster number
- the observation number or ID value of the observation
- the estimated density
- the sum of the density estimates of observations within the neighborhood that belong to the same cluster
- the sum of the density estimates of observations within the neighborhood that belong to a different cluster
- the sum of the density estimates of all the observations within the neighborhood
- the ratio of the sum of the density estimates for the same cluster to the sum of all the density estimates in the neighborhood

If you specify the LIST option and there are unassigned objects, PROC MODECLUS produces a table listing those observations. The table includes

- the observation number or ID value of the observation
- the estimated density
- the ratio of the sum of the density estimates for the same cluster to the sum of the density estimates in the neighborhood for all other clusters

If you specify the BOUNDARY option, PROC MODECLUS produces a table listing the observations in each cluster that have a neighbor belonging to a different cluster. The table includes

- the observation number or ID value of the observation
- the estimated density
- the cluster number
- the ratio of the sum of the density estimates for the same cluster to the sum of the density estimates in the neighborhood for all other clusters

If you do not specify the SHORT option, PROC MODECLUS produces a table of cluster statistics including

- the cluster number

- the cluster frequency (the number of observations in the cluster)
- the maximum estimated density within the cluster
- the number of observations in the cluster having a neighbor that belongs to a different cluster
- the estimated saddle density of the cluster

If you specify the TEST or JOIN option, the table of cluster statistics includes the following items pertaining to the saddle test:

- the number of observations within the fixed-radius density-estimation neighborhood of the modal observation
- the number of observations within the fixed-radius density-estimation neighborhood of the saddle observation
- the number of observations within the overlap of the two preceding neighborhoods
- the z statistic for comparing the preceding counts
- the approximate p -value

If you do not specify the NOSUMMARY option, PROC MODECLUS produces a table summarizing each cluster solution containing the following items:

- the smoothing parameters and cascade value
- the number of clusters
- the frequency of unclassified objects
- the likelihood cross-validation criterion if you specify the CROSS or CROSSLIST option

If you specify the JOIN option, the summary table also includes

- the number of clusters joined
- the maximum p -value of any cluster in the solution

If you specify the TRACE option, PROC MODECLUS produces a table for each cluster solution that lists each observation along with its cluster membership as it is reassigned from the “Old” cluster to the “New” cluster. This reassignment is described in **Step 1** through **Step 3** of the section “**METHOD=6**” on page 2875. Each table has a row for each observation. For each observation, the following are displayed:

- the observation number or ID value of the observation
- the estimated density

- the “Old” cluster membership. 0 represents an unassigned observation and -1 represents a seed.
- the “New” cluster membership
- “Ratio,” which is documented in the section “METHOD=6” on page 2875. The following character values can also be displayed:
 - “M” means the observation is a mode
 - “S” means the observation is a seed
 - “N” means the neighbor of a mode or seed, for which the ratio is not computed

ODS Table Names

PROC MODECLUS assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

Table 47.6. ODS Tables Produced in PROC MODECLUS

ODS Table Name	Description	Statement	Option
BoundaryFreq	Boundary objects information	PROC	BOUNDARY (or ALL)
ClusterList	Cluster listing, cluster id, freq., density etc.	PROC	LIST (or ALL)
ClusterStats	Cluster statistics	PROC	default
	Cluster statistics, significance test statistics	PROC	TEST or JOIN (or ALL)
ClusterSummary	Cluster summary	PROC	default
	Cluster summary, crossvalidation criterion	PROC	CROSS or CROSSLIST (or ALL)
	Cluster summary, clusters joined information	PROC	JOIN (or ALL)
CrossList	Cross-validated log density	PROC	CROSSLIST
ListLocal	Local dimensionality estimates	PROC	LOCAL
Neighbor	Nearest neighbor list	PROC	NEIGHBOR (or ALL)
SimpleStatistics	Simple statistics	PROC	SIMPLE (or ALL)
Trace	Trace of clustering algorithm (METHOD= 6 only)	PROC	TRACE (or ALL) with METHOD= 6
UnassignObjects	Information on unassigned objects	PROC	LIST (or ALL)

Examples

Example 47.1. Cluster Analysis of Samples from Univariate Distributions

This example uses pseudo-random samples from a uniform distribution, an exponential distribution, and a bimodal mixture of two normal distributions. Results are presented in [Output 47.1.1](#) through [Output 47.1.3](#) as plots displaying both the true density and the estimated density, as well as cluster membership.

The following statements produce [Output 47.1.1](#):

```
options noovp ps=28 ls=95;

Example 47.3. Cluster Analysis with Significance Tests

This example uses artificial data containing two clusters. One cluster is from a circular bivariate normal distribution. The other is a ring-shaped cluster that completely surrounds the first cluster. Without significance tests, the ring is divided into several sample clusters for any degree of smoothing that yields reasonable density estimates. The JOIN= option puts the ring back together. [Output 47.3.1](#) displays a short summary generated from the first PROC MODECLUS statement. [Output 47.3.2](#) contains a series of tables produced from the second PROC MODECLUS statement. The lack of *p*-value in the JOIN= option makes joining continue until only one cluster remains (see the description of the JOIN= option on page 2866). The cluster memberships are then plotted as displayed in [Output 47.3.3](#).

Output 47.3.3. Scatter Plots of Cluster Memberships by _NJOIN_

Example 47.4. Cluster Analysis: Hertzsprung-Russell Plot

This example uses computer-generated data to mimic a Hertzsprung-Russell plot (Struve and Zebergs 1962, p. 259) of the temperature and luminosity of stars. The data are plotted and displayed in [Output 47.4.1](#); see “Example 4 from Proc Modeclus” in the SAS/STAT Sample Program Library for the complete data set. It appears that there are two main groups of stars and a collection of isolated stars. The long straggling group of points appearing diagonally across the figure represents the main group of stars; the more compact group in the top right-hand corner contains giant stars. The JOIN= option is specified at a 0.05 significance level with various smoothing parameters. The CK=5 option is specified in order to prevent the numerous outliers from forming separate clusters. The results from PROC MODECLUS is displayed in [Output 47.4.2](#). The cluster memberships are then plotted by PROC GPLOT, as displayed in [Output 47.4.3](#).

Notice in [Output 47.4.3](#) that the graphic output from PROC GPLOT when `_R_ = 2.5` is not available because only one cluster remains after joining at a 5% significance level, and the results are not written to the OUT= data set. See the description of the [JOIN= option](#) on page 2866 for more information.

Output 47.4.3. Scatter Plots of Cluster Memberships by `_R_`

Example 47.5. Using the TRACE Option when METHOD=6

To illustrate how the TRACE option can help you to understand the clustering process when METHOD=6 is specified, the following data set is created with 12 observations.

```
data test;
  input x@@;
  datalines;
1 2 3 4 5 7.5 9 11.5 13 14.5 15 16
;
```

The first five observations seem to be close to each other, and the last five observations seem to be close to each other. Observation 6 is separated from the first five observations with a (Euclidean) distance of 2.5, and the same distance separates observation 7 from the last five observations. Observations 6 and 7 differ by 1.5.

Suppose METHOD=6 with a radius=2.5 is chosen for the cluster analysis. You can specify the TRACE option to understand how each observation is assigned.

The following statements produce [Output 47.5.1](#) and [Output 47.5.2](#):

```
/*-- METHOD=6 with TRACE and THRESHOLD=0.5 (default) --*/
proc modeclus method=6 r=2.5 trace short out=out;
  var x;
run;

data markobs;
  drop _r_ _method_ _obs_ density cluster;
  length function style $8 text $ 2;
```

```

retain xsys '2' ysys '2' hsys '1' when 'a';
set out;
/* create the text for obs */
function='label'; size=4;
style='swiss';
text=left(put(_obs_,2.));
position='3';
x=x; y=density;
output;
run;
legend1 frame cframe=ligr cborder=black
        position=center value=(justify=center);
axis1 label=(angle=90 rotate=0) minor=none;
axis2 minor=none;
title 'Plot of DENSITY*X=CLUSTER';
proc gplot data=out;
    plot density*x=cluster/ annotate=markobs
                                frame cframe=ligr
                                legend=legend1
                                vaxis=axis1 haxis=axis2;
run;

```

Output 47.5.1. Partial Output of METHOD=6 with TRACE and Default THRESHOLD=

The MODECLUS Procedure				
R=2.5 METHOD=6				
Trace of Clustering Algorithm				
Obs	Density	Cluster		Ratio
		Old	New	
3	0.0833333	-1	1	M
2	0.0666667	0	1	N
4	0.0666667	0	1	N
5	0.0666667	0	1	N
1	0.0500000	0	1	N
6	0.0500000	0	1	0.571
7	0.0500000	-1	1	0.500
9	0.0666667	-1	2	M
8	0.0500000	0	2	N
10	0.0666667	-1	2	S
12	0.0500000	0	2	N
11	0.0666667	-1	2	S

Output 47.5.2. Density Plot

Notice that in [Output 47.5.1](#), observation 7 is originally a seed (indicated by a value of -1 in the “Old” column) and then assigned to cluster 1. This is because the ratio of observation 7 to cluster 1 is 0.5 and is not less than the default value of THRESHOLD=(0.5).

If the value of the THRESHOLD= option is increased to 0.55, observation 7 should be excluded from cluster 1 and the cluster membership of observation 7 is changed.

The following statements produce [Output 47.5.3](#) and [Output 47.5.4](#):

```

/*-- METHOD=6 with TRACE and THRESHOLD=0.55 --*/
proc modeclus method=6 r=2.5 trace threshold=0.55 short
  out=out;
  var x;
run;

. . . (the Data Step and the PROC GPLOT statement
       are omitted because they are the same as the
       previous job)

```

Output 47.5.3. Partial Output of METHOD=6 with TRACE and THRESHOLD=.55

The MODECLUS Procedure				
R=2.5 METHOD=6				
Trace of Clustering Algorithm				
Obs	Density	Cluster		Ratio
		Old	New	
3	0.0833333	-1	1	M
2	0.0666667	0	1	N
4	0.0666667	0	1	N
5	0.0666667	0	1	N
1	0.0500000	0	1	N
6	0.0500000	0	1	0.571
9	0.0666667	-1	2	M
8	0.0500000	0	2	N
10	0.0666667	-1	2	S
12	0.0500000	0	2	N
11	0.0666667	-1	2	S
7	0.0500000	-1	2	S

Output 47.5.4. Density Plot

In [Output 47.5.3](#), observation 7 is a seed that is excluded by cluster 1 because its ratio to cluster 1 is less than 0.55. Being a neighbor of a member (observation 8) of cluster 2, observation 7 eventually joins cluster 2 even though it remains a “SEED.” (See [Step 2.2](#) in the section “[METHOD=6](#)” on page 2875.)

Chapter 48

The MULTTEST Procedure

Overview

The MULTTEST procedure addresses the multiple testing problem. This problem arises when you perform many hypothesis tests on the same data set. Carrying out multiple tests is often reasonable because of the cost of obtaining data, the discovery of new aspects of the data, and the many alternative statistical methods. However, a negative feature of multiple testing is the greatly increased probability of declaring false significances.

For example, suppose you carry out 10 hypothesis tests at the 5% level, and you assume that the distributions of the p -values from these tests are uniform and independent. Then, the probability of declaring a particular test significant under its null hypothesis is 0.05, but the probability of declaring at least 1 of the 10 tests significant is 0.401. If you perform 20 hypothesis tests, the latter probability increases to 0.642. These high chances illustrate the danger in multiple testing.

PROC MULTTEST approaches the multiple testing problem by adjusting the p -values from a family of hypothesis tests. An adjusted p -value is defined as the smallest significance level for which the given hypothesis would be rejected, when the entire family of tests is considered. The decision rule is to reject the null hypothesis when the adjusted p -value is less than α ; in most cases, this procedure controls the *familywise error rate* at or below the α level. PROC MULTTEST offers the following p -value adjustments:

- Bonferroni
- Sidak
- Stepdown methods
- Hochberg
- Hommel
- Fisher Combination
- False Discovery Rate
- Bootstrap
- Permutation

The Bonferroni and Sidak adjustments are simple functions of the raw p -values. They are computationally quick, but they can be too conservative. Stepdown methods remove some conservativeness, as do the step-up methods of Hochberg (1988). The bootstrap and permutation adjustments resample the data with and without replacement, respectively, to approximate the distribution of the minimum p -value of all

tests. This distribution is then used to adjust the individual raw p -values. The bootstrap and permutation methods are computationally intensive but appealing in that, unlike the other methods, correlations and distributional characteristics are incorporated into the adjustments (Westfall and Young 1989, 1993; Westfall *et al.* 1999).

PROC MULTTEST handles data arising from a multivariate one-way ANOVA model, possibly stratified, with continuous and discrete response variables; it can also accept raw p -values as input data. You can perform a t -test for the mean for continuous data and the following statistical tests for discrete data:

- Cochran-Armitage (CA) linear trend test
- Freeman-Tukey (FT) double arcsine test
- Peto (PETO) mortality-prevalence (log-rank) test
- Fisher (FISHER) exact test

The CA and PETO tests have exact versions that use permutation distributions and asymptotic versions that use an optional continuity correction. Also, with the exception of the FISHER test, you can use a stratification variable to construct Mantel-Haenszel type tests. All of the previously mentioned tests can be one- or two-sided.

As in the GLM procedure, you can specify linear contrasts that compare means or proportions of the treated groups. The output contains summary statistics and regular and multiplicity-adjusted p -values. You can create output data sets containing raw and adjusted p -values, test statistics and other intermediate calculations, permutation distributions, and resampling information.

Getting Started

Drug Example

Suppose you conduct a small study to test the effect of a drug on 15 subjects. You randomly divide the subjects into three balanced groups receiving 0 mg, 1 mg, and 2 mg of the drug, respectively. You carry out the experiment and record the presence or absence of 10 side effects for each subject. Your data set is as follows:

```
data Drug;
  input Dose$ SideEff1-SideEff10;
  datalines;
  0MG 0 0 1 0 0 1 0 0 0 0
  0MG 0 0 0 0 0 0 0 0 0 1
  0MG 0 0 0 0 0 0 0 0 0 0
  0MG 0 0 0 0 0 0 0 0 0 0
  0MG 0 1 0 0 0 0 0 0 0 0
  1MG 1 0 0 1 0 1 0 0 1 0
  1MG 0 0 0 1 1 0 0 1 0 1
  1MG 0 1 0 0 0 0 1 0 0 0
  1MG 0 0 1 0 0 0 0 0 0 1
  1MG 1 0 1 0 0 0 0 0 1 0
```

```

2MG 0 1 1 1 0 1 1 1 0 1
2MG 1 1 1 1 1 1 0 1 1 0
2MG 1 0 0 1 0 1 1 0 1 0
2MG 0 1 1 1 1 0 1 1 1 1
2MG 1 0 1 0 1 1 1 0 0 1
;

```

The increasing incidence of 1s for higher dosages in the preceding data set provides an initial visual indication that the drug has an effect. To explore this statistically, you decide to perform an analysis in which the possibility of side effects increases linearly with drug level. You can analyze the data for each side effect separately, but you are concerned that, with so many tests, there may be a high probability of incorrectly declaring some drug effects significant. You want to correct for this multiplicity problem in a way that accounts for the discreteness of the data and for the correlations between observations on the same unit.

PROC MULTTEST addresses these concerns by processing all of the data simultaneously and adjusting the p -values. The following statements perform a typical analysis:

```

proc multtest bootstrap nsample=20000 seed=41287 notables pvals;
  class Dose;
  test ca(SideEff1-SideEff10);
  contrast 'Trend' 0 1 2;
run;

```

This analysis uses the BOOTSTRAP option to adjust the p -values. The NSAMPLE= option requests 20,000 samples for the bootstrap analysis, and the starting seed for the random number generator is 41287. The NOTABLES option suppresses the display of summary statistics for each side effect and drug level combination.

The CLASS statement is used to specify the grouping variable, Dose. The CA(SIDEEFF1-SIDEEFF10) specification in the TEST statement requests a Cochran-Armitage linear trend test for all 10 characteristics. The CONTRAST statement gives the coefficients for the linear trend test.

The results from this analysis are as follows.

The Multtest Procedure	
Model Information	
Test for discrete variables	Cochran-Armitage
Z-score approximation used	Everywhere
Continuity correction	0
Tails for discrete tests	Two-tailed
Strata weights	None
P-value adjustment	Bootstrap
Number of resamples	20000
Seed	41287

Figure 48.1. Output Summary for the MULTTEST Procedure

Figure 48.1 describes the statistical tests performed by PROC MULTTEST. For this example, PROC MULTTEST carries out a two-tailed Cochran-Armitage linear trend test with no continuity correction or strata adjustment. This test is performed on the raw data and on 20,000 bootstrap samples.

The Multtest Procedure			
Contrast Coefficients			
Dose			
Contrast	0MG	1MG	2MG
Trend	0	1	2

Figure 48.2. Coefficients Used in the MULTTEST Procedure

Figure 48.2 displays the coefficients for the Cochran-Armitage test. They are 0, 1, and 2, as specified in the CONTRAST statement.

The Multtest Procedure			
p-Values			
Variable	Contrast	Raw	Bootstrap
SideEff1	Trend	0.0519	0.3471
SideEff2	Trend	0.1949	0.8388
SideEff3	Trend	0.0662	0.5232
SideEff4	Trend	0.0126	0.0937
SideEff5	Trend	0.0382	0.2438
SideEff6	Trend	0.0614	0.4455
SideEff7	Trend	0.0095	0.0540
SideEff8	Trend	0.0519	0.3471
SideEff9	Trend	0.1949	0.8388
SideEff10	Trend	0.2123	0.9002

Figure 48.3. Summary of p -values for the MULTTEST Procedure

Figure 48.3 lists the p -values for the drug example. The Raw column lists the p -values for the Cochran-Armitage test on the original data, and the Bootstrap column provides the bootstrap adjustment of the raw p -values.

Note that the raw p -values lead you to reject the null hypothesis of no linear trend for 3 of the 10 characteristics at the 5% level and for 7 of the 10 characteristics at the 10% level. The bootstrap p -values, however, lead to this conclusion for 0 of the 10 characteristics at the 5% level and only 2 of the 10 characteristics at the 10% level. The bootstrap adjustment gives the probability of observing a p -value as extreme as each given p -value, considering all ten tests simultaneously. This adjustment incorporates the correlation of the raw p -values, the discreteness of the data, and the multiple testing problem. Failure to account for these issues can certainly lead to misleading inferences for these data.

Syntax

The following statements are available in PROC MULTTEST.

```

PROC MULTTEST < options > ;
  BY variables ;
  CLASS variable ;
  CONTRAST 'label' values ;
  FREQ variable ;
  STRATA variable ;
  TEST name (variables < / options > ) ;

```

Items within angle brackets (< >) are optional, and statements following the PROC MULTTEST statement can appear in any order. The CLASS and TEST statements are required. The syntax of each statement is described in the following section in alphabetical order after the description of the PROC MULTTEST statement.

PROC MULTTEST Statement

```

PROC MULTTEST < options > ;

```

You can specify the following options in the PROC MULTTEST statement.

BONFERRONI

BON

specifies that the Bonferroni adjustments (number of tests \times p -value) be computed for each test. These adjustments can be extremely conservative and should be viewed with caution. When exact tests are specified via the PERMUTATION= option in the TEST statement, the actual permutation distributions are used, resulting in a much less conservative version of this procedure (Westfall and Wolfinger 1997).

BOOTSTRAP

BOOT

specifies that the p -values be adjusted using the bootstrap method to resample vectors (Westfall and Young 1993). Resampling is performed with replacement and independently within levels of the STRATA variable. Continuous variables are mean-centered by default prior to resampling. The BOOTSTRAP option is not allowed with the PETO test for theoretical reasons.

If the PERMUTATION= suboption is used with the CA test on the TEST statement, the exact permutation distribution is recomputed for each bootstrap sample. **Caution:** This can be very time-consuming. It is preferable to use permutation resampling when permutation base tests are used.

CENTER

requests that continuous variables be mean-centered prior to resampling. The default action is to mean-center for bootstrap resampling and not to mean-center for permutation resampling.

DATA=SAS-data-set

names the input SAS data set to be used by PROC MULTTEST. The default is to use the most recently created data set. The DATA= and PDATA= options cannot both be specified.

FDR

requests adjusted p -values using the method of Benjamini and Hochberg (1995). These p -values do not control the familywise error rate, but they do control the false discovery rate in some cases.

FISHER_C

requests adjusted p -values using Fisher's combination method.

HOC

requests adjusted p -values using Hochberg's (1988) step-up Bonferroni method.

HOMMEL**HOM**

requests adjusted p -values using Hommel's (1988) method.

HOLM

is an alias for the [STEPBON](#) adjustment.

NOCENTER

requests that continuous variables not be mean-centered prior to resampling. The default action is to mean-center for bootstrap resampling and not to mean-center for permutation resampling.

NOPRINT

suppresses the normal display of results. Note that this option temporarily disables the Output Delivery System (ODS); see [Chapter 14](#), "The Output Delivery System," for more information.

NOTABLES

suppresses display of the "Discrete Variable Tabulations" and "Continuous Variable Tabulations" tables.

NOZEROS

suppresses display of tables having zero occurrences for all CLASS levels.

NSAMPLE= number**N= number**

specifies the number of resamples for use with the BOOTSTRAP and PERMUTATION options; it is assumed to be 20,000 by default. Large values of *number* (20,000 or more) are usually recommended for accuracy, but long execution times may result, particularly with large data sets.

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the sorting order for the levels of the CLASS variable. By default, ORDER=FORMATTED. For ORDER=FORMATTED and ORDER=INTERNAL, the sort order is machine dependent. This ordering determines which parameters in the model correspond to each level in the data, so the ORDER= option may be useful when you use CONTRAST statements.

When ORDER=FORMATTED is in effect for numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values. In releases previous to Version 8, numeric class levels with no explicit format were ordered by their BEST12. formatted values. In order to revert to the previous method, you can specify this format explicitly for the CLASS variable. The change was implemented because the former default behavior for ORDER=FORMATTED often resulted in levels not being ordered numerically and required you to use an explicit format or to specify ORDER=INTERNAL to get the more natural ordering.

The following table shows how PROC MULTTEST interprets values of the ORDER= option.

Value of ORDER=	Levels Sorted By
DATA	order of appearance in the input data set
FORMATTED	external formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ	descending frequency count; levels with the most observations come first in the order
INTERNAL	unformatted value

For more information on sorting order, see the chapter on the SORT procedure in the *SAS Procedures Guide* and the discussion of BY-group processing in *SAS Language Reference: Concepts*.

OUT=SAS-data-set

names the output SAS data set containing variable names, contrast names, intermediate calculations, and all associated *p*-values.

OUTPERM=SAS-data-set

names the output SAS data set containing entire permutation distributions (upper-tail probabilities) for all tests when the PERMUTATION= option is used. **Caution:** This data set can be very large.

OUTSAMP=SAS-data-set

names the output SAS data set containing information from the resampled data sets when resampling is performed. **Caution:** This data set can be very large.

PDATA=SAS-data-set

names an input SAS data set containing the variable raw_p with observations that consist of raw *p*-values. The MULTTEST procedure adjusts the collection of raw *p*-values for multiplicity. Resampling-based adjustments are not permitted with this type of data input. The PDATA= and DATA= options cannot both be specified.

PERMUTATION**PERM**

specifies adjusted p -values in identical fashion as the **BOOTSTRAP** option, with the exception that PROC MULTTEST resamples without replacement rather than with replacement. Resampling is performed independently within levels of the **STRATA** variable. Continuous variables are not mean-centered prior to resampling. The **PERMUTATION** option is not allowed with the **PETO** test for theoretical reasons.

PVALS

requests that a summary table of raw and adjusted p -values be included.

SEED= number**S= number**

specifies the initial seed for the random number generator used for resampling. The value for *number* must be an integer. If you do not specify a seed, or if you specify a value less than or equal to zero, then PROC MULTTEST uses the time of day from the computer's clock to generate an initial seed. For more details about seed values, refer to *SAS Language Reference: Concepts*.

SIDAK**SID**

specifies that the Sidak adjustments be computed for each test. These adjustments take the form

$$1 - (1 - p)^n$$

where p is the raw p -value and n is the number of tests. These are slightly less conservative than the Bonferroni adjustments, but they still should be viewed with caution. When exact tests are specified via the **PERMUTATION=** option in the **TEST** statement, the actual permutation distributions are used, resulting in a much less conservative version of this procedure (Westfall and Wolfinger 1997).

STEPBON

requests adjusted p -values using the stepdown Bonferroni method of Holm (1979).

STEPBOOT

requests that adjusted p -values be computed using bootstrap resampling as described under the **BOOTSTRAP** option, but in stepdown fashion.

STEPPERM

requests that adjusted p -values be computed using permutation resampling as described under the **PERMUTATION** option, but in stepdown fashion.

STEPSID

requests adjusted p -values using the Sidak method as described in the **SIDAK** option, but in stepdown fashion.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC MULTTEST to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. The *variables* are one or more variables in the input data set.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the MIXED procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure (in base SAS software).

Since sorting the data changes the order in which PROC MULTTEST reads observations, this can affect the sorting order for the levels of the CLASS variable if you have specified ORDER=DATA in the PROC MULTTEST statement. This, in turn, affects specifications in the CONTRAST statements.

For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

CLASS Statement

CLASS *variable*;

The CLASS statement is required. It declares a single variable (character or numeric) used to identify the groups for the analysis. For example, if the variable **Treatment** defines different levels of a treatment, then the statement is

```
class Treatment;
```

The CLASS variable can be either character or numeric. By default, its levels are determined from entire formatted values. Note that this represents a slight change from previous releases in the way in which class levels are determined. In releases prior to Version 9, class levels were determined using no more than the first 16 characters of the formatted values. If you wish to revert to this previous behavior you can use the TRUNCATE option in the CLASS statement. In any case, you can use formats to group values into levels. Refer to the discussion of the FORMAT procedure in the *SAS Procedures Guide* and to the discussions of the FORMAT statement and SAS

formats in *SAS Language Reference: Dictionary*. You can adjust the order of CLASS variable levels with the **ORDER=** option in the PROC MULTTEST statement. You need to be aware of the order when using the CONTRAST statement, and you should check the “Contrast Coefficients” table to verify that it is suitable.

You can specify the following option in the CLASS statement after a slash(/):

TRUNCATE specifies that class levels should be determined using only no more than the first 16 characters of the formatted values of CLASS variables. When formatted values are longer than 16 characters, you can use this option in order to revert to the levels as determined in releases previous to Version 9.

The order of the CLASS levels used by PROC MULTTEST correspond to their formatted values; this order can be changed with the ORDER= option in the PROC MULTTEST statement.

CONTRAST Statement

CONTRAST *'label' values ;*

This statement is used to identify tests between the levels of the CLASS variable; in particular, it is used to specify the coefficients for the trend tests. The *label* is a string naming the contrast; it contains a maximum of 21 characters. The *values* are scoring coefficients across the CLASS variable levels.

You can specify multiple CONTRAST statements, thereby specifying multiple contrasts for each variable. Multiplicity adjustments are computed for all contrasts and all variables simultaneously. The coefficients are applied in the order of the CLASS variables; this order can be changed with the ORDER= option in the PROC MULTTEST statement. For example, consider a four-group experiment with CLASS variable levels A1, A2, B1, and B2 denoting two levels of two treatments. The following statements produce three linear trend tests for each variable identified in the TEST statement. PROC MULTTEST computes the multiplicity adjustments over the entire collection of tests, which is three times the number of variables.

```
contrast 'a vs b'      -1 -1  1  1;
contrast 'a linear'   -1  1  0  0;
contrast 'b linear'    0  0 -1  1;
```

As another example, consider an animal carcinogenicity experiment with dose levels 0, 4, 8, 16, and 50. You might consider trend tests defined using the following statement:

```
contrast 'arithmetic trend' 0 4 8 16 50;
```

This statement produces a trend test using the indicated scoring coefficients. Multiplicity-adjusted *p*-values are then computed over the collection of variables identified in the TEST statement. Refer to Lagakos and Louis (1985) for guidelines on the selection of contrast-scoring values.

When a Fisher test is specified in the TEST statement, the CONTRAST statement coefficients are used to group the CLASS variable's levels. Groups with a -1 contrast coefficient are combined and compared with groups with a 1 contrast coefficient for each test, and groups with a 0 coefficient are not included in the contrast. For example, the statements

```
contrast 'c vs all' 1 -1 -1 -1;
contrast 'c vs t1' 1 -1 0 0;
contrast 'c vs t3' 1 0 0 -1;
```

compute Fisher exact tests for (a) control versus the combined treatment groups, (b) control versus the first treatment group, and (c) control versus the third treatment group. Multiplicity adjustments are then computed over the entire collection of tests and variables. Only -1 , 1 , and 0 are acceptable CONTRAST coefficients when the Fisher test is specified; PROC MULTTEST ignores the CONTRAST statement if any other coefficients appear.

If you specify the FISHER test and no CONTRAST statements, then all contrasts of control versus treatment are automatically generated, with the first level of the CLASS variable deemed to be the control. In this case, the control level is assigned the value 1 in each contrast and the other treatment levels are assigned -1 . You should therefore use the LOWERTAILED option to test for higher success rates in the treatment groups.

For tests other than FISHER, CONTRAST values are $0,1,2,\dots$ by default. For t -tests for the mean using continuous data (and for the FT tests), the contrast coefficients are centered to have mean 0 . The resulting centered scoring coefficients are then applied to the sample means (or to the double-arcsine-transformed proportions in the case of the FT tests).

FREQ Statement

FREQ *variable* ;

The FREQ statement names a variable that provides frequencies for each observation in the DATA= data set. Specifically, if n is the value of the FREQ variable for a given observation, then that observation is used n times.

If the value of the FREQ variable is missing or is less than 1 , the observation is not used in the analysis. If the value is not an integer, only the integer portion is used.

STRATA Statement

STRATA *variable* ;

The STRATA statement identifies a single variable to use as a stratification variable in the analysis. This yields tests similar to those discussed in Mantel and Haenszel (1959) and Hoel and Walburg (1972) for binary data and pooled-means tests for continuous data. For example, when you test for prevalence in a carcinogenicity study, it is common to stratify on intervals of the time at death; the first level of the stratification variable may represent weeks $0-52$, the second weeks $53-80$, and so on. In

multicenter clinical studies, each level of the stratification variable may represent a particular center.

The following option is available in the STRATA statement after a slash (/):

WEIGHT=

specifies the type of strata weighting to use when computing the Freeman-Tukey and *t*-tests for the mean. Valid values are SAMPLESIZE, HARMONIC, and EQUAL. SAMPLESIZE requests weights proportional to the within-stratum sample sizes, and is the default method. HARMONIC sets up weights equal to the harmonic mean of the non-missing within-stratum CLASS sizes, and is similar to a Type 2 analysis in PROC GLM. EQUAL specifies equal weights, and is similar to a Type 3 analysis in PROC GLM.

TEST Statement

TEST *name* (*variables* < / *options* >);

The TEST statement is required. It identifies statistical tests to be performed and the discrete and continuous variables to be tested. The following tests are permitted as *name* in the TEST statement.

CA	requests the Cochran-Armitage linear trend tests for group comparisons. The test variables should take the value 0 for a failure and 1 for a success. The PERMUTATION= option can be used to request an exact permutation test; otherwise, a <i>Z</i> -score approximation is used. The CONTINUITY= option can be used to specify a continuity correction for the <i>Z</i> -score approximation.
FISHER	requests Fisher exact tests for comparing two treatment groups. The test variables should take the value 0 for a failure and 1 for a success.
FT	requests <i>Z</i> -score CA tests based upon the Freeman-Tukey double arcsine transformation of the frequencies. The test variables should take the value 0 for a failure and 1 for a success.
MEAN	requests the <i>t</i> -test for the mean. The test variables can take on any numeric values.
PETO	requests the Peto mortality-prevalence test. The test variables should take the value 0 for a nonoccurrence, 1 for an incidental occurrence, and 2 for a fatal occurrence. The TIME= option should be used with the PETO test to specify a variable giving the age at death. The CONTINUITY= option can be used to specify a continuity correction for the test.

If the value of a TEST variable is invalid, the observation is not used in the analysis. You can specify two tests only if one of them is MEAN. For example, the following statement is valid

```
test ca(d1-d2) mean(c1-c2);
```

but the statement

```
test ca(d1-d2) ft(d1-d2);
```

is invalid.

You can specify the following options in the TEST statement (some apply to only one test).

BINOMIAL

specifies that the binomial variance estimate be used for CA and PETO tests in their asymptotic normal approximations. The default is to use the hypergeometric variance.

CONTINUITY= *number*

C= *number*

specifies *number* as a particular continuity correction for the Z -score approximation in the CA and PETO tests. The default is 0.

LOWERTAILED

LOWER

is used to make all tests lower-tailed. All tests are two-tailed by default.

PERMUTATION= *number*

PERM= *number*

specifies that p -values for the CA and PETO tests be computed using exact permutation distributions when marginal success or failure totals within a stratum are *number* or less. For values greater than *number* (or when the PERMUTATION= option is omitted), PROC MULTTEST uses standard normal approximations with a continuity correction chosen to approximate the permutation distribution. PROC MULTTEST computes the appropriate convolution distributions when you use the STRATA statement along with the PERMUTATION= option.

TIME= *variable*

identifies the PETO test variable containing the age at death, which is assumed to be integer valued. If the TIME= option is omitted, all ages are assumed to equal 1.

UPPERTAILED

UPPER

is used to make all tests upper-tailed. All tests are two-tailed by default.

Details

Statistical Tests

The following section discusses the statistical tests performed in the MULTTEST procedure. For continuous data, a t -test for the mean is available. For discrete variables, available tests are the Cochran-Armitage (CA) linear trend test, the Freeman-Tukey (FT) double arcsine test, the Peto mortality-prevalence test, and the Fisher exact test.

Throughout this section, the discrete and continuous variables are denoted by S_{vgsr} and X_{vgsr} , respectively, where v is the variable, g is the treatment group, s is the stratum, and r is the replication. A plus sign (+) subscript denotes summation over an index. Note that the tests are invariant to the location and scale of the contrast coefficients t_g .

Cochran-Armitage Linear Trend Test

The Cochran-Armitage linear trend test (Cochran 1954; Armitage 1955; Agresti 1990) is implemented using a Z -score approximation, an exact permutation distribution, or a combination of both.

Z-Score Approximation

Let m_{vgs} denote the sample size for a binary variable v within group g and stratum s . The pooled probability estimate for variable v and stratum s is

$$p_{vs} = \frac{S_{v+s+}}{m_{v+s}}$$

The expected value (under constant within-stratum treatment probabilities) for variable v , group g , and stratum s is

$$E_{vgs} = m_{vgs}p_{vs}$$

The test statistic for variable v has numerator

$$N_v = \sum_s \sum_g t_g (S_{vgs+} - E_{vgs})$$

where t_g denotes the contrast trend coefficients specified by the CONTRAST statement. The binomial variance estimate for this statistic is

$$V_v = \sum_s p_{vs}(1 - p_{vs}) \sum_g m_{vgs}(t_g - \bar{t}_{vs})^2$$

where

$$\bar{t}_{vs} = \sum_g \frac{m_{vgs}t_g}{m_{v+s}}$$

The hypergeometric variance estimate (the default) is

$$V_v = \sum_s \{m_{v+s}/(m_{v+s} - 1)\} p_{vs}(1 - p_{vs}) \sum_g m_{vgs}(t_g - \bar{t}_{vs})^2$$

For any strata s with $m_{v+s} \leq 1$, the contribution to the variance is taken to be zero.

PROC MULTTEST computes the Z -score statistic

$$Z_v = \frac{N_v}{\sqrt{V_v}}$$

The p -value for this statistic comes from the standard normal distribution. Whenever a 0 is computed for the denominator, the p -value is set to 1. This p -value approximates the probability obtained from the exact permutation distribution, discussed in the following text.

The Z -score statistic can be continuity-corrected to better approximate the permutation distribution. With continuity correction c , the upper-tailed p -value is computed from

$$Z_v = \frac{N_v - c}{\sqrt{V_v}}$$

For two-tailed, noncontinuity-corrected tests, PROC MULTTEST reports the p -value as $2 \min(p, 1-p)$, where p is the upper-tailed p -value. The same formula holds for the continuity-corrected test, with the exception that when the noncontinuity-corrected Z and the continuity-corrected Z have opposite signs, the two-tailed p -value is 1.

When the PERMUTATION= option is specified and no STRATA variable is specified, PROC MULTTEST uses a continuity correction selected to optimally approximate the upper-tail probability of permutation distributions with smaller marginal totals (Westfall and Lin 1988). Otherwise, the continuity correction is specified using the CONTINUITY= option in the TEST statement.

The CA Z -score statistic is the Hoel-Walburg (Mantel-Haenszel) statistic reported by Dinse (1985).

Exact Permutation Test

When you use the PERMUTATION= option for CA in the TEST statement, PROC MULTTEST computes the exact permutation distribution of the trend score

$$T_v = \sum_s \sum_g t_g S_{vgs+}$$

and then compares the observed value of this trend with the permutation distribution to obtain the p -value

$$p_v = \Pr(X \geq \text{observed } T_v)$$

where X is a random variable from the permutation distribution and where upper-tailed tests are requested. This probability can be viewed as a binomial probability, where the within-stratum probabilities are constant and where the probability is conditional with respect to the marginal totals S_{v+s+} . It also can be considered a rerandomization probability.

Because the computations can be quite time-consuming with large data sets, specifying the `PERMUTATION=number` option in the `TEST` statement limits the situations where `PROC MULTTEST` computes the exact permutation distribution. When marginal total success or total failure frequencies exceed *number* for a particular stratum, the permutation distribution is approximated using a continuity-corrected normal distribution. You should be cautious in using the `PERMUTATION=` option in conjunction with bootstrap resampling because the permutation distribution is recomputed for each bootstrap sample. This recomputation is not necessary with permutation resampling.

The permutation distribution is computed in two steps:

1. The permutation distributions of the trend scores are computed within each stratum.
2. The distributions are convolved to obtain the distribution of the total trend.

As long as the total success or failure frequency does not exceed *number* for any stratum, the computed distributions are exact. In other words, if $S_{v+s+} \leq \textit{number}$ or $(m_{v+s} - S_{v+s+}) \leq \textit{number}$ for all s , then the permutation trend distribution for variable v is computed exactly.

In step 1, the distribution of the within-stratum trend

$$\sum_g t_g S_{vgs+}$$

is computed using the multivariate hypergeometric distribution of the S_{vgs+} , provided *number* is not exceeded. This distribution can be written as

$$\Pr(S_{v1s+}, S_{v2s+}, \dots, S_{vGs+}) = \prod_{g=1}^G \frac{\binom{m_{vgs}}{S_{vgs+}}}{\binom{m_{v+s}}{S_{v+s+}}}$$

The distribution of the within-stratum trend is then computed by summing these probabilities over appropriate configurations. For further information on this technique, refer to Bickis and Krewski (1986) and Westfall and Lin (1988). In step 2, the exact convolution distribution is obtained for the trend statistic summed over all strata having totals that meet the threshold criterion. This distribution is obtained by applying the fast Fourier transform to the exact within-stratum distributions. A description of this general method can be found in Pagano and Tritchler (1983) and Good (1987).

The convolution distribution of the overall trend is then computed by convolving the exact distribution with the distribution of the continuity-corrected standard normal approximation. To be more specific, let S_1 denote the subset of stratum indices that satisfy the threshold criterion, and let S_2 denote the subset of indices that do not satisfy the criterion. Let T_{v1} denote the combined trend statistic from the set S_1 , which has an exact distribution obtained using Fourier analysis as previously outlined, and let T_{v2} denote the combined trend statistic from the set S_2 . Then the distribution of the overall trend $T_v = T_{v1} + T_{v2}$ is obtained by convolving the analytic distribution of T_{v1} with the continuity-corrected normal approximation for T_{v2} . Using the notation from the “Z-Score Approximation” section on page 2948, this convolution can be written as

$$\begin{aligned} \Pr(T_{v1} + T_{v2} \geq u) &= \sum_{u1} \Pr(T_{v1} + T_{v2} \geq u \mid T_{v1} = u1) \Pr(T_{v1} = u1) \\ &\approx \sum_{u1} \Pr(Z \geq z) \Pr(T_{v1} = u1) \end{aligned}$$

where Z is a standard normal random variable, and

$$z = \frac{1}{\sqrt{V_v}} \left(u - u1 - \sum_{S_2} p_{vs} \sum_g t_g m_{vgs} - c \right)$$

In this expression, the summation of s in V_v is over S_2 , and c is the continuity correction discussed under the Z -score approximation.

When a two-tailed test is requested, the expected trend

$$E_v = \sum_s \sum_g t_g E_{vgs}$$

is computed, and the two-tailed p -value is reported as the permutation tail probability for the observed trend T_v plus the permutation tail probability for $2E_v - T_v$, the reflected trend.

Freeman-Tukey Double Arcsine Test

For this test, the contrast trend coefficients t_1, \dots, t_G are centered to the values c_1, \dots, c_G , where $c_g = t_g - \bar{t}$, $\bar{t} = \sum_g t_g / G$, and G is the number of groups. The numerator of this test statistic is

$$N_v = \sum_s w_{vs} \sum_g c_g f(S_{vgs+}, m_{vgs})$$

where the weights w_{vs} take on three different types of values depending upon your specification of the WEIGHT= option in the STRATA statement. The default value

is the within-strata sample size m_{v+s} , ensuring comparability with the ordinary CA trend statistic. WEIGHT=HARMONIC sets w_{vs} equal to the harmonic mean

$$\left[\left(\sum_g \frac{1}{m_{vgs}} \right) / G^* \right]^{-1}$$

where G^* is the number of non-missing groups and the summation is over only the non-missing elements. The harmonic means analysis places more weight on the smaller sample sizes than does the default sample size method, and is similar to a Type 2 analysis in PROC GLM. WEIGHT=EQUAL sets $w_{vs} = 1$ for all v and s , and is similar to a Type 3 analysis in PROC GLM.

The function $f(r, n)$ is the double arcsine transformation:

$$f(r, n) = \arcsin \left(\sqrt{\frac{r}{n+1}} \right) + \arcsin \left(\sqrt{\frac{r+1}{n+1}} \right)$$

The variance estimate is

$$V_v = \sum_s w_{vs}^2 \sum_g \frac{c_g^2}{m_{vgs} + \frac{1}{2}}$$

and the test statistic is

$$Z_v = \frac{N_v}{\sqrt{V_v}}$$

The Freeman-Tukey transformation and its variance are described by Freeman and Tukey (1950) and Miller (1978). Since its variance is not weighted by the pooled probabilities, as is the CA test, the FT test can be more useful than the CA test for tests involving only a subset of the groups.

Peto Mortality-Prevalence Trend Test

The Peto test is a modified Cochran-Armitage procedure incorporating mortality and prevalence information. It represents a special case in PROC MULTTEST because the data structure requirements are different, and the resampling methods used for adjusting p -values are not valid. The TIME= option variable is required to specify “death” times or, more generally, time of occurrence. In addition, the test variables must assume one of the following three values.

- 0 = no occurrence
- 1 = incidental occurrence
- 2 = fatal occurrence

Use the TIME= option variable to define the mortality strata, and use the STRATA statement variable to define the prevalence strata.

The Peto test is computed like two Cochran-Armitage Z -score approximations, one for prevalence and one for mortality.

In the following notation, the subscript v represents the variable, g represents the treatment group, s represents the stratum, and t represents the time. Recall that a plus sign (+) in a subscript location denotes summation over that subscript.

Let S_{vgs}^P be the number of incidental occurrences, and let m_{vgs}^P be the total sample size for variable v in group g , stratum s , excluding fatal tumors.

Let S_{vgt}^F be the number of fatal occurrences in time period t , and let m_{vgt}^F be the number alive at the end of time $t - 1$.

The pooled probability estimates are

$$p_{vs}^P = \frac{S_{v+s}^P}{m_{v+s}^P}$$

$$p_{vt}^F = \frac{S_{v+t}^F}{m_{v+t}^F}$$

The expected values are

$$E_{vgs}^P = m_{vgs}^P p_{vs}^P$$

$$E_{vgt}^F = m_{vgt}^F p_{vt}^F$$

Define the numerator terms:

$$N_v^P = \sum_s \sum_g t_g (S_{vgs}^P - E_{vgs}^P)$$

$$N_v^F = \sum_t \sum_g t_g (S_{vgt}^F - E_{vgt}^F)$$

where t_g denotes a contrast trend coefficient. Define the denominator variance terms (using the binomial variance):

$$V_v^P = \sum_s p_{vs}^P (1 - p_{vs}^P) \left[\left(\sum_g m_{vgs}^P t_g^2 \right) - \frac{1}{m_{v+s}^P} \left(\sum_g m_{vgs}^P t_g \right)^2 \right]$$

$$V_v^F = \sum_s p_{vt}^F (1 - p_{vt}^F) \left[\left(\sum_g m_{vgt}^F t_g^2 \right) - \frac{1}{m_{v+t}^F} \left(\sum_g m_{vgt}^F t_g \right)^2 \right]$$

The hypergeometric variances (the default) are calculated by weighting the within-strata variances as discussed in the “Z-Score Approximation” section on page 2948.

The Peto statistic is computed as

$$Z_v = \frac{N_v^P + N_v^F - c}{\sqrt{V_v^P + V_v^F}}$$

where c is a continuity correction. The p -value is determined from the standard normal distribution unless the PERMUTATION=*number* option is used. When you use the PERMUTATION= option for PETO in the TEST statement, PROC MULTTEST computes the “discrete approximation” permutation distribution described by Mantel (1980) and Soper and Tonkonoh (1993). Specifically, the permutation distribution of

$$\sum_s \sum_g t_g S_{vgs}^P + \sum_t \sum_g t_g S_{vgt}^F$$

is computed, assuming that $\{\sum_g t_g S_{vgs}^P\}$ and $\{\sum_g t_g S_{vgt}^F\}$ are independent over all s and t . The p -values are exact under this independence assumption. However, the independence assumption is valid only asymptotically, which is why these p -values are called “approximate.”

An exact permutation distribution is available only under the assumption of equal risk of censoring in all treatment groups; even then, computing this distribution can be cumbersome. Soper and Tonkonoh (1993) describe situations where the discrete approximation distribution closely fits the exact permutation distribution.

Fisher Exact Test

The CONTRAST statement in PROC MULTTEST enables you to compute Fisher exact tests for two-group comparisons. No stratification variable is allowed for this test. Note, however, that the FISHER exact test is a special case of the exact permutation tests performed by PROC MULTTEST and that these permutation tests allow a stratification variable. Recall that contrast coefficients can be -1 , 0 , or 1 for the Fisher test. The frequencies and sample sizes of the groups scored as -1 are combined, as are the frequencies and sample sizes of the groups scored as 1 . Groups scored as 0 are excluded. The -1 group is then compared with the 1 group using the Fisher exact test.

Letting x and m denote the frequency and sample size of the 1 group, and y and n denote those of the -1 group, the p -value is calculated as

$$\Pr(X \geq x \mid X + Y = x + y) = \sum_{i=x}^m \frac{\binom{m}{i} \binom{n}{x+y-i}}{\binom{m+n}{x+y}}$$

where X and Y are independent binomially distributed random variables with sample sizes m and n and common probability parameters. The hypergeometric distribution is used to determine the stated probability; Yates (1984) discusses this technique.

PROC MULTTEST computes the two-tailed p -values by adding probabilities from both tails of the hypergeometric distribution. The first tail is from the observed x and y , and the other tail is chosen so that the resulting probability is as large as possible without exceeding the probability from the first tail.

***t*-Test for the Mean**

For continuous variables, PROC MULTTEST automatically centers the contrast trend coefficients, as in the Freeman-Tukey test. These centered coefficients c_g are then used to form a t -statistic contrasting the within-group means. Let n_{vgs} denote the sample size within group g and stratum s ; it depends on variable v only when there are missing values. Define

$$\bar{X}_{vgs+} = \frac{1}{n_{vgs}} \sum_r X_{vgsr}$$

as the sample mean within a group-and-stratum combination, and define

$$s_v^2 = \frac{\sum_s \sum_g \sum_r (X_{vgsr} - \bar{X}_{vgs+})^2}{\sum_s \sum_g (n_{vgs} - 1)}$$

as the pooled sample variance. Assume constant variance for all group-and-stratum combinations. Then the t -statistic for the mean is

$$M_v = \frac{\sum_s w_{vs} \sum_g c_g \bar{X}_{vgs+}}{\sqrt{s_v^2 \left(\sum_s w_{vs}^2 \sum_g \frac{c_g^2}{n_{vgs}} \right)}}$$

where the weights w_{vs} are determined as in the Freeman-Tukey test with n_{vgs} replacing m_{vgs} .

Let μ_{vgs} denote the treatment means. Then under the null hypothesis that

$$\sum_s w_{vs} \sum_g c_g \mu_{vgs} = 0$$

and assuming normality, independence, and homoscedasticity, M_v follows a t -distribution with $\sum_s \sum_g (n_{vgs} - 1)$ degrees of freedom.

Whenever a denominator of 0 is computed, the p -value is set to 1. When missing data force $n_{vgs} = 0$, then the contribution to the denominator of the pooled variance is 0 and not -1 . This is also true for degrees of freedom.

p-Value Adjustments

PROC MULTTEST offers p -value adjustments using Bonferroni, Sidak, Bootstrap resampling, and Permutation resampling, all with single-step or stepdown versions. In addition, Hochberg's (1988) and Benjamini and Hochberg's (1995) step-up methods are offered, as are Hommel's (1988) and Fisher's combination method. The Bonferroni and Sidak methods are calculated from the permutation distributions when exact permutation tests are used with CA or PETO tests.

All methods but the resampling methods are calculated using simple functions of the raw p -values or marginal permutation distributions; the permutation and bootstrap adjustments require the raw data. Because the resampling techniques incorporate distributional and correlational structures, they tend to be less conservative than the other methods.

When a resampling (bootstrap or permutation) method is used with only one test, the adjusted p -value is the bootstrap or permutation p -value for that test, with no adjustment for multiplicity, as described by Westfall and Soper (1994).

Bonferroni

Suppose that PROC MULTTEST performs R statistical tests, yielding p -values p_1, \dots, p_R . Then the Bonferroni p -value for test r is simply Rp_r . If the adjusted p -value exceeds 1, it is set to 1.

If the unadjusted p -values are computed using exact permutation distributions, then the Bonferroni adjustment for p_r is $p_1^* + \dots + p_R^*$, where p_j^* is the largest p -value from the permutation distribution of test j satisfying $p_j^* \leq p_r$, or 0 if all permutational p -values of test j are greater than p_r . These adjustments are much less conservative than the ordinary Bonferroni adjustments because they incorporate the discrete distributional characteristics. However, they remain conservative in that they do not incorporate correlation structures between multiple contrasts and multiple variables (Westfall and Wolfinger 1997).

Sidak

A technique slightly less conservative than Bonferroni is the Sidak p -value (Sidak 1967), which is $1 - (1 - p_r)^R$. It is exact when all of the p -values are uniformly distributed and independent, and it is conservative when the test statistics satisfy the positive orthant dependence condition (Holland and Copenhaver 1987).

If the unadjusted p -values are computed using exact permutation distributions, then the Sidak adjustment for p_r is $1 - (1 - p_1^*) \dots (1 - p_R^*)$, where the p_j^* are as described previously. These adjustments are less conservative than the corresponding Bonferroni adjustments, but they do not incorporate correlation structures between multiple contrasts and multiple variables (Westfall and Wolfinger 1997).

Bootstrap

The bootstrap method creates pseudo-data sets by sampling observations with replacement from each within-stratum pool of observations. An entire data set is thus created, and *p*-values for all tests are computed on this pseudo-data set. A counter records whether the minimum *p*-value from the pseudo-data set is less than or equal to the actual *p*-value for each base test. (If there are *R* tests, then there are *R* such counters.) This process is repeated a large number of times, and the proportion of resampled data sets where the minimum pseudo-*p*-value is less than or equal to an actual *p*-value is the adjusted *p*-value reported by PROC MULTTEST. The algorithms are described by Westfall and Young (1993).

In the case of continuous data, the pooling of the groups is not likely to recreate the shape of the null hypothesis distribution, since the pooled data are likely to be multimodal. For this reason, PROC MULTTEST automatically mean-centers all continuous variables prior to resampling. Such mean-centering is akin to resampling residuals in a regression analysis, as discussed by Freedman (1981). You can specify the NOCENTER option if you do not want to center the data. (In most situations, it does not seem to make much difference whether or not you center the data.)

The bootstrap method explicitly incorporates all sources of correlation, from both the multiple contrasts and the multivariate structure. The adjusted *p*-values incorporate all correlations and distributional characteristics.

Permutation

The permutation-style adjusted *p*-values are computed in identical fashion as the bootstrap adjusted *p*-values, with the exception that the within-stratum resampling is performed without replacement instead of with replacement. This produces a rerandomization analysis such as in Brown and Fears (1981) and Heyse and Rom (1988). In the spirit of rerandomization analyses, the continuous variables are not centered prior to resampling. This default can be overridden by using the CENTER option.

The permutation method explicitly incorporates all sources of correlation, from both the multiple contrasts and the multivariate structure. The adjusted *p*-values incorporate all correlations and distributional characteristics.

Stepdown Methods

Stepdown testing is available for the Bonferroni, Sidak, bootstrap, and permutation methods. The benefit of using stepdown methods is that the tests are made more powerful (smaller adjusted *p*-values) while, in most cases, maintaining strong control of the familywise error rate. The stepdown method was pioneered by Holm (1979) and further developed by Shaffer (1986), Holland and Copenhaver (1987), and Hochberg and Tamhane (1987).

Suppose the base test p -values are ordered as $p_1 < p_2 < \cdots < p_R$. The Bonferroni stepdown p -values s_1, \dots, s_R are obtained from

$$\begin{aligned} s_1 &= Rp_1 \\ s_2 &= \max(s_1, (R-1)p_2) \\ s_3 &= \max(s_2, (R-2)p_3) \\ &\vdots \end{aligned}$$

As always, if any adjusted p -value exceeds 1, it is set to 1. The Sidak stepdown p -values are determined similarly:

$$\begin{aligned} s_1 &= 1 - (1 - p_1)^R \\ s_2 &= \max(s_1, 1 - (1 - p_2)^{R-1}) \\ s_3 &= \max(s_2, 1 - (1 - p_3)^{R-2}) \\ &\vdots \end{aligned}$$

Stepdown Bonferroni adjustments using exact tests are defined as

$$\begin{aligned} s_1 &= p_1^* + \cdots + p_R^* \\ s_2 &= \max(s_1, p_2^* + \cdots + p_R^*) \\ s_3 &= \max(s_2, p_3^* + \cdots + p_R^*) \\ &\vdots \end{aligned}$$

where the p_j^* are defined as before. Note that p_j^* is taken from the permutation distribution corresponding to the j th smallest unadjusted p -value. Also, any s_j greater than 1.0 is truncated to 1.0.

Stepdown Sidak adjustments for exact tests are defined analogously by substituting $1 - (1 - p_j^*) \cdots (1 - p_R^*)$ for $p_j^* + \cdots + p_R^*$.

The resampling-style stepdown method is analogous to the preceding stepdown methods; the most extreme p -value is adjusted according to all R tests, the second-most extreme p -value is adjusted according to $(R-1)$ tests, and so on. The difference is that all correlational and distributional characteristics are incorporated when you use resampling methods. More specifically, assuming the same ordering of p -values as discussed previously, the resampling-style stepdown adjusted p -value for test r is the probability that the minimum pseudo- p -value of tests r, \dots, R is less than or equal to p_r .

This probability is evaluated using Monte Carlo, as are the previously described resampling-style adjusted p -values. In fact, the computations for stepdown adjusted p -values are essentially no more time-consuming than the computations for the non-stepdown adjusted p -values. After Monte Carlo, the stepdown adjusted p -values are corrected to ensure monotonicity; this correction leaves the first adjusted p -values

alone, then corrects the remaining ones as needed. The stepdown method approximately controls the familywise error rate, and it is described in more detail by Westfall and Young (1993), Westfall *et al.* (1999), and Westfall and Wolfinger (2000).

Hochberg

Assuming *p*-values are independent and uniformly distributed under their respective null hypotheses, Hochberg (1988) demonstrated that Holm’s stepdown adjustments control the familywise error rate even when calculated in *step-up* fashion. Since the adjusted *p*-values are uniformly smaller for Hochberg’s method than for Holm’s method, the Hochberg method is more powerful. However, this improved power comes at the cost of having to make the assumption of independence.

The Hochberg adjusted *p*-values are defined in reverse order as the stepdown Bonferroni:

$$\begin{aligned} s_R &= p_R \\ s_{(R-1)} &= \min(s_R, 2p_{(R-1)}) \\ s_{(R-2)} &= \min(s_{(R-1)}, 3p_{(R-2)}) \\ &\vdots \end{aligned}$$

Hommel

Hommel’s (1988) method is a closed testing procedure based on Simes’ (1986) test. The Simes *p*-value for a joint test of any set of *S* hypotheses with *p*-values $p_1 \leq p_2 \leq \dots \leq p_S$ is $\min((S/1)p_1, (S/2)p_2, \dots, (S/S)p_S)$. The Hommel adjusted *p*-value for test *j* is the maximum of all such Simes *p*-values, taken over all joint tests that include *j* as one of their components.

Hochberg adjusted *p*-values are always as large or larger than Hommel adjusted *p*-values. Sarker and Chang (1997) showed that Simes’ method is valid under independent or positively dependent *p*-values, so Hommel’s and Hochberg’s methods also are valid in such cases by the closure principle.

Fisher Combination

The FISHER_C option requests adjusted *p*-values using closed tests, based on the idea of Fisher’s combination test. The Fisher combination test for a joint test of any set of *S* hypotheses with *p*-values uses the chi-square statistic $\chi^2 = -2 \sum \log(p_i)$, with $2S$ degrees of freedom. The FISHER_C adjusted *p*-value for test *j* is the maximum of all *p*-values for the combination tests, taken over all joint tests that include *j* as one of their components. Independence of *p*-values is required for the validity of this method.

False Discovery Rate

The FDR option requests *p*-values that control the “false discovery rate,” described by Benjamini and Hochberg (1995). These adjustments are potentially much less conservative than the Hochberg adjustments; however, they do not necessarily control the familywise error rate. Furthermore, they are guaranteed to control the false

discovery rate only with independent p -values that are uniformly distributed under their respective null hypotheses.

The FDR adjusted p -values are defined in step-up fashion, like the Hochberg adjustments, but with less conservative multipliers:

$$\begin{aligned} s_R &= p_R \\ s_{(R-1)} &= \min(s_R, [R/(R-1)]p_{(R-1)}) \\ s_{(R-2)} &= \min(s_{(R-1)}, [R/(R-2)]p_{(R-2)}) \\ &\vdots \end{aligned}$$

Missing Values

If a CLASS or STRATA variable has a missing value, then PROC MULTTEST removes that observation from the analysis.

When there are missing values for test variables, the within group-and-stratum sample sizes may differ from variable to variable. In most cases this is not a problem; however, it is possible for all data to be missing for a particular group within a particular stratum. For continuous variables and Freeman-Tukey tests, PROC MULTTEST recenters the contrast trend coefficients within strata where all data for a particular group are missing. The Cochran-Armitage and Peto tests are unaffected by this situation.

PROC MULTTEST uses missing values for resampling if they exist in the original data set. If all variables have missing values for any observation, then PROC MULTTEST removes it prior to resampling. Otherwise, PROC MULTTEST treats all missing values as ordinary observations in the resampling. This means that different resampled data sets can have different group sizes. In some cases it means that a resampled data set can have all missing values for a particular variable in a particular group/stratum combination, even when values exist for that combination in the original data. For this reason, PROC MULTTEST recomputes all quantities within each pseudo-data set, including such items as centered scoring coefficients and degrees of freedom for p -values.

While PROC MULTTEST does provide analyses in missing value cases, you should not feel that it completely solves the missing value problem. If you are concerned about the adverse effects of missing data on a particular analysis, you should consider using imputation and sensitivity analyses to assess the effects of the missing data.

Computational Resources

PROC MULTTEST keeps all of the data in memory to expedite resampling. A large portion of the memory requirement is thus $8 \times \text{NOBS} \times \text{NVAR}$ bytes, where NOBS is the number of observations in the data set, and NVAR is the number of variables analyzed, including CLASS, FREQ, and STRATA variables.

If you specify PERMUTATION=*number* (for exact permutation distributions), then PROC MULTTEST requires additional memory. This requirement is approximately $4 * NTEST * NSTRATA * CMAX * number * (number + 1)$ bytes, where NTEST is the number of contrasts, NSTRATA is the number of STRATA levels, and CMAX is the maximum contrast coefficient.

The execution time is linear in the number of resamples; that is, 10,000 resamples will take 10 times longer than 1,000 resamples.

Output Data Sets

OUT= Data Set

The OUT= data set contains contrast names (`_test_`), variable names (`_var_`), the contrast label (`_contrast_`), raw p -values (`raw_p`), and all requested adjusted p -values (`bon_p`, `sid_p`, `stpbon_p`, `stpsid_p`, `boot_p`, `perm_p`, `stpbootp`, `stp-permp`, `hoc_p`, or `fdr_p`).

If a resampling-based adjusted p -value is requested, then the simulation standard error is included as either `sim_se` or `stpsimse`, depending upon whether single-step or stepdown adjustments are requested. The simulation standard errors are used to bound the true resampling-based adjusted p -value. For example, if the resampling-based estimate is 0.0312 and the simulation standard error is 0.00123, then a 95% confidence interval for the true adjusted p -value is $0.0312 \pm 1.96(0.00123)$, or 0.0288 to 0.0336.

Intermediate statistics used to calculate the p -values are also written to the OUT= data set. The statistics are separated by the `_strat_` level. When `_strat_` is reported as missing, then the statistics refer to the pooled analysis over all `_strat_` levels. The p -values are provided only for the pooled analyses and are therefore reported as missing for the strata-specific statistics.

For the PETO test, an additional variable, `_tstrat_`, is included to indicate whether the stratum is an incidental occurrence stratum (`_tstrat_=0`) or a fatal occurrence stratum (`_tstrat_=1`).

The statistic `_value_` is the per-strata contribution to the numerator of the overall test statistic. In the case of the MEAN test, this is the contrast function of the sample means multiplied by the total number of observations within the stratum. For the FT test, `_value_` is the contrast function of the double-arcsine transformed proportions, again multiplied by the total number of observations within the stratum. For the CA and PETO tests, `_value_` is the observed value of the trend statistic within that stratum.

When either PETO or CA is requested, the variable `_exp_` is included; this variable contains the expected value of the trend statistic for the given stratum.

The statistic `_se_` is the square root of the variance of the per-strata `_value_` value for any of the tests.

For MEAN tests, the variable `_nval_` is included. When reported with an individual stratum level (that is, when the `_strat_` value is nonmissing), the value `_nval_`

refers to the within-stratum sample size. For the combined analysis (that is, the value of the `_strat_` is missing), the value `_nval_` contains degrees of freedom of the t -distribution used to compute the unadjusted p -value.

When the FISHER test is requested, the OUT= data set contains variables `_xval_`, `_mval_`, `_yval_`, and `_nval_`, which define observations and sample sizes in the two groups defined by the CONTRAST statement.

For example, the OUT= data set from the drug example in the “Getting Started” section on page 2936 is displayed in Figure 48.4.

Obs	_test_	_var_	_contrast_	_value_	_exp_	_se_	raw_p	boot_p	sim_se

Figure 48.4. Output Data for the MULTTEST Procedure

OUTPERM= Data Set

The OUTPERM= data set contains contrast names (`_contrast_`), variable names (`_var_`), and the associated permutation distributions (`_value_` and `upper_p`). PROC MULTTEST computes the permutation distributions when you use the PERMUTATION= option with the CA or Peto tests. The `_value_` variable represents the support of the distributions, and `upper_p` represents their cumulative upper-tail probabilities. The size of this data set depends on the number of variables and the support of their permutation distributions. For information on how this distribution is computed, see the “Exact Permutation Test” section on page 2949. For an illustration, see Example 48.1 on page 2964.

OUTSAMP= Data Set

The OUTSAMP= data set contains the data sets used in the resampling analysis, if such an analysis is requested. The variable `_sample_` indicates the number of the resampled data set. This variable ranges from 1 to NSAMPLE. For each value of the `_sample_` variable, an entire resampled data set is included, with `_strat_`, `_class_`, and all other variables in the original data set. The values of the original variables are mean-centered for the mean test, if requested. The variable `_obs_` indicates the observation’s position in the original data set.

Each new data set is randomly drawn from the original data set, either with (bootstrap) or without (permutation) replacement. The size of this data set is, thus, the number of observations in the original data set times the number of samples.

Displayed Output

The output produced by PROC MULTTEST is divided into several tables:

- The “Model Information” table provides a list of the options and settings used for that particular invocation of the procedure. Included in this list are the following items:
 - statistical tests
 - support of the exact permutation distribution for the CA and PETO tests
 - continuity corrections used for the CA test
 - test tails
 - strata adjustment
 - p -value adjustments
 - centering of continuous variables
 - number of samples and seed
- The “Contrast Coefficients” table lists the coefficients used in constructing the statistical tests. These coefficients are either specified in CONTRAST statements or generated by default. The coefficients apply to the levels of the CLASS statement variable.
- The “Variable Tabulations” tables provide summary statistics for each variable listed in the TEST statement. Included for discrete variables are the count, sample size, and percentage of occurrences. For continuous variables, the mean, sample standard deviation, and sample size are displayed. All of the previously mentioned statistics are computed for distinct combinations of the CLASS and STRATA statement variables.
- The “p-Values” table is a collection of the raw and adjusted p -values from this run of PROC MULTTEST. The p -values are listed by variable and test.

ODS Table Names

PROC MULTTEST assigns a name to each table it creates, and you must use this name to reference the table when using the Table Delivery System (ODS). These names are listed in the following table. For more information on ODS, see [Chapter 14, “Using the Output Delivery System.”](#)

Table 48.1. ODS Tables Created by the MULTTEST Procedure

ODS Table Name	Description	Statement
Continuous	Continuous variable tabulations	TEST with MEAN
Contrasts	Contrast coefficients	default
Discrete	Discrete variable tabulations	TEST with CA, FT, PETO, or FISHER
ModelInfo	Model information	default
pValues	p -values from the tests	default

Examples

Example 48.1. Cochran-Armitage Test with Permutation Resampling

This example, from Keith Soper at Merck, illustrates the exact permutation Cochran-Armitage test carried out on permutation resamples. In the following data set, each observation represents an animal. The binary variables **S1** and **S2** indicate two tumor types, with 0s indicating no tumor (failure) and 1 indicating a tumor (success); note that they have perfect negative association. The grouping variable is **Dose**.

```

data a;
  input S1 S2 Dose @@;
  datalines;
0 1 1   1 0 1   0 1 1
0 1 1   0 1 1   1 0 1
1 0 2   1 0 2   0 1 2
1 0 2   0 1 2   1 0 2
1 0 3   1 0 3   1 0 3
0 1 3   0 1 3   1 0 3
;
proc multtest data=a permutation nsample=10000
              seed=36607 outperm=pmt pvals;
  test ca(S1 S2 / permutation=10 uppertailed);
  class Dose;
  contrast 'CA Linear Trend' 0 1 2;
run;
proc print data=pmt;
run;

```

The PROC MULTTEST statement requests 10,000 permutation resamples. The OUTPERM=PMT option creates an output SAS data set for the exact permutation distribution computed for the CA test.

The TEST statement specifies an upper-tailed Cochran-Armitage linear trend test for **S1** and **S2**. The cutoff for exact permutation calculations is 10, as specified with the PERMUTATION= option in the TEST statement. Since **S1** and **S2** have ten and eight successes, respectively, PROC MULTTEST uses exact permutation distributions to compute the *p*-values for both variables.

The groups for the CA test are the levels of **Dose** from the CLASS statement. The trend coefficients applied to these groups are 0, 1, and 2, respectively, as specified in the CONTRAST statement.

Finally, PROC PRINT displays the SAS data set containing the permutation distributions.

The results from this analysis are listed in [Output 48.1.1](#) through [Output 48.1.5](#).

Output 48.1.1. Cochran-Armitage Test with Permutation Resampling

The Multtest Procedure	
Model Information	
Test for discrete variables	Cochran-Armitage
Exact permutation distribution used	Everywhere
Tails for discrete tests	Upper-tailed
Strata weights	None
P-value adjustment	Permutation
Number of resamples	10000
Seed	36607

You should check the preceding table to verify that the analysis specifications are correct.

Output 48.1.2. Contrast Coefficients

The Multtest Procedure			
Contrast Coefficients			
	Dose		
Contrast	1	2	3
CA Linear Trend	0	1	2

The preceding table lists the label and coefficients from the CONTRAST statement.

Output 48.1.3. Summary Statistics

The Multtest Procedure					
Discrete Variable Tabulations					
Variable	Dose	Count	NumObs	Percent	
S1	1	2	6	33.33	
S1	2	4	6	66.67	
S1	3	4	6	66.67	
S2	1	4	6	66.67	
S2	2	2	6	33.33	
S2	3	2	6	33.33	

The preceding table contains summary statistics for the two test variables, S1 and S2. The Count column lists the number of successes for each level of the class variable, Dose. The NumObs column is the sample size, and the Percent column is the percentage of successes in the sample.

Output 48.1.4. Resulting p -Values

The Multtest Procedure			
p-Values			
Variable	Contrast	Raw	Permutation
S1	CA Linear Trend	0.1993	0.4058
S2	CA Linear Trend	0.9220	1.0000

The Raw column in the preceding “ p -Values” table contains the p -values from the CA test, and the Permutation column contains the permutation-adjusted p -values.

This table shows that, for **S1**, the adjusted p -value is almost twice the raw p -value. In fact, from theoretical considerations, the permutation-adjusted p -value for **S1** should be $2 \times 0.1993 = 0.3986$; the difference is due to resampling error. For **S2**, the raw p -value is 0.9220, and the adjusted p -value equals 1, as you would expect from theoretical considerations. The permutation p -values for **S1** and **S2** also happen to be the Bonferroni-adjusted p -values for this example.

Output 48.1.5. Exact Permutation Distribution

Obs	_contrast_	_var_	_value_	upper_p
1	CA Linear Trend	S1	0	1.00000

19	CA Linear Trend	S1	18	0.00000
20	CA Linear Trend	S1	19	0.00000
21	CA Linear Trend	S1	20	0.00000
22	CA Linear Trend	S2	0	1.00000
23	CA Linear Trend	S2	1	1.00000
24	CA Linear Trend	S2	2	1.00000
25	CA Linear Trend	S2	3	0.99966
26	CA Linear Trend	S2	4	0.99609
27	CA Linear Trend	S2	5	0.97827
28	CA Linear Trend	S2	6	0.92205
29	CA Linear Trend	S2	7	0.80070
30	CA Linear Trend	S2	8	0.61011
31	CA Linear Trend	S2	9	0.38989
32	CA Linear Trend	S2	10	0.19930
33	CA Linear Trend	S2	11	0.07795
34	CA Linear Trend	S2	12	0.02173
35	CA Linear Trend	S2	13	0.00391
36	CA Linear Trend	S2	14	0.00034
37	CA Linear Trend	S2	15	0.00000
38	CA Linear Trend	S2	16	0.00000

The preceding table lists the OUTPERM= data set, which contains the exact permutation distributions for S1 and S2 in terms of cumulative probabilities.

Example 48.2. Freeman-Tukey and *t*-Tests with Bootstrap Resampling

The data for the following example are the same as for [Example 48.1](#), except that a continuous variable *T*, which indicates the time of death of the animal, has been added.

```

data a;
  input S1 S2 T Dose @@;
  datalines;
0 1 104 1 1 0 80 1 0 1 104 1
0 1 104 1 0 1 100 1 1 0 104 1
1 0 85 2 1 0 60 2 0 1 89 2
1 0 96 2 0 1 96 2 1 0 99 2
1 0 60 3 1 0 50 3 1 0 80 3
0 1 98 3 0 1 99 3 1 0 50 3
;
proc multtest data=a bootstrap nsample=10000
  pvals seed=37081 outsamp=res;
  test ft(S1 S2 / lowertailed) mean(T / lowertailed);
  class Dose;
  contrast 'Linear Trend' 0 1 2;
run;
proc print data=res(obs=36);
run;

```

The `BOOTSTRAP` option in the `PROC MULTTEST` statement requests bootstrap resampling, and `NSAMPLE=10000` requests 10,000 bootstrap samples. The seed for the random number generation is 37081. The `OUTSAMP=RES` option creates an output SAS data set containing the 10,000 bootstrap samples.

The `TEST` statement specifies the Freeman-Tukey test for *S1* and *S2* and specifies the *t*-test for *T*. Both tests are lower-tailed. The grouping variable in the `CLASS` statement is `Dose`, and the coefficients across the levels of `Dose` are 0, 1, and 2, as specified in the `CONTRAST` statement. `PROC PRINT` displays the first 36 observations of the `RES` data set containing the bootstrap samples.

The results from this analysis are listed in [Output 48.2.1](#) through [Output 48.2.5](#).

Output 48.2.1. FT and *t*-tests with Bootstrap Resampling

The Multtest Procedure	
Model Information	
Test for discrete variables	Freeman-Tukey
Test for continuous variables	Mean t-test
Tails for discrete tests	Lower-tailed
Tails for continuous tests	Lower-tailed
Strata weights	None
P-value adjustment	Bootstrap
Center continuous variables	Yes
Number of resamples	10000
Seed	37081

The information in the preceding table corresponds to the specifications in the invocation of PROC MULTTEST.

Output 48.2.2. Contrast Coefficients

The Multtest Procedure			
Contrast Coefficients			
	Dose		
Contrast	1	2	3
Linear Trend	0	1	2

The preceding table shows the coefficients from the CONTRAST statement, and they model a linear trend.

Output 48.2.3. Summary Statistics

The Multttest Procedure				
Discrete Variable Tabulations				
Variable	Dose	Count	NumObs	Percent
S1	1	2	6	33.33
S1	2	4	6	66.67
S1	3	4	6	66.67
S2	1	4	6	66.67
S2	2	2	6	33.33
S2	3	2	6	33.33
Continuous Variable Tabulations				
Variable	Dose	NumObs	Mean	Standard Deviation
T	1	6	99.3333	9.6056
T	2	6	87.5000	14.4326
T	3	6	72.8333	22.7017

The summary statistics in the preceding table for S1 and S2 are the same as those from [Example 48.1](#). The variables S1 and S2 are discrete, and T is a continuous variable. The mean, standard deviation, and sample size for each level of Dose is listed in the table for T. The p -values for S1 and S2 are from the Freeman-Tukey test, and the p -values for T are from the t -test.

Output 48.2.4. p -Values

The Multttest Procedure			
p-Values			
Variable	Contrast	Raw	Bootstrap
S1	Linear Trend	0.8547	1.0000
S2	Linear Trend	0.1453	0.4471
T	Linear Trend	0.0070	0.0253

The p -values are listed in the preceding table. The Raw column contains the results from the tests on the original data, and the Bootstrap column contains the bootstrap resampled adjustment to `raw_p`. Note that the adjusted p -values are larger than the raw p -values for all three variables. The adjusted p -values more accurately reflect the correlation of the raw p -values, the small size of the data, and the multiple testing.

Output 48.2.5. Resampling Data Set

Obs	_sample_	_class_	_obs_	S1	S2	T
1	1	1	11	0	1	8.5000
2	1	1	16	0	1	25.1667
3	1	1	16	0	1	25.1667

10	1	2	7	1	0	-2.5000
11	1	2	3	0	1	4.6667
12	1	2	12	1	0	11.5000
13	1	3	13	1	0	-12.8333
14	1	3	5	0	1	0.6667
15	1	3	8	1	0	-27.5000
16	1	3	5	0	1	0.6667
17	1	3	13	1	0	-12.8333
18	1	3	6	1	0	4.6667
19	2	1	8	1	0	-27.5000
20	2	1	3	0	1	4.6667
21	2	1	9	0	1	1.5000
22	2	1	13	1	0	-12.8333
23	2	1	14	1	0	-22.8333
24	2	1	12	1	0	11.5000
25	2	2	14	1	0	-22.8333
26	2	2	18	1	0	-22.8333
27	2	2	15	1	0	7.1667
28	2	2	6	1	0	4.6667
29	2	2	13	1	0	-12.8333
30	2	2	1	0	1	4.6667
31	2	3	7	1	0	-2.5000
32	2	3	7	1	0	-2.5000
33	2	3	6	1	0	4.6667
34	2	3	13	1	0	-12.8333
35	2	3	4	0	1	4.6667
36	2	3	6	1	0	4.6667

The preceding table lists the first 36 observations of the SAS data set resulting from the OUTSAMP=RES option in the PROC MULTTEST statement. The entire data set has 180,000 observations, which is 10,000 times the number of observations in the data set. The `_sample_` variable is the sample indicator and `_class_` indicates the resampling group, that is, the level of the CLASS variable Dose assigned to the new observation. The number of the observation in the original data set is represented by `_obs_`. Also listed are the values of the original test variables, S1 and S2, and the mean-centered values of T.

Example 48.3. Peto Mortality-Prevalence Test

This example illustrates the use of the Peto mortality-prevalence test. The test is a combination of analyses about the prevalence of incidental tumors in the population and mortality due to fatal tumors.

In the data set, each observation represents an animal. The variables S1–S3 are three tumor types, with a value of 0 indicating no tumor, 1 indicating an incidental (nonlethal) tumor, and 2 indicating a lethal tumor. The time variable T indicates the time of death of the animal, a strata variable B is constructed from T, and the grouping variable Dose is drug dosage.

```

data a;
  input S1-S3 T Dose @@;
  if T<=90 then B=1; else B=2;
  datalines;
0 0 0 104 0   2 0 1   80 0   0 0 1 104 0
0 0 0 104 0   0 2 0 100 0   1 0 0 104 0
2 0 0   85 1   2 1 0   60 1   0 1 0   89 1
2 0 1   96 1   0 0 0   96 1   2 0 1   99 1
2 1 1   60 2   2 0 0   50 2   2 0 1   80 2
0 0 2   98 2   0 0 1   99 2   2 1 1   50 2
;
proc multtest data=a notables out=p stepsid;
  test peto(S1-S3 / permutation=20 time=T uppertailed);
  class Dose;
  strata B;
  contrast 'mort-prev' 0 1 2;
run;
proc print data=p;
run;

```

The NOTABLES option in the PROC MULTTEST statement suppresses the display of the summary statistics for each variable. The OUT=P option creates an output SAS data set containing all p -values and intermediate statistics. The STEPSID option is used to adjust the p -values.

The TEST statement specifies an upper-tailed Peto test for S1–S3. The mortality strata are defined by TIME=T, the death times. The CLASS statement contains the grouping variable Dose. The prevalence strata are defined by the STRATA statement as the blocking variable B. The CONTRAST statement lists the default linear trend coefficients. PROC PRINT displays the requested p -value data set.

The results from this analysis are listed in [Output 48.3.1](#) through [Output 48.3.4](#).

Output 48.3.1. Peto Test

The Multtest Procedure	
Model Information	
Test for discrete variables	Peto
Exact permutation distribution used	Everywhere
Tails for discrete tests	Upper-tailed
Strata weights	Sample size
P-value adjustment	Stepdown Sidak

The preceding information corresponds to the PROC MULTTEST invocation. In this case the totals for all prevalence and fatality strata are less than 20, so exact permutation tests are used everywhere, and the STEPSID adjustments are computed from these permutation distributions.

Output 48.3.2. Contrast Coefficients

The Multtest Procedure			
Contrast Coefficients			
	Dose		
Contrast	0	1	2
mort-prev	0	1	2

The contrast trend coefficients are listed in the preceding table. They happen to be the same as the levels of the DOSE variable.

Output 48.3.3. *p*-Values

The Multtest Procedure			
p-Values			
Variable	Contrast	Raw	Stepdown Sidak
S1	mort-prev	0.0681	0.0814
S2	mort-prev	0.5000	0.5000
S3	mort-prev	0.0363	0.0781

In the preceding “*p*-Values” table, the *p*-values for the Peto tests are listed in the Raw column, and the stepdown Sidak adjusted *p*-values are in the Stepdown Sidak column.

Significant *p*-values support the claim that higher dosage levels promote higher mortality and prevalence. The raw Peto test is significant at the 5% level for S3, but the adjusted S3 test is no longer significant at 5%. The raw and adjusted *p*-values for S2 are the same because of the stepdown technique.

Output 48.3.4. OUT= Data Set

The preceding table lists the OUT= data set. The first 30 observations correspond to intermediate statistics used to compute the Peto p -values. The `_test_` variable lists the name of the test, the `_var_` variable lists the name of the TEST variables, and the `_contrast_` variable lists the CONTRAST label. The `_strat_` variable lists the level of the STRATA variable, and the `_tstrat_` variable indicates whether or not the stratum corresponds to values of the TIME= variable. The `_value_` variable is the observed contrast for a stratum and the `_exp_` variable is its expected value. The variable `_se_` contains the square root of the variance terms summed to form the denominator of the Peto statistics.

The final three observations correspond to the three Peto tests, with their p -values listed under the `raw_p` variable. The `stpsid_p` variable contains the stepdown Sidak adjusted p -values.

Example 48.4. Fisher Test with Permutation Resampling

These data, from Brown and Fears (1981), are the results from an 80-week carcinogenesis bioassay with female mice. Six tissue sites are examined at necropsy; 1 indicates the presence of a tumor and 0 the absence. A frequency variable `Freq` is included. A control and four different doses of a drug (in parts per milliliter) make up the levels of the grouping variable `Dose`.

  test fisher(Liver Lung Lymph Cardio Pitui Ovary /
    lowertailed);
  class Dose;
  freq Freq;
run;
proc print data=p;
run;

```

In the PROC MULTTEST statement, the ORDER=DATA option is required to keep the levels of DOSE in the order in which they appear in the data set. Without this option, the levels are sorted by their formatted value, resulting in an alphabetic ordering. The NOTABLES option suppresses the display of summary statistics, and the OUT=P option requests an output data set containing p -values. The PERMUTATION option specifies permutation resampling, NSAMPLE=1000 requests 1000 samples, and SEED=764511 provides a starting value for the random number generator. You should specify a seed if you need to duplicate resampling results.

To test for higher rates of tumor occurrence in the treatment groups compared to the control group, the `LOWERTAILED` option is specified in the `TEST` statement to produce a lower-tailed Fisher exact test for the six tissue sites. The Fisher test is appropriate for comparing a treatment and a control, but multiple testing can be a problem. Brown and Fears (1981) use a multivariate permutation to evaluate the entire collection of tests. `PROC MULTTEST` adjusts the p -values by simulation.

The treatments make up the levels of the grouping variable `Dose`, listed in the `CLASS` statement. Since no `CONTRAST` statement is specified, `PROC MULTTEST` uses the default pairwise contrasts with the first level of `Dose`. The `FREQ` statement is used since this is summary data containing frequency counts of occurrences.

The results from this analysis are listed in [Output 48.4.1](#) through [Output 48.4.4](#).

Output 48.4.1. Fisher Test with Permutation Resampling

The Multtest Procedure	
Model Information	
Test for discrete variables	Fisher
Tails for discrete tests	Lower-tailed
Strata weights	None
P-value adjustment	Permutation
Number of resamples	1000
Seed	764511

The preceding table lists the `PROC MULTTEST` specifications.

Output 48.4.2. Default Contrast Coefficients

The Multtest Procedure					
Contrast Coefficients					
Contrast	Dose				
	CTRL	4PPM	8PPM	16PPM	50PPM
CTRL vs. 4PPM	1	-1	0	0	0
CTRL vs. 8PPM	1	0	-1	0	0
CTRL vs. 16PPM	1	0	0	-1	0
CTRL vs. 50PPM	1	0	0	0	-1

The preceding table lists the default contrasts for the Fisher test. Note that each dose is compared with the control.

Output 48.4.3. *p*-Values

The Multtest Procedure				
p-Values

Ovary	CTRL vs. 8PPM	0.8126	1.0000	
Ovary	CTRL vs. 16PPM	0.7760	1.0000	
Ovary	CTRL vs. 50PPM	0.3689	0.9950	

The preceding “*p*-Values” table lists *p*-values for the Fisher exact tests and their permutation-based adjustments. As noted by Brown and Fears, only one of the twenty-four tests is significant at the 5% level (Lymph, CTRL vs. 16PPM). Brown and Fears report a 12% chance of observing at least one significant raw *p*-value for 16PPM and a 9% chance of observing at least one significant raw *p*-value for Lymph (both at the 5% level). Adjusted *p*-values exhibit much lower chances of false significances. For this example, none of the adjusted *p*-values are close to significant.

Output 48.4.4. OUT= Data Set

The preceding table lists the OUT= data set. The `_test_`, `_var_`, and `_contrast_` variables provide the TEST name, TEST variable, and CONTRAST label, respectively. The `_xval_`, `_mval_`, `_yval_`, and `_nval_` variables contain the components used to compute the Fisher exact tests from the hypergeometric distribution. The `raw_p` variable contains the p -values from the Fisher exact tests, and the `perm_p` variable contains their permutation-based adjustments. The variable `sim_se` is the simulation standard error from the permutation resampling.

Example 48.5. Inputting Raw p -Values

This example illustrates how to use PROC MULTTEST to multiplicity-adjust a collection of raw p -values obtained from some other source. This is a valuable option for those cases where PROC MULTTEST cannot compute the raw p -values directly.

```

data a;
  input Test$ Raw_P;
  datalines;
test1 .09108
test2 .69122
test3 .00177
test4 .57181
test5 .03121
test6 .01413
;
proc multtest pdata=a holm hoc fdr;
run;

```

Note that there are no statements other than the PROC MULTTEST statement using the p -value input mode. In this example, the raw p -values are adjusted using the

Holm, Hochberg, and Benjamini and Hochberg (FDR) methods.

The output from this analysis is listed in [Output 48.5.1](#).

Output 48.5.1. Inputting Raw p -Values

The Multtest Procedure				
p-Values				
Test	Raw	Stepdown Bonferroni	Hochberg	False Discovery Rate
1	0.0911	0.2732	0.2732	0.1366
2	0.6912	1.0000	0.6912	0.6912
3	0.0018	0.0106	0.0106	0.0106
4	0.5718	1.0000	0.6912	0.6862
5	0.0312	0.1248	0.1248	0.0624
6	0.0141	0.0707	0.0707	0.0424

Note that the adjusted p -values for the Hochberg method (`hoc_p`) are less than or equal to those for the Holm method (`stpbon_p`). In turn, the adjusted p -values for the Benjamini and Hochberg method (`fdr_p`) are less than or equal to those for the Hochberg method. These comparisons hold generally for all p -value configurations. The FDR method controls the false discovery rate and not the familywise error rate. The Hochberg method controls the familywise error rate under independence. The Holm method controls the familywise error rate without assuming independence.

Chapter 49

The NESTED Procedure

Overview

The NESTED procedure performs random effects analysis of variance for data from an experiment with a nested (hierarchical) structure.* A random effects model for data from a completely nested design with two factors has the following form:

$$y_{ijr} = \mu + \alpha_i + \beta_{ij} + \epsilon_{ijr}$$

where

y_{ijr} is the value of the dependent variable observed at the r th replication with the first factor at its i th level and the second factor at its j th level.

μ is the overall (fixed) mean of the sampling population.

$\alpha_i, \beta_{ij}, \epsilon_{ijr}$ are mutually uncorrelated random effects with zero means and respective variances $\sigma_\alpha^2, \sigma_\beta^2$, and σ_ϵ^2 (the variance components).

This model is appropriate for an experiment with a multi-stage nested sampling design. An example of this is given in [Example 49.1](#) on page 2994, where four turnip plants are randomly chosen (the first factor), then three leaves are randomly chosen from each plant (the second factor nested within the first), and then two samples are taken from each leaf (the different replications at fixed levels of the two factors).

Note that PROC NESTED is appropriate for models with only classification effects; it does not handle models that contain continuous covariates. For random effects models with covariates, use either the GLM or MIXED procedure.

Contrasted with Other SAS Procedures

The NESTED procedure performs a computationally efficient analysis of variance for data with a nested design, estimating the different components of variance and also testing for their significance if the design is balanced (see the “[Unbalanced Data](#)” section on page 2990). Although other procedures (such as GLM and MIXED) provide similar analyses, PROC NESTED is both easier to use and computationally more efficient for this special type of design. This is especially true when the design involves a large number of factors, levels, or observations.

For example, to specify a four-factor completely nested design in the GLM procedure, you use the form

*PROC NESTED is modeled after the General Purpose Nested Analysis of Variance program of the Dairy Cattle Research Branch of the United States Department of Agriculture. That program was originally written by M.R. Swanson, Statistical Reporting Service, United States Department of Agriculture.

```
class a b c d;
model y=a b(a) c(a b) d(a b c);
```

However, to specify the same design in PROC NESTED, you simply use the form

```
class a b c d;
var y;
```

In addition, other procedures require TEST statements to perform appropriate tests, whereas the NESTED procedure produces the appropriate tests automatically. However, PROC NESTED makes one assumption about the input data that the other procedures do not: **PROC NESTED assumes that the input data set is sorted by the classification (CLASS) variables defining the effects.** If you use PROC NESTED on data that is not sorted by the CLASS variables, then the results may not be valid.

Getting Started

Reliability of Automobile Models

A study is performed to compare the reliability of several models of automobiles. Three different automobile models (**Model**) from each of four domestic automobile manufacturers (**Make**) are tested. Three different cars of each make and model are subjected to a reliability test and given a score between 1 and 100 (**Score**), where higher scores indicate greater reliability.

The following statements create the SAS data set `auto`.

```
title 'Reliability of Automobile Models';
data auto;
  input Make $ Model Score @@;
  datalines;
a 1 62 a 2 77 a 3 59
a 1 67 a 2 73 a 3 64
a 1 60 a 2 79 a 3 60
b 1 72 b 2 58 b 3 80
b 1 75 b 2 63 b 3 84
b 1 69 b 2 57 b 3 89
c 1 94 c 2 76 c 3 81
c 1 90 c 2 75 c 3 85
c 1 88 c 2 78 c 3 85
d 1 69 d 2 73 d 3 90
d 1 72 d 2 88 d 3 87
d 1 76 d 2 87 d 3 92
;
```

The **Make** variable contains the make of the automobile, represented here by 'a', 'b', 'c', or 'd', while the **Model** variable represents the automobile model with a '1', '2', or '3'. The **Score** variable contains the reliability scores given to the three sampled

cars from each Make-Model group. Since the automobile models are nested within their makes, the NESTED procedure is used to analyze this data. The NESTED procedure requires the data to be sorted by Make and, within Make, by Model, so the following statements execute a PROC SORT before completing the analysis.

```
proc sort;
  by Make Model;
proc nested;
  class Make Model;
  var Score;
run;
```

The Model variable appears after the Make variable in the CLASS statement because it is nested within Make. The VAR statement specifies the response variable. The output is displayed in Figure 49.1.

Reliability of Automobile Models								
The NESTED Procedure								
Coefficients of Expected Mean Squares								
Source	Make	Model	Error					
Make	9	3	1					
Model	0	3	1					
Error	0	0	1

Score Mean						75.94444444		
Standard Error of Score Mean						3.97794848		

Figure 49.1. Output from PROC NESTED

Figure 49.1 first displays the coefficients of the variance components that make up each of the expected mean squares, then the ANOVA table is displayed. The results do not indicate significant variation between the different automobile makes ($F = 2.15, p = 0.1719$). However, they do suggest that there is significant variation between the different models within the makes ($F = 18.16, p < 0.0001$). This is evident in the fact that the make of car accounts for only 25.7% of the total variation in the data, while the car model accounts for 63.3% (as shown in the Percent of Total column). The estimated variance components are shown in the Variance Component column.

Syntax

The following statements are available in PROC NESTED.

```
PROC NESTED < options > ;  
  CLASS variables < / option > ;  
  VAR variables ;  
  BY variables ;
```

The PROC NESTED and CLASS statements are required. The BY, CLASS, and VAR statements are described after the PROC NESTED statement.

PROC NESTED Statement

```
PROC NESTED < options > ;
```

The PROC NESTED statement has the following options:

AOV

displays only the analysis of variance statistics when there is more than one dependent variable. The “analysis of covariation” statistics are suppressed (see the “[Analysis of Covariation](#)” section on page 2990).

DATA=SAS-data-set

names the SAS data set to be used by PROC NESTED. By default, the procedure uses the most recently created SAS data set.

BY Statement

```
BY variables ;
```

You can specify a BY statement with PROC NESTED to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in the order of the BY variables.

Note: When you use the NESTED procedure, your data must be sorted first by the BY variables and, within the BY variables, by the CLASS variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the NESTED procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure (in base SAS software).

For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

CLASS Statement

CLASS *variables* < / *option* > ;

You must include a CLASS statement with PROC NESTED specifying the classification variables for the analysis.

Values of a variable in the CLASS statement denote the levels of an effect. The name of that variable is also the name of the corresponding effect. The second effect is assumed to be nested within the first effect, the third effect is assumed to be nested within the second effect, and so on.

By default, class levels are determined from the entire formatted values of the CLASS variables. Note that this represents a slight change from previous releases in the way in which class levels are determined. In releases prior to Version 9, class levels were determined using no more than the first 8 characters of the formatted values, except for numeric variables with no explicit format, for which class levels were determined from the raw numeric values. If you wish to revert to this previous behavior you can use the TRUNCATE option on the CLASS statement. In any case, you can use formats to group values into levels. Refer to the discussion of the FORMAT procedure in the *SAS Procedures Guide*, and the discussions for the FORMAT statement and SAS formats in *SAS Language Reference: Dictionary*.

Note: The data set must be sorted by the classification variables in the order that they are given in the CLASS statement. Use PROC SORT to sort the data if they are not already sorted.

You can specify the following option in the CLASS statement after a slash(/):

TRUNCATE

specifies that class levels should be determined using only up to the first 16 characters of the formatted values of CLASS variables. When formatted values are longer than 16 characters, you can use this option in order to revert to the levels as determined in releases previous to Version 9.

VAR Statement

VAR *variables* ;

The VAR statement lists the dependent variables for the analysis. The dependent variables must be numeric variables. If you do not specify a VAR statement, PROC NESTED performs an analysis of variance for all numeric variables in the data set, except those already specified in the CLASS statement.

Details

Missing Values

An observation with missing values for any of the variables used by PROC NESTED is omitted from the analysis. Blank values of CLASS character variables are treated as missing values.

Unbalanced Data

A completely nested design is defined to be unbalanced if the groups corresponding to the levels of some classification variable are not all of the same size. The NESTED procedure can compute unbiased estimates for the variance components in an unbalanced design, but because the sums of squares on which these estimates are based no longer have χ^2 distributions under a Gaussian model for the data, F tests for the significance of the variance components cannot be computed. PROC NESTED checks to see that the design is balanced. If it is not, a warning to that effect is placed on the log, and the columns corresponding to the F tests in the analysis of variance are left blank.

General Random Effects Model

A random effects model for data from a completely nested design with n factors has the general form

$$y_{i_1 i_2 \dots i_n r} = \mu + \alpha_{i_1} + \beta_{i_1 i_2} + \dots + \epsilon_{i_1 i_2 \dots i_n r}$$

where

$y_{i_1 i_2 \dots i_n r}$ is the value of the dependent variable observed at the r th replication with factor j at level i_j , for $j = 1, \dots, n$.

μ is the overall (fixed) mean of the sampled population.

$\alpha_{i_1}, \beta_{i_1 i_2}, \dots, \epsilon_{i_1 i_2 \dots i_n r}$ are mutually uncorrelated random effects with zero means and respective variances $\sigma_\alpha^2, \sigma_\beta^2, \dots, \sigma_\epsilon^2$.

Analysis of Covariation

When you specify more than one dependent variable, the NESTED procedure produces a descriptive analysis of the covariance between each pair of dependent variables in addition to a separate analysis of variance for each variable. The analysis of covariation is computed under the basic random effects model for each pair of dependent variables:

$$\begin{aligned} y_{i_1 i_2 \dots i_n r} &= \mu + \alpha_{i_1} + \beta_{i_1 i_2} + \dots + \epsilon_{i_1 i_2 \dots i_n r} \\ y'_{i_1 i_2 \dots i_n r} &= \mu' + \alpha'_{i_1} + \beta'_{i_1 i_2} + \dots + \epsilon'_{i_1 i_2 \dots i_n r} \end{aligned}$$

where the notation is the same as that used in the preceding general random effects model.

There is an additional assumption that all the random effects in the two models are mutually uncorrelated except for corresponding effects, for which

$$\begin{aligned}\text{Corr}(\alpha_{i_1}, \alpha'_{i_1}) &= \rho_\alpha \\ \text{Corr}(\beta_{i_1 i_2}, \beta'_{i_1 i_2}) &= \rho_\beta \\ &\vdots \\ \text{Corr}(\epsilon_{i_1 i_2 \dots i_n r}, \epsilon'_{i_1 i_2 \dots i_n r}) &= \rho_\epsilon\end{aligned}$$

Error Terms in F Tests

Random effects ANOVAs are distinguished from fixed effects ANOVAs by which error mean squares are used as the denominator for F tests. Under a fixed effects model, there is only one true error term in the model, and the corresponding mean square is used as the denominator for all tests. This is how the usual analysis is computed in PROC ANOVA, for example. However, in a random effects model for a nested experiment, mean squares are compared sequentially. The correct denominator in the test for the first factor is the mean square due to the second factor; the correct denominator in the test for the second factor is the mean square due to the third factor; and so on. Only the mean square due to the last factor, the one at the bottom of the nesting order, should be compared to the error mean square.

Computational Method

The building blocks of the analysis are the sums of squares for the dependent variables for each classification variable within the factors that precede it in the model, corrected for the factors that follow it. For example, for a two-factor nested design, PROC NESTED computes the following sums of squares:

$$\begin{aligned}\text{Total SS} & \sum_{ijr} (y_{ijr} - y_{...})^2 \\ \text{SS for Factor 1} & \sum_i n_{i.} \left(\frac{y_{i.}}{n_{i.}} - \frac{y_{...}}{n_{..}} \right)^2 \\ \text{SS for Factor 2 within Factor 1} & \sum_{ij} n_{ij} \left(\frac{y_{ij.}}{n_{ij}} - \frac{y_{i.}}{n_{i.}} \right)^2 \\ \text{Error SS} & \sum_{ijr} \left(y_{ijr} - \frac{y_{ij.}}{n_{ij}} \right)^2\end{aligned}$$

where y_{ijr} is the r th replication, n_{ij} is the number of replications at level i of the first factor and level j of the second, and a dot as a subscript indicates summation over the corresponding index. If there is more than one dependent variable, PROC NESTED also computes the corresponding sums of crossproducts for each pair. The expected value of the sum of squares for a given classification factor is a linear combination of the variance components corresponding to this factor and to the factors that are nested within it. For each factor, the coefficients of this linear combination are computed. (The efficiency of PROC NESTED is partly due to the fact that these various sums can be accumulated with just one pass through the data, assuming that the data have been sorted by the classification variables.) Finally, estimates of the variance components are derived as the solution to the set of linear equations that arise from equating the mean squares to their expected values.

Displayed Output

PROC NESTED displays the following items for each dependent variable:

- Coefficients of Expected Mean Squares, which are the coefficients of the $n + 1$ variance components making up the expected mean square. Denoting the element in the i th row and j th column of this matrix by C_{ij} , the expected value of the mean square due to the i th classification factor is

$$C_{i1}\sigma_1^2 + \cdots + C_{in}\sigma_n^2 + C_{i,n+1}\sigma_\epsilon^2.$$

C_{ij} is always zero for $i > j$, and if the design is balanced, C_{ij} is equal to the common size of all classification groups of the j th factor for $i \leq j$. Finally, the mean square for error is always an unbiased estimate of σ_ϵ^2 . In other words, $C_{n+1,n+1} = 1$.

For every dependent variable, PROC NESTED displays an analysis of variance table. Each table contains the following:

- each Variance Source in the model (the different components of variance) and the total variance
- degrees of freedom (DF) for the corresponding sum of squares
- Sum of Squares for each classification factor. The sum of squares for a given classification factor is the sum of squares in the dependent variable within the factors that precede it in the model, corrected for the factors that follow it. (See the “[Computational Method](#)” section on page 2991.)
- F Value for a factor, which is the ratio of its mean square to the appropriate error mean square. The next column, labeled PR > F, gives the significance levels that result from testing the hypothesis that each variance component equals zero.
- the appropriate Error Term for an F test, which is the mean square due to the next classification factor in the nesting order. (See the “[Error Terms in F Tests](#)” section on page 2991.)

- Mean Square due to a factor, which is the corresponding sum of squares divided by the degrees of freedom
- estimates of the Variance Components. These are computed by equating the mean squares to their expected values and solving for the variance terms. (See the “[Computational Method](#)” section on page 2991.)
- Percent of Total, the proportion of variance due to each source. For the i th factor, the value is

$$100 \times \frac{\text{source variance component}}{\text{total variance component}}$$

- Mean, the overall average of the dependent variable. This gives an unbiased estimate of the mean of the population. Its variance is estimated by a certain linear combination of the estimated variance components, which is identical to the mean square due to the first factor in the model divided by the total number of observations when the design is balanced.

If there is more than one dependent variable, then the NESTED procedure displays an “analysis of covariation” table for each pair of dependent variables (unless the AOV option is specified in the PROC NESTED statement). See the “[Analysis of Covariation](#)” section on page 2990 for details. For each source of variation, this table includes the following:

- Degrees of Freedom
- Sum of Products
- Mean Products
- Covariance Component, the estimate of the covariance component

Items in the analysis of covariation table are computed analogously to their counterparts in the analysis of variance table. The analysis of covariation table also includes the following:

- Variance Component Correlation for a given factor. This is an estimate of the correlation between corresponding effects due to this factor. This correlation is the ratio of the covariance component for this factor to the square root of the product of the variance components for the factor for the two different dependent variables. (See the “[Analysis of Covariation](#)” section on page 2990.)
- Mean Square Correlation for a given classification factor. This is the ratio of the Mean Products for this factor to the square root of the product of the Mean Squares for the factor for the two different dependent variables.

ODS Table Names

PROC NESTED assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

Table 49.1. ODS Tables Produced in PROC NESTED

ODS Table Name	Description	Statement
ANCOVA	Analysis of covariance	default with more than one dependent variable
ANOVA	Analysis of variance	default
EMSCoef	Coefficients of expected mean squares	default
Statistics	Overall statistics for fit	default

Example

Example 49.1. Variability of Calcium Concentration in Turnip Greens

In the following example from Snedecor and Cochran (1976), an experiment is conducted to study the variability of calcium concentration in turnip greens. Four plants are selected at random; then three leaves are randomly selected from each plant. Two 100-mg samples are taken from each leaf. The amount of calcium is determined by microchemical methods.

Because the data are read in sorted order, it is not necessary to use PROC SORT on the CLASS variables. Leaf is nested in Plant; Sample is nested in Leaf and is left for the residual term. All the effects are random effects. The following statements read the data and invoke PROC NESTED. These statements produce [Output 49.1.1](#):

```

title 'Calcium Concentration in Turnip Leaves'
  '--Nested Random Model';
title2 'Snedecor and Cochran, "Statistical Methods"'
  ', 1976, p. 286';
data Turnip;
  do Plant=1 to 4;
    do Leaf=1 to 3;
      do Sample=1 to 2;
        input Calcium @@;
        output;
      end;
    end;
  end;
  datalines;
3.28 3.09 3.52 3.48 2.88 2.80 2.46 2.44
1.87 1.92 2.19 2.19 2.77 2.66 3.74 3.44
2.55 2.55 3.78 3.87 4.07 4.12 3.31 3.31
;

```

```
proc nested;
  class Plant Leaf;
  var Calcium;
run;
```

Output 49.1.1. Analysis of Calcium Concentration in Turnip Greens Using PROC NESTED

Calcium Concentration in Turnip Leaves--Nested Random Model Snedecor and Cochran, 'Statistical Methods', 1976, p. 286			
The NESTED Procedure			
Coefficients of Expected Mean Squares			
Source	Plant	Leaf	Error
Plant	6	2	1
Leaf	0	2	1
Error	0	0	1

Calcium Concentration in Turnip Leaves--Nested Random Model Snedecor and Cochran, 'Statistical Methods', 1976, p. 286								
The NESTED Procedure								
Nested Random Effects Analysis of Variance for Variable Calcium								
Variance Source	DF	Sum of Squares	F Value	Pr > F	Error Term	Mean Square	Variance Component	Percent of Total
Total	23	10.270396				0.446539	0.532938	100.0000
Plant	3	7.560346	7.67	0.0097	Leaf	2.520115	0.365223	68.5302
Leaf	8	2.630200	49.41	<.0001	Error	0.328775	0.161060	30.2212
Error	12	0.079850				0.006654	0.006654	1.2486
Calcium Mean						3.01208333		
Standard Error of Calcium Mean						0.32404445		

The results indicate that there is significant (nonzero) variation from plant to plant ($Pr > F$ is 0.0097) and from leaf to leaf within a plant ($Pr > F$ is less than 0.0001). Notice that the variance component for Plant uses the Leaf mean square as an error term in the model rather than the error mean square.

Chapter 50

The NLIN Procedure

Overview

The NLIN procedure produces least squares or weighted least squares estimates of the parameters of a nonlinear model. Nonlinear models are more difficult to specify and estimate than linear models. Instead of simply listing regressor variables, you must write the regression expression, declare parameter names, and supply initial parameter values. Some models are difficult to fit, and there is no guarantee that the procedure can fit the model successfully.

For each nonlinear model to be analyzed, you must specify the model (using a single dependent variable) and the names and starting values of the parameters to be estimated.

Using PROC NLIN, you can also

- confine the estimation procedure to a certain range of values of the parameters by imposing bounds on the estimates
- produce new SAS data sets containing predicted values, residuals, parameter estimates and SSE at each iteration, the covariance matrix of parameter estimates, and other statistics
- define your own objective function to be minimized

Estimation of a nonlinear model is an iterative process. To begin this process the NLIN procedure first examines the starting value specifications of the parameters. If a grid of values is specified, PROC NLIN evaluates the residual sum of squares at each combination of parameter values to determine the set of parameter values producing the lowest residual sum of squares. These parameter values are used for the initial step of the iteration.

Then PROC NLIN uses one of these five iterative methods:

- steepest-descent or gradient method
- Newton method
- modified Gauss-Newton method
- Marquardt method

These methods use derivatives or approximations to derivatives of the SSE with respect to the parameters to guide the search for the parameters producing the smallest SSE.

You can use the NLIN procedure for segmented models (see [Example 50.1](#)) or robust regression (see [Example 50.2](#)). You can also use it to compute maximum-likelihood estimates for certain models (refer to Jennrich and Moore 1975; Charnes, Frome, and Yu 1976).

Getting Started

The NLIN procedure performs univariate nonlinear regression using the least squares method. Nonlinear regression analysis is indicated when you have information specifying that the functional relationship between the predictor and response variables is nonlinear in the parameters. Such information might come from direct knowledge of the true model, theoretical developments, or previous studies. *Nonlinear*, in this sense, means that the mathematical relationship between the variables and parameters is not required to have a linear form. For example, consider the following two models:

$$Y = aX^2 + b$$

$$Y = \frac{1}{a}X + b$$

where a and b are parameters and X and Y are random variables. The first model is linear in the parameters; the second model is nonlinear.

Estimating the Nonlinear Model

As an example of a nonlinear regression analysis, consider the following theoretical model of enzyme kinetics. The model relates the initial velocity of an enzymatic reaction to the substrate concentration.

$$f(\mathbf{x}, \boldsymbol{\theta}) = \frac{\theta_1 x_i}{\theta_2 + x_i}, \text{ for } i = 1, 2, \dots, n$$

where x_i represents the amount of substrate for n trials and $f(\mathbf{x}, \boldsymbol{\theta})$ is the velocity of the reaction. The vector $\boldsymbol{\theta}$ contains the rate parameters.

Suppose that you want to study the relationship between concentration and velocity for a particular enzyme/substrate pair. You record the reaction rate (velocity) observed at different substrate concentrations. Your data set is as follows:

```

data Enzyme;
  input Concentration Velocity @@;
  datalines;
0.26 124.7    0.30 126.9    0.48 135.9    0.50 137.6
0.54 139.6    0.68 141.1    0.82 142.8    1.14 147.6
1.28 149.8    1.38 149.4    1.80 153.9    2.30 152.5
2.44 154.5    2.48 154.7
;

```

The SAS data set `Enzyme` contains the two variables `Concentration` (substrate concentration) and `Velocity` (reaction rate). The double trailing at sign (`@@`) in the `INPUT` statement specifies that observations are input from each line until all of the values are read.

The following statements request a nonlinear regression analysis:

```
proc nlin data=Enzyme method=marquardt hougard;
  parms theta1=155
         theta2=0 to 0.07 by 0.01;
  model Velocity = theta1*Concentration / (theta2 + Concentration);
run;
```

The `DATA=` option specifies that the SAS data set `Enzyme` be used in the analysis. The `METHOD=` option directs `PROC NLIN` to use the `MARQUARDT` iterative method. The `HOUGAARD` option requests that a skewness measure be calculated for the parameters.

The `MODEL` statement specifies the enzymatic reaction model

$$V = \frac{\theta_1 C}{\theta_2 + C}$$

where V represents the velocity or reaction rate and C represents the substrate concentration.

The `PARMS` statement declares the parameters and specifies their initial values. In this example, the initial estimates in the `PARMS` statement are obtained as follows. Since the model is a monotonic increasing function in C , and

$$\lim_{C \rightarrow \infty} \left(\frac{\theta_1 C}{\theta_2 + C} \right) = \theta_1$$

take the largest observed value of the variable `Velocity` (154.7) as the initial value for the parameter `Theta1`. Thus, the `PARMS` statement specifies 155 as the initial value for `Theta1`, which is approximately equal to the maximum observed velocity.

To obtain an initial value for the parameter θ_2 , first rearrange the model equation to solve for θ_2 :

$$\theta_2 = \frac{\theta_1 C}{V} - C$$

By substituting the initial value of `Theta1` for θ_1 and taking each pair of observed values of `Concentration` and `Velocity` for C and V , respectively, you obtain a set of possible starting values for `Theta2` ranging from about 0.01 to 0.07.

You can choose any value within this range as a starting value for `Theta2`, or you can direct `PROC NLIN` to perform a preliminary search for the best initial `Theta2` value

within that range of values. The PARMs statement specifies a range of values for Theta2, which results in a search over the grid points from 0 to 0.07 in increments of 0.01. The output from this PROC NLIN invocation are displayed in the following figures.

PROC NLIN evaluates the model at each point on the specified grid for the Theta2 parameter. Figure 50.1 displays the calculations resulting from the grid search.

The NLIN Procedure			
Dependent Variable Velocity			
Grid Search			
theta1	theta2	Sum of Squares	
155.0	0	3075.4	
155.0	0.0100	2074.1	
155.0	0.0200	1310.3	
155.0	0.0300	752.0	
155.0	0.0400	371.9	
155.0	0.0500	147.2	
155.0	0.0600	58.1130	
155.0	0.0700	87.9662	

The NLIN Procedure			
Dependent Variable Velocity			
Method: Marquardt			
Iterative Phase			
Iter	theta1	theta2	Sum of Squares
0	155.0	0.0600	58.1130
1	158.0	0.0736	19.7017
2	158.1	0.0741	19.6606
3	158.1	0.0741	19.6606

NOTE: Convergence criterion met.

Figure 50.1. Nonlinear Least Squares Grid Search from the NLIN Procedure

The parameter Theta1 is held constant at its specified initial value of 155, the grid is traversed, and the residual sums of squares are computed at each point. The “best” starting value is the point that corresponds to the smallest value of the residual sum of squares. Figure 50.1 shows that the best starting value for Theta2 is 0.06. PROC NLIN uses this point as the initial value for Theta2 in the following iterative phase.

PROC NLIN determines convergence using the relative offset measure of Bates and Watts (1981). When this measure is less than 10^{-5} , convergence is declared. Figure 50.1 displays the iteration history.

The NLIN Procedure	
Estimation Summary	
Method	Marquardt
Iterations	3
R	5.861E-6
PPC(theta2)	8.569E-7
RPC(theta2)	0.000078
Object	2.902E-7
Objective	19.66059
Observations Read	14
Observations Used	14
Observations Missing	0

Figure 50.2. Estimation Summary from the NLIN Procedure

Figure 50.2 displays a summary of the estimation including several convergence measures R, PPC, RPC, and Object.

The R measure is the relative offset convergence measure of Bates and Watts. A PPC value of 8.569E-7 indicates that the parameter *Theta2* (which has the largest PPC value of all the parameters) would change by that relative amount were PROC NLIN to take an additional iteration step. The RPC value indicates that *Theta2* changed by 0.000078, relative to its value in the last iteration. These changes are measured before steplength adjustments are made. The Object measure indicates that the objective function value changed 2.902E-7 in relative value from the last iteration.

The NLIN Procedure					
NOTE: An intercept was not specified for this model.					
Source	DF	Sum of Squares	Mean Square	F Value	Approx Pr > F
Model	2	290116	145058	88537.2	<.0001
Error	12	19.6606	1.6384		
Uncorrected Total	14	290135			

Figure 50.3. Nonlinear Least Squares Summary from the NLIN Procedure

Figure 50.3 displays the least squares summary statistics for the model. The degrees of freedom, sums of squares, and mean squares are listed.

The NLIN Procedure					
Parameter	Estimate	Approx Std Error	Approximate 95% Confidence Limits		Skewness
theta1	158.1	0.6737	156.6	159.6	0.0152
theta2	0.0741	0.00313	0.0673	0.0809	0.0362

Figure 50.4. Parameter Estimates from the NLIN Procedure

Figure 50.4 displays the estimates for each parameter, the associated asymptotic standard error, and the upper and lower values for the asymptotic 95% confidence interval. PROC NLIN also displays the asymptotic correlations between the estimated parameters (not shown).

The skewness measures of 0.0152 and 0.0362 indicate that the parameters are nearly linear and that their standard errors and confidence intervals can be safely used for inferences.

Thus, the estimated nonlinear model relating reaction velocity and substrate concentration can be written as

$$\hat{V} = \frac{158.105C}{0.0741 + C}$$

where V represents the velocity or rate of the reaction, and C represents the substrate concentration.

Syntax

```

PROC NLIN < options > ;
  MODEL dependent=expression ;
  PARAMETERS parameter=values < , . . . , parameter=values >;
  other program statements
  BOUNDS inequality < , . . . , inequality > ;
  BY variables ;
  DER.parameter=expression ;
  DER.parameter.parameter=expression ;
  ID variables ;
  OUTPUT OUT=SAS-data-set keyword=names < , . . . , keyword=names >;
  CONTROL variable <=values> < . . . variable <=values>> ;

```

A vertical bar (|) denotes a choice between two specifications. The *other program statements* are valid SAS expressions that can appear in the DATA step. PROC NLIN enables you to create new variables within the procedure and use them in the nonlinear analysis. The NLIN procedure automatically creates several variables that are also available for use in the analysis. See the section “[Special Variables](#)” beginning

on page 3020 for more information. The PROC NLIN, PARMs, and MODEL statements are required.

The statements used in PROC NLIN, in addition to the PROC statement, are as follows:

BOUNDS	constrains the parameter estimates within specified bounds
BY	specifies variables to define subgroups for the analysis
DER	specifies the first or second partial derivatives
ID	specifies additional variables to add to the output data set
MODEL	defines the relationship between the dependent and independent variables
OUTPUT	creates an output data set containing statistics for each observation
PARMS	identifies parameters to be estimated and the starting values for each parameter
<i>other program statements</i>	includes assignment statements, ARRAY statements, DO loops, and program control statements

PROC NLIN Statement

PROC NLIN < *options* > ;

The PROC NLIN statement invokes the procedure. The following table lists the options available with the PROC NLIN statement. Explanations follow in alphabetical order.

Task	Options
Specify data sets	DATA= OUTEST= SAVE
Grid search	BEST=
Choose an iteration method	METHOD=
Control step size	MAXSUBIT= NOHALVE RHO= SMETHOD= TAU=
Specify details of iteration	G4 UNCORRECTEDDF SIGSQ=
Minimization Tuning	CONVERGE= CONVERGEOBJ= CONVERGEPARM= SINGULAR= MAXITER=
Modify Amount of Output	HOUGAARD NOITPRINT NOPRINT
List Model Structure	LIST LISTALL LISTCODE LISTDEP LISTDER XREF
Trace Model Execution	FLOW PRINT TRACE

BEST=*n*

requests that PROC NLIN display the residual sums of squares only for the best *n* combinations of possible starting values from the grid. If you do not specify the BEST= option, PROC NLIN displays the residual sum of squares for every combination of possible parameter starting values.

CONVERGE=*c*

specifies the convergence criteria for PROC NLIN. For all iterative methods the relative offset convergence measure of Bates and Watts is used by default to determine convergence. This measure is labeled "R" in the Estimation Summary table. The

iterations are said to have converged for `CONVERGE=c` if

$$\sqrt{\frac{r'X(X'X)^{-1}X'r}{\text{LOSS}^i}} < c$$

where r is the residual vector and X is the Jacobian matrix. The default LOSS function is the sum of squared errors (SSE). By default, `CONVERGE=10-5`. The R convergence measure cannot be computed accurately in the special case of a perfect fit (residuals close to zero). When the SSE is less than the value of the `SINGULAR=` option, convergence is assumed.

CONVERGEOBJ=c

uses the change in the LOSS function as the convergence criterion. For more details on the LOSS function, see the section [“Special Variable Used to Determine Convergence Criteria”](#) on page 3021. The iterations are said to have converged for `CONVERGEOBJ=c` if

$$\frac{\text{LOSS}^{i-1} - \text{LOSS}^i}{\text{LOSS}^i + 10^{-6}} < c$$

where LOSS^i is the LOSS for the i th iteration. The default LOSS function is the sum of squared errors (SSE). The constant c should be a small positive number. See the [“Computational Methods”](#) section beginning on page 3024 for more details. If specified, the `CONVERGEOBJ=` option overrides the default `CONVERGE=` convergence criterion so that NLIN performs as it did in version 6 releases of the procedure.

CONVERGEPARM=c

uses the maximum change among parameter estimates as the convergence criterion. The iterations are said to have converged for `CONVERGEPARM=c` if

$$\max_j \left(\frac{|\beta_j^{i-1} - \beta_j^i|}{|\beta_j^{i-1}|} \right) < c$$

where β_j^i is the value of the j th parameter at the i th iteration.

The default convergence criterion is `CONVERGE`. If you specify `CONVERGEPARM=c`, the maximum change in parameters is used as the convergence criterion. If you specify both the `CONVERGEOBJ=` and `CONVERGEPARM=` options, PROC NLIN continues to iterate until the decrease in LOSS is sufficiently small (as determined by the `CONVERGEOBJ=` option) and the maximum change among the parameters is sufficiently small (as determined by the `CONVERGEPARM=` option).

DATA=SAS-data-set

specifies the SAS data set containing the data to be analyzed by PROC NLIN. If you omit the `DATA=` option, the most recently created SAS data set is used.

FLOW

displays a message for each statement in the model program as it is executed. This debugging option is rarely needed, and it produces large amounts of output.

G4

uses a Moore-Penrose (g_4) inverse in parameter estimation. Refer to Kennedy and Gentle (1980) for details.

HOUGAARD

adds Hougaard's measure of skewness to the parameter estimation table. Computation of the measure requires derivatives (see the section "[Hougaard's Measure of Skewness](#)" on page 3019).

LIST

displays the model program and variable lists, including the statements added by macros. Note that the expressions displayed by the LIST option do not necessarily represent the way the expression is actually calculated, since intermediate results for common subexpressions can be reused but are shown in expanded form by the LIST option. To see how the expression is actually evaluated, see the description for the LISTCODE option, which follows.

LISTALL

selects the LIST, LISTDEP, LISTDER, and LISTCODE options.

LISTCODE

displays the derivative tables and compiled model program code. The LISTCODE option is a debugging feature and is not normally needed.

LISTDEP

produces a report that lists, for each variable in the model program, the variables that depend on it and on which it depends.

LISTDER

displays a table of derivatives. The derivatives table lists each nonzero derivative computed for the problem. The derivative listed can be a constant, a variable in the model program, or a special derivative variable created to hold the result of the derivative expression.

MAXITER=*i*

limits the number of iterations PROC NLIN performs before it gives up trying to converge. The i value must be a positive integer. By default, MAXITER=100.

MAXSUBIT=*i*

places a limit on the number of step halvings. By default, MAXSUBIT=30. The value of MAXSUBIT must be a positive integer.

METHOD=GAUSS | MARQUARDT | NEWTON | GRADIENT

specifies the iterative method that PROC NLIN uses. The GAUSS, MARQUARDT and NEWTON methods are more robust than the GRADIENT method. If you omit the METHOD= option, METHOD=GAUSS is used. See the "[Computational Methods](#)" section beginning on page 3024 for more information.

NOITPRINT

suppresses the display of the results of each iteration.

NOHALVE

removes the restriction that the objective value must decrease at every iteration. Step halving is still used to satisfy BOUNDS and to ensure that the number of observations that can be evaluated does not decrease. NOHALVE is useful for iteratively reweighted least squares problems.

NOPRINT

suppresses the display of the output. Note that this option temporarily disables the Output Delivery System (ODS). For more information, see [Chapter 14, “Using the Output Delivery System.”](#)

OUTEST=SAS-data-set

specifies an output data set to contain the parameter estimates produced at each iteration. See the [“Output Data Sets”](#) section on page 3028 for details. If you want to create a permanent SAS data set, you must specify a two-level name. See the chapter [“SAS Files,”](#) in *SAS Language Reference: Concepts* for more information on permanent SAS data sets.

PRINT

displays the result of each statement in the program as it is executed. This option produces large amounts of output.

RHO=value

specifies a value to use in controlling the step-size search. By default, RHO=0.1 except when METHOD=MARQUARDT, in which case RHO=10. See the section [“Computational Methods”](#) beginning on page 3024 for more details.

SAVE

specifies that, when the iteration limit is exceeded, the parameter estimates from the final iteration are output to the OUTEST= data set. These parameter estimates are located in the observation with _TYPE_=FINAL. If you omit the SAVE option, the parameter estimates from the final iteration are not output to the data set unless convergence is attained.

SIGSQ=value

specifies a value to replace the mean square error for computing the standard errors of the estimates. The SIGSQ= option is used with maximum-likelihood estimation.

SINGULAR=s

specifies the singularity criterion, s , which is the absolute magnitude of the smallest pivot value allowed when inverting the Hessian or approximation to the Hessian. The default value is 1E-8.

SMETHOD=HALVE | GOLDEN | CUBIC

specifies the step-size search method that PROC NLIN uses. The default is SMETHOD=HALVE. See the section [“Computational Methods”](#) beginning on page 3024 for details.

TAU=value

specifies a value to use in controlling the step-size search. By default, TAU=1 except when METHOD=MARQUARDT, in which case TAU=0.01. See the section “Computational Methods” beginning on page 3024 for details.

TRACE

displays the result of each operation in each statement in the model program as it is executed, in addition to the information displayed by the FLOW and PRINT options. This debugging option is needed very rarely, and it produces even more output than the FLOW and PRINT options.

XREF

displays a cross-reference of the variables in the model program showing where each variable is referenced or given a value. The XREF listing does not include derivative variables.

UNCORRECTEDDF

specifies that no degrees of freedom are lost when a bound is active. When the UNCORRECTEDDF option is not specified, an active bound is treated as if a restriction was applied to the set of parameters so one parameter degree of freedom is deducted.

BOUNDS Statement

BOUNDS *inequality* <, . . . , *inequality* > ;

The BOUNDS statement restrains the parameter estimates within specified bounds. In each BOUNDS statement, you can specify a series of bounds separated by commas. The series of bounds is applied simultaneously. Each bound contains a list of parameters, an inequality comparison operator, and a value. In a single-bounded expression, these three elements follow one another in the order described. The following are examples of valid single-bounded expressions:

```
bounds a1-a10<=20;
bounds c>30;
bounds a b c > 0;
```

Multiple-bounded expressions are also permitted. For example,

```
bounds 0<=B<=10;
bounds 15<x1<=30;
bounds r <= s <= p < q;
```

If you need to restrict an expression involving several parameters (for example, $A + B < 1$), you can reparameterize the model so that the expression becomes a parameter.

For SAS versions 7.01 and later, lagrange multipliers are reported for all bounds that are enforced (active) when the estimation terminates. In the estimates table the Lagrange multiplier estimates are identified with names *Bound1*, *Bound2* An

active bound is treated as if a restriction was applied to the set of parameters so one parameter degree of freedom is deducted. The option UNCORRECTEDDF specifies that no degrees of freedom are lost when a bound is active.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC NLIN to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the NLIN procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure.

For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

CONTROL Statement

CONTROL *variable* <=*values*> < ... *variable* <=*values*>> ;

The CONTROL statement declares control variables and specifies their values. A control variable is like a retained variable (see the section “[RETAIN Statement](#)” on page 3016) except that it is retained *across* iterations and the derivative of the model with respect to a control variable is always zero.

DER Statements

DER. *parameter=expression* ;

DER. *parameter.parameter=expression* ;

The DER statement specifies first or second partial derivatives. By default, analytical derivatives are automatically computed. However, you can specify the derivatives yourself by using the DER.parm syntax. Use the first form shown to specify first partial derivatives, and use the second form to specify second partial derivatives. Note that the DER.parm syntax is retained for backward compatibility. The automatic analytical derivatives are, in general, a better choice. For additional information on automatic analytical derivatives, see the section “[Automatic Derivatives](#)” beginning on page 3017.

For most of the computational methods, you need only specify the first partial derivative for each parameter to be estimated. For the NEWTON method, specify both the first and the second derivatives. If any needed derivatives are not specified, they are automatically computed.

If you use the `_LOSS_` variable, you can specify the derivative of `_LOSS_` with respect to the parameters using the `DER.` syntax. For more information, see the “[Special Variable Used to Determine Convergence Criteria](#)” section on page 3021.

The expression can be an algebraic representation of the partial derivative of the expression in the `MODEL` statement with respect to the parameter or parameters that appear in the left-hand side of the `DER` statement. Numerical derivatives can also be used. The expression in the `DER` statement must conform to the rules for a valid SAS expression, and it can include any quantities that the `MODEL` statement expression contains.

ID Statement

ID *variables* ;

The `ID` statement specifies additional variables to place in the output data set created by the `OUTPUT` statement. Any variable on the left-hand side of any assignment statement is eligible. Also, the special variables created by the procedure can be specified. Variables in the input data set do not need to be specified in the `ID` statement since they are automatically included in the output data set.

MODEL Statement

MODEL *dependent=expression* ;

The `MODEL` statement defines the prediction equation by declaring the dependent variable and defining an expression that evaluates predicted values. The expression can be any valid SAS expression yielding a numeric result. The expression can include parameter names, variables in the data set, and variables created by program statements in the `NLIN` procedure. Any operators or functions that can be used in a `DATA` step can also be used in the `MODEL` statement.

A statement such as

```
model y=expression ;
```

is translated into the form

```
model.y = expression ;
```

using the compound variable name `model.y` to hold the predicted value. You can use this assignment as an alternative to the `MODEL` statement. Either a `MODEL` statement or an assignment to a compound variable such as `model.y` must appear.

OUTPUT Statement

OUTPUT OUT= SAS-data-set keyword=names <, . . . , keyword=names>;

The OUTPUT statement specifies an output data set to contain statistics calculated for each observation. For each statistic, specify the keyword, an equal sign, and a variable name for the statistic in the output data set. All of the names appearing in the OUTPUT statement must be valid SAS names, and none of the new variable names can match a variable already existing in the data set to which PROC NLIN is applied.

If an observation includes a missing value for one of the independent variables, both the predicted value and the residual value are missing for that observation. If the iterations fail to converge, all the values of all the variables named in the OUTPUT statement are missing values.

You can specify the following options in the OUTPUT statement. For a description of computational formulas, see [Chapter 2, “Introduction to Regression Procedures.”](#)

OUT=SAS-data-set

specifies the SAS data set to be created by PROC NLIN when an OUTPUT statement is included. The new data set includes all the variables in the data set to which PROC NLIN is applied. Also included are any ID variables specified in the ID statement, plus new variables with names that are specified in the OUTPUT statement.

The following values can be calculated and output to the new data set.

H=name

specifies a variable to contain the leverage, $x_i(\mathbf{X}'\mathbf{X})^{-1}x_i'$, where $\mathbf{X} = \partial\mathbf{F}/\partial\boldsymbol{\beta}$ and x_i is the i th row of \mathbf{X} . If you specify the special variable `_WEIGHT_`, the leverage is $w_i x_i(\mathbf{X}'\mathbf{W}\mathbf{X})^{-1}x_i'$.

L95M=name

specifies a variable to contain the lower bound of an approximate 95% confidence interval for the expected value (mean). See also the description for the U95M= option, which follows.

L95=name

specifies a variable to contain the lower bound of an approximate 95% confidence interval for an individual prediction. This includes the variance of the error as well as the variance of the parameter estimates. See also the description for the U95= option, which follows.

PARMS=names

specifies variables in the output data set to contain parameter estimates. These can be the same variable names as listed in the PARAMETERS statement; however, you can choose new names for the parameters identified in the sequence from the parameter estimates table. A note log indicates which variable in the output data set is associated with each parameter name. Note that, for each of these new variables, the values are the same for every observation in the new data set.

PREDICTED=*name***P=***name*

specifies a variable in the output data set to contain the predicted values of the dependent variable.

RESIDUAL=*name***R=***name*

specifies a variable in the output data set to contain the residuals (actual values minus predicted values).

SSE=*name***ESS=***name*

specifies a variable to include in the new data set. The values for the variable are the residual sums of squares finally determined by the procedure. The values of the variable are the same for every observation in the new data set.

STDI=*name*

specifies a variable to contain the standard error of the individual predicted value.

STDP=*name*

specifies a variable to contain the standard error of the mean predicted value.

STDR=*name*

specifies a variable to contain the standard error of the residual.

STUDENT=*name*

specifies a variable to contain the studentized residuals, which are residuals divided by their standard errors.

U95M=*name*

specifies a variable to contain the upper bound of an approximate 95% confidence interval for the expected value (mean). See also the description for the L95M= option.

U95=*name*

specifies a variable to contain the upper bound of an approximate 95% confidence interval for an individual prediction. See also the description for the L95= option.

WEIGHT=*name*

specifies a variable in the output data set that contains values of the special variable `_WEIGHT_`.

PARAMETERS Statement

PARAMETERS *parameter=values* ... ;

PARMS *parameter=values* ... ;

A **PARAMETERS** (or **PARMS**) statement must come before the **RUN** statement. Several parameter names and values can appear. The parameter names must all be valid SAS names and must not duplicate the names of any variables in the data set to which the NLIN procedure is applied. Any parameters specified but not used in the **MODEL** statement are dropped from the estimation.

In each *parameter=values* specification, the parameter name identifies a parameter to be estimated, both in subsequent procedure statements and in the output. *Values* specify the possible starting values of the parameter.

Usually, only one value is specified for each parameter. If you specify several values for each parameter, PROC NLIN evaluates the model at each point on the grid. The value specifications can take any of several forms:

- m* a single value
- m1, m2, . . . , mn* several values
- m TO n* a sequence where *m* equals the starting value, *n* equals the ending value, and the increment equals 1
- m TO n BY i* a sequence where *m* equals the starting value, *n* equals the ending value, and the increment is *i*
- m1, m2 TO m3* mixed values and sequences

This PARMs statement specifies five parameters and sets their possible starting values as shown:

```
parms  b0=0
       b1=4 to 8
       b2=0 to .6 by .2
       b3=1, 10, 100
       b4=0, .5, 1 to 4;
```

Possible starting values					
B0	B1	B2	B3	B4	
0	4	0.0	1	0.0	
		5	0.2	10	0.5
		6	0.4	100	1.0
		7	0.6		2.0
		8			3.0
					4.0

Residual sums of squares are calculated for each of the $1 \times 5 \times 4 \times 3 \times 6 = 360$ combinations of possible starting values. (This can take a long time.) See the “[Special Variables](#)” section beginning on page 3020 for information on programming parameter starting values.

RETAIN Statement

RETAIN *variable* <=*values*> < ... *variable* <=*values*>> ;

The RETAIN statement declares retained variables and specifies their values. A retained variable is like a control variable (see the section “[CONTROL Statement](#)” on page 3011) except that it is retained only *within* iterations. An iteration involves a single pass through the data set.

Other Program Statements with PROC NLIN

PROC NLIN supports many statements that are similar to SAS programming statements used in a DATA step. However, there are some differences in capabilities; for additional information, see the section “[Incompatibilities with 6.11 and Earlier Versions of PROC NLIN](#)” beginning on page 3031.

Several SAS program statements can be used after the PROC NLIN statement. These statements can appear anywhere in the PROC NLIN statement, but new variables must be created before they appear in other statements. For example, the following statements are valid since they create the variable `temp` before they use it in the MODEL statement:

```
proc nlin;
  parms b0=0 to 2 by 0.5 b1=0.01 to 0.09 by 0.01;
  temp=exp(-b1*x);
  model y=b0*(1-temp);
```

The following statements result in missing values for `y` because the variable `temp` is undefined before it is used:

```
proc nlin;
  parms b0=0 to 2 by 0.5 b1=0.01 to 0.09 by 0.01;
  model y=b0*(1-temp);
  temp=exp(-b1*x);
```

PROC NLIN can process assignment statements, explicitly or implicitly subscripted ARRAY statements, explicitly or implicitly subscripted array references, IF statements, SAS functions, and program control statements. You can use program statements to create new SAS variables for the duration of the procedure. These variables are not permanently included in the data set to which PROC NLIN is applied. Program statements can include variables in the DATA= data set, parameter names, variables created by preceding program statements within PROC NLIN, and special variables used by PROC NLIN. All of the following SAS program statements can be used in PROC NLIN:

- ARRAY
- assignment ($y = a*x + b$;))
- CALL

- DO
- iterative DO
- DO UNTIL
- DO WHILE
- END
- FILE
- GO TO
- IF-THEN/ELSE
- LINK-RETURN
- PUT (defaults to the list)
- RETURN
- SELECT
- sum ($y + 1$;)

These statements can use the special variables created by PROC NLIN. Consult the section “[Special Variables](#)” beginning on page 3020 for more information on special variables.

Details

Automatic Derivatives

Depending on the optimization method you select, analytical first- and second-order derivatives are computed automatically. Derivatives can still be supplied using the DER.parm syntax. These DER.parm derivatives are not verified by the differentiator. If any needed derivatives are not supplied, they are computed and added to the program statements. To view the computed derivatives, use the LISTDER or LIST option.

The following model is solved using Newton’s method. Analytical first- and second-order derivatives are automatically computed.

```
proc nlin data=Enzyme method=newton list;  
  parms x1=4 x2=2 ;  
  model Velocity = x1 * exp (x2 * Concentration);  
run;
```

```

Figure 50.6. LISTCODE Output

Note that, in the generated code, only one exponentiation is performed. The generated code reuses previous operations to be more efficient.

Hougaard's Measure of Skewness

A “close-to-linear” nonlinear regression model, first described by Ratkowsky (1990), is a model that produces parameters having properties similar to those produced by a linear regression model. That is, the least squares estimates of the parameters are close to being unbiased, normally distributed, minimum variance estimators.

A nonlinear regression model sometimes fails to be close to linear due to the properties of a single parameter. When this occurs, bias in the parameters can render inferences using the reported standard errors and confidence limits invalid. You can often fix the problem with reparameterization, replacing the offending parameter by one with better estimation properties.

You can use Hougaard's measure of skewness, g_{1i} , to assess whether a parameter is close to linear or whether it contains considerable nonlinearity. Specify the HOUGAARD option in the PROC NLIN statement to compute Hougaard's measure of skewness.

According to Ratkowsky (1990), if $|g_{1i}| < 0.1$, the estimator $\hat{\theta}_i$ of parameter θ_i is very close-to-linear in behavior and, if $0.1 < |g_{1i}| < .25$, the estimator is reasonably close-to-linear. If $|g_{1i}| > .25$, the skewness is very apparent. For $|g_{1i}| > 1$, the nonlinear behavior is considerable.

Hougaard's measure is computed as follows

$$E[\hat{\theta}_i - E(\hat{\theta}_i)]^3 = -(mse)^2 \sum_{jkl}^{np} L^{ij} L^{ik} L^{il} (W_{jkl} + W_{kjl} + W_{ljk})$$

where the sum is a triple sum over the number of parameters and

$$L = (X'X)^{-1}$$

$$W_{jkl} = \sum_{m=1}^n J_m^j H_m^{kl}$$

In the preceding equation, J_m is the Jacobian vector and H_m is the Hessian matrix evaluated at observation m . This third moment is normalized using the standard error as

$$g_{1i} = E[\hat{\theta}_i - E(\hat{\theta}_i)]^3 / (mse * L^{ii})^{3/2}$$

Missing Values

If the value of any one of the SAS variables involved in the model is missing from an observation, that observation is omitted from the analysis. If only the value of the dependent variable is missing, that observation has a predicted value calculated for it when you use an OUTPUT statement and specify the PREDICTED= option.

If an observation includes a missing value for one of the independent variables, both the predicted value and the residual value are missing for that observation. If the iterations fail to converge, all the values of all the variables named in the OUTPUT statement are missing values.

Special Variables

Several special variables are created automatically and can be used in PROC NLIN program statements.

Special Variables with Values that are Set by PROC NLIN

The values of the following six special variables are set by PROC NLIN and should not be reset to a different value by programming statements:

ERROR is set to 1 if a numerical error or invalid argument to a function occurs during the current execution of the program. It is reset to 0 before each new execution.

ITER represents the current iteration number. The variable **_ITER_** is set to -1 during the grid search phase.

MODEL is set to 1 for passes through the data when only the predicted values are needed, not the derivatives. It is 0 when both predicted values and derivatives are needed. If your derivative calculations consume a lot of time, you can save resources by coding

```
if _model_ then return;
```

after your MODEL statement but before your derivative calculations. The derivatives generated by PROC NLIN do this automatically.

N indicates the number of times the PROC NLIN step has been executed. It is never reset for successive passes through the data set.

OBS indicates the observation number in the data set for the current program execution. It is reset to 1 to start each pass through the data set (unlike the **_N_** variable).

SSE has the error sum of squares of the last iteration. During the grid search phase, the **_SSE_** variable is set to 0. For iteration 0, the **_SSE_** variable is set to the SSE associated with the point chosen from the grid search.

Special Variable Used to Determine Convergence Criteria

The special variable `_LOSS_` can be used to determine convergence criteria:

`_LOSS_` is used to determine the criterion function for convergence and step shortening. PROC NLIN looks for the variable `_LOSS_` in the program statements and, if it is defined, uses the (weighted) sum of this value instead of the residual sum of squares to determine the criterion function for convergence and step shortening. This feature is useful in certain types of maximum-likelihood estimation where the residual sum of squares is not the basic criterion.

Weighted Regression with the Special Variable `_WEIGHT_`

To get weighted least squares estimates of parameters, the `_WEIGHT_` variable can be given a value in an assignment statement:

```
_weight_ = expression;
```

When this statement is included, the expression on the right-hand side of the assignment statement is evaluated for each observation in the data set to be analyzed. The values obtained are taken as inverse elements of the diagonal variance-covariance matrix of the dependent variable.

When a variable name is given after the equal sign, the values of the variable are taken as the inverse elements of the variance-covariance matrix. The larger the `_WEIGHT_` value, the more importance the observation is given.

The `_WEIGHT_` variable can be a function of the estimated parameters. For estimation purposes the derivative of the `_WEIGHT_` variable with-respect-to the parameters is not included in the gradient and the Hessian of the loss function. This is normally the desired approach for iteratively reweighted least squares estimation. With the `_WEIGHT_` variable a function of parameters, the gradient and the Hessian used may lead to poor convergence or non-convergence of the requested estimation. To have the derivative of the `_WEIGHT_` variable with-respect-to the parameters included in the gradient and the Hessian of the loss function, do not use the `_WEIGHT_` variable. Instead, redefine the model as

$$(y - f(x, \beta)) / \sqrt{wgt(\beta)}$$

where y is the original dependent variable, $f(x, \beta)$ is the nonlinear model, and $wgt(\beta)$ is the weight that is a function of the parameters.

If the `_WEIGHT_ =` statement is not used, the default value of 1 is used, and regular least squares estimates are obtained.

Troubleshooting

This section describes a number of problems that can occur in your analysis with PROC NLIN.

Excessive Time

If you specify a grid of starting values that contains many points, the analysis may take excessive time since the procedure must go through the entire data set for each point on the grid.

The analysis may also take excessive time if your problem takes many iterations to converge since each iteration requires as much time as a linear regression with predicted values and residuals calculated.

Dependencies

The matrix of partial derivatives may be singular, possibly indicating an over-parameterized model. For example, if `b0` starts at zero in the following model, the derivatives for `b1` are all zero for the first iteration.

```
parms b0=0 b1=.022;
model pop=b0*exp(b1*(year-1790));
der.b0=exp(b1*(year-1790));
der.b1=(year-1790)*b0*exp(b1*(year-1790));
```

The first iteration changes a subset of the parameters; then the procedure can make progress in succeeding iterations. This singularity problem is local. The next example displays a global problem.

You may have a term `b2` in the exponent that is nonidentifiable since it trades roles with `b0`.

```
parms b0=3.9 b1=.022 b2=0;
model pop=b0*exp(b1*(year-1790)+b2);
der.b0=exp(b1*(year-1790)+b2);
der.b1=(year-1790)*b0*exp(b1*(year-1790)+b2);
der.b2=b0*exp(b1*(year-1790)+b2);
```

Unable to Improve

The method may lead to steps that do not improve the estimates even after a series of step halvings. If this happens, the procedure issues a message stating that it is unable to make further progress, but it then displays the warning message

```
PROC NLIN failed to converge
```

and displays the results. This often means that the procedure has not converged at all. If you provided the derivatives, check them very closely and then check the sum-of-squares error surface before proceeding. If PROC NLIN has not converged, try a different set of starting values, a different METHOD= specification, the G4 option, or a different model.

Divergence

The iterative process may diverge, resulting in overflows in computations. It is also possible that parameters enter a space where arguments to such functions as LOG and SQRT become illegal. For example, consider the following model:

```
parms b=0;
model y=x / b;
```

Suppose that y happens to be all zero and x is nonzero. There is no least squares estimate for b since the SSE declines as b approaches infinity or minus infinity. The same model could be parameterized with no problem into $y = a*x$.

If you have divergence problems, try reparameterizing, selecting different starting values, increasing the maximum allowed number of iterations (the MAXITER= option), specifying an alternative METHOD= option, or including a BOUNDS statement.

Local Minimum

The program may converge to a local rather than a global minimum. For example, consider the following model.

```
parms a=1 b=-1;
model y=(1-a*x)*(1-b*x);
```

Once a solution is found, an equivalent solution with the same SSE can be obtained by swapping the values of a and b .

Discontinuities

The computational methods assume that the model is a continuous and smooth function of the parameters. If this is not true, the method does not work. For example, the following models do not work:

```
model y=a+int(b*x);

model y=a+b*x+4*(z>c);
```

Responding to Trouble

PROC NLIN does not necessarily produce a good solution the first time. Much depends on specifying good initial values for the parameters. You can specify a grid of values in the PARMS statement to search for good starting values. While most practical models should give you no trouble, other models may require switching to a different iteration method or an inverse computation method. Specifying the option METHOD=MARQUARDT sometimes works when the default method (Gauss-Newton) does not work.

Computational Methods

For the system of equations represented by the nonlinear model

$$\mathbf{Y} = \mathbf{F}(\beta_0, \beta_1, \dots, \beta_r, \mathbf{Z}_1, \mathbf{Z}_2, \dots, \mathbf{Z}_n) + \epsilon = \mathbf{F}(\boldsymbol{\beta}^*) + \epsilon$$

where \mathbf{Z} is a matrix of the independent variables, $\boldsymbol{\beta}^*$ is a vector of the parameters, ϵ is the error vector, and \mathbf{F} is a function of the independent variables and the parameters, there are two approaches to solving for the minimum. The first method is to minimize

$$L(\boldsymbol{\beta}) = 0.5(\mathbf{e}'\mathbf{e})$$

where $\mathbf{e} = \mathbf{Y} - \mathbf{F}(\boldsymbol{\beta})$ and $\boldsymbol{\beta}$ is an estimate of $\boldsymbol{\beta}^*$.

The second method is to solve the nonlinear “normal” equations

$$\mathbf{X}'\mathbf{F}(\boldsymbol{\beta}) = \mathbf{X}'\mathbf{Y}$$

where

$$\mathbf{X} = \frac{\partial \mathbf{F}}{\partial \boldsymbol{\beta}}$$

In the nonlinear situation, both \mathbf{X} and $\mathbf{F}(\boldsymbol{\beta})$ are functions of $\boldsymbol{\beta}$ and a closed-form solution generally does not exist. Thus, PROC NLIN uses an iterative process: a starting value for $\boldsymbol{\beta}$ is chosen and continually improved until the error sum of squares $\mathbf{e}'\mathbf{e}$ is minimized.

The iterative techniques that PROC NLIN uses are similar to a series of linear regressions involving the matrix \mathbf{X} evaluated for the current values of $\boldsymbol{\beta}$ and $\mathbf{e} = \mathbf{Y} - \mathbf{F}(\boldsymbol{\beta})$, the residuals evaluated for the current values of $\boldsymbol{\beta}$.

The iterative process begins at some point $\boldsymbol{\beta}_0$. Then \mathbf{X} and \mathbf{Y} are used to compute a $\boldsymbol{\Delta}$ such that

$$\text{SSE}(\boldsymbol{\beta}_0 + k\boldsymbol{\Delta}) < \text{SSE}(\boldsymbol{\beta}_0)$$

The four methods differ in how $\boldsymbol{\Delta}$ is computed to change the vector of parameters.

$$\text{Steepest descent: } \boldsymbol{\Delta} = \mathbf{X}'\mathbf{e}$$

$$\text{Gauss-Newton: } \boldsymbol{\Delta} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{e}$$

$$\text{Newton: } \boldsymbol{\Delta} = (\mathbf{G}^{-})\mathbf{X}'\mathbf{e}$$

$$\text{Marquardt: } \boldsymbol{\Delta} = (\mathbf{X}'\mathbf{X} + \lambda \text{diag}(\mathbf{X}'\mathbf{X}))^{-1}\mathbf{X}'\mathbf{e}$$

The default method used to compute $(\mathbf{X}'\mathbf{X})^{-}$ is the sweep operator producing a reflexive generalized (g_2) inverse. In some cases it would be preferable to use a Moore-Penrose (g_4) inverse. If the G4 option is specified in the PROC NLIN statement, a g_4 inverse is used to calculate Δ on each iteration.

The Gauss-Newton and Marquardt iterative methods regress the residuals onto the partial derivatives of the model with respect to the parameters until the estimates converge. The Newton iterative method regresses the residuals onto a function of the first and second derivatives of the model with respect to the parameters until the estimates converge. Analytical first- and second-order derivatives are automatically computed.

Steepest Descent (Gradient)

The steepest descent method is based on the gradient of $\epsilon'\epsilon$:

$$\frac{1}{2} \frac{\partial L(\beta)}{\partial \beta} = -\mathbf{X}\mathbf{Y} + \mathbf{X}\mathbf{F}(\beta) = -\mathbf{X}'\mathbf{e}$$

The quantity $-\mathbf{X}'\mathbf{e}$ is the gradient along which $\epsilon'\epsilon$ increases. Thus $\Delta = \mathbf{X}'\mathbf{e}$ is the direction of steepest descent.

If the automatic variables `_WEIGHT_` and `_RESID_` are used, then

$$\Delta = \mathbf{X}'\mathbf{W}^{\text{SSE}}\mathbf{r}$$

is the direction, where

\mathbf{W}^{SSE} is an $n \times n$ diagonal matrix with elements w_i^{SSE} of weights from the `_WEIGHT_` variable. Each element w_i^{SSE} contains the value of `_WEIGHT_` for the i th observation.

\mathbf{r} is a vector with elements r_i from `_RESID_`. Each element r_i contains the value of `_RESID_` evaluated for the i th observation.

Using the method of steepest descent, let

$$\beta_{k+1} = \beta_k + \alpha\Delta$$

where the scalar α is chosen such that

$$\text{SSE}(\beta_i + \alpha\Delta) < \text{SSE}(\beta_i)$$

Note: The steepest descent method may converge very slowly and is therefore not generally recommended. It is sometimes useful when the initial values are poor.

Newton

The Newton method uses the second derivatives and solves the equation

$$\Delta = \mathbf{G}^{-1} \mathbf{X}' \mathbf{e}$$

where

$$\mathbf{G} = (\mathbf{X}'\mathbf{X}) + \sum_{i=1}^n H_i(\boldsymbol{\beta}) \mathbf{e}_i$$

and $H_i(\boldsymbol{\beta})$ is the Hessian of \mathbf{e} :

$$[H_i]_{jk} = \left[\frac{\partial^2 \mathbf{e}_i}{\partial \beta_j \partial \beta_k} \right]_{jk}$$

If the automatic variables `_WEIGHT_`, `_WGTJPJ_`, and `_RESID_` are used, then

$$\Delta = \mathbf{G}^{-1} \mathbf{X}' \mathbf{W}^{\text{SSE}} \mathbf{r}$$

is the direction, where

$$\mathbf{G} = \mathbf{X}' \mathbf{W}^{\text{XPX}} \mathbf{X} + \sum_{i=1}^n \mathbf{H}_i(\boldsymbol{\beta}) w_i^{\text{XPX}} r_i$$

and

\mathbf{W}^{SSE} is an $n \times n$ diagonal matrix with elements w_i^{SSE} of weights from the `_WEIGHT_` variable. Each element w_i^{SSE} contains the value of `_WEIGHT_` for the i th observation.

\mathbf{W}^{XPX} is an $n \times n$ diagonal matrix with elements w_i^{XPX} of weights from the `_WGTJPJ_` variable.

Each element w_i^{XPX} contains the value of `_WGTJPJ_` for the i th observation.

\mathbf{r} is a vector with elements r_i from the `_RESID_` variable. Each element r_i contains the value of `_RESID_` evaluated for the i th observation.

Gauss-Newton

The Gauss-Newton method uses the Taylor series

$$\mathbf{F}(\boldsymbol{\beta}) = \mathbf{F}(\boldsymbol{\beta}_0) + \mathbf{X}(\boldsymbol{\beta} - \boldsymbol{\beta}_0) + \dots$$

where $\mathbf{X} = \partial\mathbf{F}/\partial\boldsymbol{\beta}$ is evaluated at $\boldsymbol{\beta} = \boldsymbol{\beta}_0$.

Substituting the first two terms of this series into the normal equations

$$\begin{aligned}\mathbf{X}'\mathbf{F}(\boldsymbol{\beta}) &= \mathbf{X}'\mathbf{Y} \\ \mathbf{X}'(\mathbf{F}(\boldsymbol{\beta}_0) + \mathbf{X}(\boldsymbol{\beta} - \boldsymbol{\beta}_0)) &= \mathbf{X}'\mathbf{Y} \\ (\mathbf{X}'\mathbf{X})(\boldsymbol{\beta} - \boldsymbol{\beta}_0) &= \mathbf{X}'\mathbf{Y} - \mathbf{X}'\mathbf{F}(\boldsymbol{\beta}_0) \\ (\mathbf{X}'\mathbf{X})\boldsymbol{\Delta} &= \mathbf{X}'\mathbf{e}\end{aligned}$$

and therefore

$$\boldsymbol{\Delta} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{e}$$

Caution: If $\mathbf{X}'\mathbf{X}$ is singular or becomes singular, PROC NLIN computes $\boldsymbol{\Delta}$ using a generalized inverse for the iterations after singularity occurs. If $\mathbf{X}'\mathbf{X}$ is still singular for the last iteration, the solution should be examined.

Marquardt

The Marquardt updating formula is as follows:

$$\boldsymbol{\Delta} = (\mathbf{X}'\mathbf{X} + \lambda\text{diag}(\mathbf{X}'\mathbf{X}))^{-1}\mathbf{X}'\mathbf{e}$$

The Marquardt method is a compromise between the Gauss-Newton and steepest descent methods (Marquardt 1963). As $\lambda \rightarrow 0$, the direction approaches Gauss-Newton. As $\lambda \rightarrow \infty$, the direction approaches steepest descent.

Marquardt's studies indicate that the average angle between Gauss-Newton and steepest descent directions is about 90° . A choice of λ between 0 and infinity produces a compromise direction.

By default, PROC NLIN chooses $\lambda = 10^{-7}$ to start and computes a $\boldsymbol{\Delta}$. If $\text{SSE}(\boldsymbol{\beta}_0 + \boldsymbol{\Delta}) < \text{SSE}(\boldsymbol{\beta}_0)$, then $\lambda = \lambda/10$ for the next iteration. Each time $\text{SSE}(\boldsymbol{\beta}_0 + \boldsymbol{\Delta}) > \text{SSE}(\boldsymbol{\beta}_0)$, then $\lambda = 10\lambda$.

Note: If the SSE decreases on each iteration, then $\lambda \rightarrow 0$, and you are essentially using the Gauss-Newton method. If SSE does not improve, then λ is increased until you are moving in the steepest descent direction.

Marquardt's method is equivalent to performing a series of ridge regressions and is useful when the parameter estimates are highly correlated or the objective function is not well approximated by a quadratic.

Step-Size Search

The default method of finding the step size k is step halving using SMETHOD=HALVE. If $SSE(\beta_0 + \Delta) > SSE(\beta_0)$, compute $SSE(\beta_0 + 0.5\Delta)$, $SSE(\beta_0 + 0.25\Delta)$, . . . , until a smaller SSE is found.

If you specify SMETHOD=GOLDEN, the step size k is determined by a golden section search. The parameter TAU determines the length of the initial interval to be searched, with the interval having length TAU or $2 \times \text{TAU}$, depending on $SSE(\beta_0 + \Delta)$. The RHO parameter specifies how fine the search is to be. The SSE at each endpoint of the interval is evaluated, and a new subinterval is chosen. The size of the interval is reduced until its length is less than RHO. One pass through the data is required each time the interval is reduced. Hence, if RHO is very small relative to TAU, a large amount of time can be spent determining a step size. For more information on the GOLDEN search, refer to Kennedy and Gentle (1980).

If you specify SMETHOD=CUBIC, the NLIN procedure performs a cubic interpolation to estimate the step size. If the estimated step size does not result in a decrease in SSE, step halving is used.

Output Data Sets

The data set produced by the OUTEST= option in the PROC NLIN statement contains the parameter estimates on each iteration including the grid search.

The variable _ITER_ contains the iteration number. The variable _TYPE_ denotes whether the observation contains iteration parameter estimates ('ITER'), final parameter estimates ('FINAL'), or covariance estimates ('COVB'). The variable _NAME_ contains the parameter name for covariances, and the variable _SSE_ contains the objective function value for the parameter estimates. The variable _STATUS_ indicates whether the estimates have converged.

The data set produced by the OUTPUT statement contains statistics calculated for each observation. In addition, the data set contains all the variables in the input data set and any ID variables that are specified in the ID statement.

Confidence Intervals

Parameter Confidence Intervals

The parameter confidence intervals are computed using the Wald based formula:

$$\hat{\beta}_i \pm \text{stderr}_i * t(N - P, 0.05/2)$$

where stderr_i is the standard error of the i^{th} parameter $\hat{\beta}_i$ and $t(N - P, 0.05/2)$ is a t statistic with $N - P$ degrees of freedom, N is the number of observations, and P is the number of parameters. The confidence intervals are only asymptotically valid.

Model Confidence Intervals

Model confidence intervals are output when an OUT= data set is specified and one or more of the options L95M=, L95=, U95M=, or U95= is specified. The values of these terms are

$$\begin{aligned}
 H &= w_i x_i (\mathbf{X}' \mathbf{W} \mathbf{X})^{-1} x_i' \\
 L95M &= f(\beta, \mathbf{z}_i) - \sqrt{MSE * H / w_i} * t(N - P, 0.975/2) \\
 U95M &= f(\beta, \mathbf{z}_i) + \sqrt{MSE * H / w_i} * t(N - P, 0.975/2) \\
 L95 &= f(\beta, \mathbf{z}_i) - \sqrt{MSE(H + 1/w_i)} * t(N - P, 0.975/2) \\
 U95 &= f(\beta, \mathbf{z}_i) + \sqrt{MSE(H + 1/w_i)} * t(N - P, 0.975/2)
 \end{aligned}$$

where $\mathbf{X} = \partial f / \partial \beta$ and x_i is the i th row of \mathbf{X} . These results are derived for linear systems. The intervals are approximate for nonlinear models.

Parameter Covariance Matrix

For unconstrained estimates (no active bounds), the parameter covariance matrix is

$$(X'X)^{-1} * mse$$

for the gradient, Marquardt, and Gauss methods and

$$H^{-1} * mse$$

for Newton method. The mse is computed as

$$r'r / (nused - np)$$

where $nused$ is the number of non-missing observations and np is the number of estimable parameters. The standard error reported for the parameters is the sqrt of the corresponding diagonal element of this matrix.

Equality restrictions can be written as a vector function

$$h(\theta) = 0$$

Inequality restrictions are either active or inactive. When an inequality restriction is active, it is treated as an equality restriction.

For the following, assume the vector $h(\theta)$ contains all the current active restrictions. The constraint matrix A is

$$A(\hat{\theta}) = \frac{\partial h(\hat{\theta})}{\partial \hat{\theta}}$$

The covariance matrix for the restricted parameter estimates is computed as

$$Z(Z'HZ)^{-1}Z'$$

where H is Hessian or approximation to the Hessian, and Z is the last $(np - nc)$ columns of Q . Q is from an LQ factorization of the constraint matrix, nc is the number of active constraints, and np is the number of parameters. Refer to Gill, Murray, and Wright (1981) for more details on LQ factorization.

The covariance matrix for the Lagrange multipliers is computed as

$$(AH^{-1}A')^{-1}$$

Reported Convergence Measures

NLIN computes and reports four convergence measures labeled R, PPC, RPC, and OBJECT.

R is the primary convergence measure for the parameters. It measures the degree to which the residuals are orthogonal to the Jacobian columns, and it approaches 0 as the gradient of the objective function becomes small. R is defined as

$$\sqrt{\frac{r'X(X'X)^{-1}X'r}{\text{LOSS}^i}}$$

PPC is the prospective parameter change measure. PPC measures the maximum relative change in the parameters implied by the parameter-change vector computed for the next iteration. At the k th iteration, PPC is the maximum over the parameters

$$\frac{|\theta_i^{k+1} - \theta_i^k|}{|\theta_i^k + 1E - 6|}$$

where θ_i^k is the current value of the i th parameter and θ_i^{k+1} is the prospective value of this parameter after adding the change vector computed for the next iteration. These changes are measured before steplength adjustments are made. The parameter with the maximum prospective relative change is displayed with the value of PPC, unless the PPC is nearly 0.

RPC is the retrospective parameter change measure. RPC measures the maximum relative change in the parameters from the previous iteration. At the k th iteration, RPC is the maximum over i of

$$\frac{|\theta_i^k - \theta_i^{k-1}|}{|\theta_i^{k-1} + 1E - 6|}$$

where θ_i^k is the current value of the i th parameter and θ_i^{k-1} is the previous value of this parameter. These changes are measured before steplength adjustments are made. The name of the parameter with the maximum retrospective relative change is displayed with the value of RPC, unless the RPC is nearly 0.

OBJECT measures the relative change in the objective function value between iterations:

$$\frac{|O^k - O^{k-1}|}{|O^{k-1} + 1E - 6|}$$

where O^{k-1} is the value of the objective function (O^k) from the previous iteration. This is the old CONVERGEOBJ= criterion.

Displayed Output

In addition to the output data sets, PROC NLIN also produces the following items:

- the estimates of the parameters and the residual Sums of Squares determined in each iteration
- a list of the residual Sums of Squares associated with all or some of the combinations of possible starting values of parameters
- an analysis-of-variance table including as sources of variation Regression, Residual, Uncorrected Total, Corrected Total, and F test

If the convergence criterion is met, PROC NLIN produces

- Estimation Summary Table
- Parameter Estimates
- an asymptotically valid standard error of the estimate, Asymptotic Standard Error.
- an Asymptotic 95% Confidence Interval for the estimate of the parameter
- an Asymptotic Correlation Matrix of the parameters

Incompatibilities with 6.11 and Earlier Versions of PROC NLIN

The NLIN procedure now uses a compiler that is different from the DATA step compiler. The compiler was changed so that analytical derivatives could be computed automatically. For the most part, the syntax accepted by the old NLIN procedure can be used in the new NLIN procedure. However, there are several differences that should be noted.

- You cannot specify a character index variable in the DO statement, and you cannot specify a character test in the IF statement. Thus DO I=1,2,3; is supported, but DO I='ONE','TWO','THREE'; is not supported. And IF 'THIS' < 'THAT' THEN . . .; is supported, but "IF 'THIS' THEN . . .;" is not supported.
- The PUT statement, which is used mostly for program debugging in PROC NLIN, supports only some of the features of the DATA step PUT statement, and it has some new features that the DATA step PUT statement does not.
 - The PUT statement does not support line pointers, factored lists, iteration factors, overprinting, the _INFILE_ option, the ':' format modifier, or the symbol '\$'.
 - The PUT statement does support expressions inside of parentheses. For example, PUT (SQRT(X)); produces the square root of X.
 - The PUT statement also supports the option _PDV_ to display a formatted listing of all the variables in the program. The statement PUT _PDV_; prints a much more readable listing of the variables than PUT _ALL_; does.
- You cannot use the '*' subscript, but you can specify an array name in a PUT statement without subscripts. Thus, ARRAY A . . .; PUT A; is acceptable, but PUT A[*] ; is not. The statement PUT A; displays all the elements of the array A. The PUT A=; statement displays all the elements of A with each value labeled by the name of the element variable.
- You cannot specify any arguments in the ABORT statement.
- You can specify more than one target statement in the WHEN and OTHERWISE statements. That is, DO/END groups are not necessary for multiple WHEN statements, for example, SELECT; WHEN(exp1); stmt1; stmt2; WHEN(exp2); stmt3; stmt4; END;.
- You can specify only the options LOG, PRINT, and LIST in the FILE statement.
- The RETAIN statement retains only values across one pass through the data set. If you need to retain values across iterations, use the CONTROL statement to make a control variable.

The ARRAY statement in PROC NLIN is similar to, but not the same as, the ARRAY statement in the SAS DATA step. The ARRAY statement is used to associate a name (of no more than 8 characters) with a list of variables and constants. The array name can then be used with subscripts in the program to refer to the items in the list.

The ARRAY statement supported by PROC NLIN does not support all the features of the DATA step ARRAY statement. You cannot specify implicit indexing variables; all array references must have explicit subscript expressions. You can specify simple array dimensions; lower bound specifications are not supported. A maximum of six dimensions are accepted.

On the other hand, the ARRAY statement supported by PROC NLIN does accept both variables and constants as array elements. (Constant array elements cannot be changed with assignment statements.)

```

proc nlin data=nld;
array b[4] 1 2 3 4;      /* Constant array */
array c[4] ( 1 2 3 4 ); /* Numeric array with initial values */

b[1] = 2;                /* This is an ERROR, b is a constant array*/
c[2] = 7.5;              /* This is allowed */
...

```

Both dimension specification and the list of elements are optional, but at least one must be specified. When the list of elements is not specified, or fewer elements than the size of the array are listed, array variables are created by suffixing element numbers to the array name to complete the element list.

If the array is used as a pure array in the program rather than a list of symbols (the individual symbols of the array are not referenced in the code), the array is converted to a numerical array. A pure array is literally a vector of numbers that are accessed only by index. Using these types of arrays results in faster derivatives and compiled code.

```

proc nlin data=nld;
array c[4] ( 1 2 3 4 ); /* Numeric array with initial values */

c[2] = 7.5;             /* This is C used as a pure array */
c1 = -92.5;             /* This forces C to be a list of symbols */

```

ODS Table Names

PROC NLIN assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see [Chapter 14, “Using the Output Delivery System.”](#)

Table 50.1. ODS Tables Produced in PROC NLIN

ODS Table Name	Description	Statement
ANOVA	Analysis of variance	default
CodeDependency	Variable cross reference	LISTDEP
CodeList	Listing of program statements	LISTCODE
ConvergenceStatus	Convergence status	default
CorrB	Correlation of the parameters	default
EstSummary	Summary of the estimation	default
FirstDerivatives	First derivative table	LISTDER
IterHistory	Iteration output	default
MissingValues	Missing values generated by the program	default
ParameterEstimates	Parameter estimates	default
ProgList	Listing of the compiled program	LIST

Convergence Status Table

The ConvergenceStatus table can be used to programmatically check on the status of an estimation. The ConvergenceStatus table contains the variable STATUS that takes on one of the values, 0, 1, or 3. If STATUS equals 0, then the convergence criterion were met. If STATUS equals 1, then the convergence criterion were met but notes were added to the log that may indicate a problem with the model. If STATUS equals 3, then the convergence criterion were not met.

The following sample program demonstrates how the ConvergenceStatus table can be used.

```

                /* Save the ConvergenceStatus    */
                /* table to the dataset "status" */
ods output ConvergenceStatus=status;
proc nlin data=a ;
  parameters a=1 b=1 c=1;
  model wgt=a+x/(b*y+c*z);
run;

data _NULL_; set status;
  if status > 0 then put "A problem Occurred";
run;

```

Examples

Example 50.1. Segmented Model

From theoretical considerations, you can hypothesize that

$$\begin{aligned}
 y &= a + b x + c x^2 && \text{if } x < x_0 \\
 y &= p && \text{if } x \geq x_0
 \end{aligned}$$

That is, for values of x less than x_0 , the equation relating y and x is quadratic (a parabola); and, for values of x greater than x_0 , the equation is constant (a horizontal line). PROC NLIN can fit such a segmented model even when the joint point, x_0 , is unknown.

The curve must be continuous (the two sections must meet at x_0), and the curve must be smooth (the first derivatives with respect to x are the same at x_0).

These conditions imply that

$$x_0 = -b/2c$$

$$p = a - b^2/4c$$

The segmented equation includes only three parameters; however, the equation is nonlinear with respect to these parameters.

You can write program statements with PROC NLIN to conditionally execute different sections of code for the two parts of the model, depending on whether x is less than x_0 .

A PUT statement is used to print the constrained parameters every time the program is executed for the first observation (where $x = 1$). The following statements perform the analysis.

```

*-----FITTING A SEGMENTED MODEL USING NLIN-----*
|
|  Y      QUADRATIC      PLATEAU

```

Output 50.1.1 indicates that the join point is 12.75 and the plateau value is 0.78. As displayed in the following plot of the predicted values (YP) and the actual values, the selected join point and plateau value is reasonable. The predicted values for the estimation are written to the data set b with the OUTPUT statement.

Output 50.1.3. Observed and Predicted Values for the Quadratic Model

Example 50.2. Iteratively Reweighted Least Squares

The NLIN procedure is suited to methods that make the weight a function of the parameters in each iteration since the `_WEIGHT_` variable can be computed with program statements.

The `NOHALVE` option is used because the SSE definition is modified at each iteration and the step-shortening criteria is thus circumvented.

Iteratively reweighted least squares (IRLS) can produce estimates for many of the robust regression criteria suggested in the literature. These methods act like automatic outlier rejectors since large residual values lead to very small weights. Holland and Welsch (1977) outline several of these robust methods. For example, the biweight criterion suggested by Beaton and Tukey (1974) tries to minimize

$$S_{biweight} = \sum \rho(r)$$

where

$$\rho(r) = (B^2/2)(1 - (1 - (r/B)^2)^2) \quad \text{if } |r| \leq B$$

or

$$\rho(r) = (B^2/2) \quad \text{otherwise}$$

where r is $|residual|/\sigma$, σ is a measure of scale of the error, and B is a tuning constant.

The weighting function for the biweight is

$$w_i = (1 - (r_i/B)^2)^2 \quad \text{if } |r_i| \leq B$$

or

$$w_i = 0 \quad \text{if } |r_i| > B$$

The biweight estimator depends on both a measure of scale (like the standard deviation) and a tuning constant; results vary if these values are changed.

The data are the population of the United States (in millions), recorded at ten-year intervals starting in 1790 and ending in 1990.

Output 50.2.2 displays the computed weights. The observations for 1940 and 1950 are highly discounted because of their large residuals.

Example 50.3. Probit Model with Likelihood function

The data, taken from Lee (1974), consist of patient characteristics and a variable indicating whether cancer remission occurred. This example demonstrates how to use PROC NLIN with a likelihood function. In this case, the likelihood function to minimize is

$$-2 \log L = -2 \sum_{i=1}^N wght_i \log(\hat{p}_i(y_i, \mathbf{x}_i))$$

where

$$\hat{p}_i(y_i, \mathbf{x}_i) = \begin{cases} \Phi(\alpha + \beta' \mathbf{x}_i) & y_i = 0 \\ 1 - \Phi(\alpha + \beta' \mathbf{x}_i) & y_i = 1 \end{cases}$$

and Φ is the normal probability function. This is the likelihood function for a binary probit model. This likelihood is strictly positive so that you can take a square root of $\log(\hat{p}_i(y_i, \mathbf{x}_i))$ and use this as your residual in PROC NLIN. The DATA step also creates a zero-valued dummy variable, like, that is used as the dependent variable.

;
run;

```

```

proc nlin data=remiss method=newton sigsq=1;
  parms a -2 b -1 c 6 int -10;

  /* Linear portion of model -----*/
  eq1 = a*cell + b*li + c*temp +int;

  /* probit */
  p = probnorm(eq1);

  if ( remiss = 1 ) then p = 1-p;

  model.like = sqrt(- 2 * log( p));
  output out=p p=predict;
run;

```

Note that the asymptotic standard errors of the parameters are computed under the least squares assumptions. The SIGSQ=1 option on the PROC NLIN statement forces PROC NLIN to replace the usual mean square error with 1. Also, METHOD=NEWTON is selected so the true Hessian of the likelihood function is used to calculate parameter standard errors rather than the crossproducts approximation to the Hessian.

Output 50.3.1. Nonlinear Least Squares Analysis from PROC NLIN

Beaton/Tukey Biweight Robust Regression using IRLS					
The NLIN Procedure					
NOTE: An intercept was not specified for this model.					
Source	DF	Sum of Squares	Mean Square	F Value	Approx Pr > F
Model	4	-21.9002	-5.4750	-5.75	.

Chapter 51

The NLMIXED Procedure

Overview

Introduction

The NLMIXED procedure fits nonlinear mixed models, that is, models in which both fixed and random effects enter nonlinearly. These models have a wide variety of applications, two of the most common being pharmacokinetics and overdispersed binomial data. PROC NLMIXED enables you to specify a conditional distribution for your data (given the random effects) having either a standard form (normal, binomial, Poisson) or a general distribution that you code using SAS programming statements.

PROC NLMIXED fits nonlinear mixed models by maximizing an approximation to the likelihood integrated over the random effects. Different integral approximations are available, the principal ones being adaptive Gaussian quadrature and a first-order Taylor series approximation. A variety of alternative optimization techniques are available to carry out the maximization; the default is a dual quasi-Newton algorithm.

Successful convergence of the optimization problem results in parameter estimates along with their approximate standard errors based on the second derivative matrix of the likelihood function. PROC NLMIXED enables you to use the estimated model to construct predictions of arbitrary functions using empirical Bayes estimates of the random effects. You can also estimate arbitrary functions of the nonrandom parameters, and PROC NLMIXED computes their approximate standard errors using the delta method.

Literature on Nonlinear Mixed Models

Davidian and Giltinan (1995) and Vonesh and Chinchilli (1997) provide good overviews as well as general theoretical developments and examples of nonlinear mixed models. Pinheiro and Bates (1995) is a primary reference for the theory and computational techniques of PROC NLMIXED. They describe and compare several different integrated likelihood approximations and provide evidence that adaptive Gaussian quadrature is one of the best methods. Davidian and Gallant (1993) also use Gaussian quadrature for nonlinear mixed models, although the smooth nonparametric density they advocate for the random effects is currently not available in PROC NLMIXED.

Traditional approaches to fitting nonlinear mixed models involve Taylor series expansions, expanding around either zero or the empirical best linear unbiased predictions of the random effects. The former is the basis for the well-known first-order method of Beal and Sheiner (1982, 1988) and Sheiner and Beal (1985), and it is optionally available in PROC NLMIXED. The latter is the basis for the estimation method of Lindstrom and Bates (1990), and it is not available in PROC NLMIXED. However, the closely related Laplacian approximation is an option; it is equivalent to adaptive

Gaussian quadrature with only one quadrature point. The Laplacian approximation and its relationship to the Lindstrom-Bates method are discussed by Beal and Sheiner (1992), Wolfinger (1993), Vonesh (1992, 1996), Vonesh and Chinchilli (1997), and Wolfinger and Lin (1997).

A parallel literature exists in the area of generalized linear mixed models, in which random effects appear as a part of the linear predictor inside of a link function. Taylor-series methods similar to those just described are discussed in articles such as Harville and Mee (1984), Stiratelli, Laird, and Ware (1984), Gilmour, Anderson, and Rae (1985), Goldstein (1991), Schall (1991), Engel and Keen (1992), Breslow and Clayton (1993), Wolfinger and O'Connell (1993), and McGilchrist (1994), but such methods have not been implemented in PROC NLMIXED because they can produce biased results in certain binary data situations (Rodriguez and Goldman 1995, Lin and Breslow 1996). Instead, a numerical quadrature approach is available in PROC NLMIXED, as discussed in Pierce and Sands (1975), Anderson and Aitkin (1985), Crouch and Spiegelman (1990), Hedeker and Gibbons (1994), Longford (1994), McCulloch (1994), Liu and Pierce (1994), and Diggle, Liang, and Zeger (1994).

Nonlinear mixed models have important applications in pharmacokinetics, and Roe (1997) provides a wide-ranging comparison of many popular techniques. Yuh et al. (1994) provide an extensive bibliography on nonlinear mixed models and their use in pharmacokinetics.

PROC NLMIXED Compared with Other SAS Procedures and Macros

The models fit by PROC NLMIXED can be viewed as generalizations of the random coefficient models fit by the MIXED procedure. This generalization allows the random coefficients to enter the model nonlinearly, whereas in PROC MIXED they enter linearly. With PROC MIXED you can perform both maximum likelihood and restricted maximum likelihood (REML) estimation, whereas PROC NLMIXED only implements maximum likelihood. This is because the analog to the REML method in PROC NLMIXED would involve a high dimensional integral over all of the fixed-effects parameters, and this integral is typically not available in closed form. Finally, PROC MIXED assumes the data to be normally distributed, whereas PROC NLMIXED enables you to analyze data that are normal, binomial, or Poisson or that have any likelihood programmable with SAS statements.

PROC NLMIXED does not implement the same estimation techniques available with the NLINMIX and GLIMMIX macros. These macros are based on the estimation methods of Lindstrom and Bates (1990), Breslow and Clayton (1993), and Wolfinger and O'Connell (1993), and they iteratively fit a set of generalized estimating equations (refer to Chapters 11 and 12 of Littell et al. 1996 and to Wolfinger 1997). In contrast, PROC NLMIXED directly maximizes an approximate integrated likelihood.

This remark also applies to the SAS/IML macros MIXNLIN (Vonesh and Chinchilli 1997) and NLMEM (Galecki 1998).

PROC NLMIXED has close ties with the NLP procedure in SAS/OR software. PROC NLMIXED uses a subset of the optimization code underlying PROC NLP and has many of the same optimization-based options. Also, the programming statement functionality used by PROC NLMIXED is the same as that used by PROC NLP and the MODEL procedure in SAS/ETS software.

Getting Started

Nonlinear Growth Curves with Gaussian Data

As an introductory example, consider the orange tree data of Draper and Smith (1981). These data consist of seven measurements of the trunk circumference (in millimeters) on each of five orange trees. You can input these data into a SAS data set as follows:

```
data tree;
  input tree day y;
  datalines;
1 118 30
1 484 58
1 664 87
1 1004 115
1 1231 120
1 1372 142
1 1582 145
2 118 33
2 484 69
2 664 111
2 1004 156
2 1231 172
2 1372 203
2 1582 203
3 118 30
3 484 51
3 664 75
3 1004 108
3 1231 115
3 1372 139
3 1582 140
4 118 32
4 484 62
4 664 112
4 1004 167
4 1231 179
4 1372 209
4 1582 214
```

```

5 118 30
5 484 49
5 664 81
5 1004 125
5 1231 142
5 1372 174
5 1582 177
;
```

Lindstrom and Bates (1990) and Pinheiro and Bates (1995) propose the following logistic nonlinear mixed model for these data:

$$y_{ij} = \frac{b_1 + u_{i1}}{1 + \exp[-(d_{ij} - b_2)/b_3]} + e_{ij}$$

Here, y_{ij} represents the j th measurement on the i th tree ($i = 1, \dots, 5$; $j = 1, \dots, 7$), d_{ij} is the corresponding day, b_1, b_2, b_3 are the fixed-effects parameters, u_{i1} are the random-effect parameters assumed to be iid $N(0, \sigma_u^2)$, and e_{ij} are the residual errors assumed to be iid $N(0, \sigma_e^2)$ and independent of the u_{i1} . This model has a logistic form, and the random-effect parameters u_{i1} enter the model linearly.

The statements to fit this nonlinear mixed model are as follows:

```

proc nlmixed data=tree;
  parms b1=190 b2=700 b3=350 s2u=1000 s2e=60;
  num = b1+u1;
  ex = exp(-(day-b2)/b3);
  den = 1 + ex;
  model y ~ normal(num/den,s2e);
  random u1 ~ normal(0,s2u) subject=tree;
run;
```

The PROC NLMIXED statement invokes the procedure and inputs the TREE data set. The PARMS statement identifies the unknown parameters and their starting values. Here there are three fixed-effects parameters (B1, B2, B3) and two variance components (S2U, S2E).

The next three statements are SAS programming statements specifying the logistic mixed model. A new variable U1 is included to identify the random effect. These statements are evaluated for every observation in the data set when PROC NLMIXED computes the log likelihood function and its derivatives.

The MODEL statement defines the dependent variable and its conditional distribution given the random effects. Here a normal (Gaussian) conditional distribution is specified with mean NUM/DEN and variance S2E.

The RANDOM statement defines the single random effect to be U1, and specifies that it follows a normal distribution with mean 0 and variance S2U. The SUBJECT= argument defines a variable indicating when the random effect obtains new realizations; in this case, it changes according to the values of the TREE variable. PROC NLMIXED assumes that the input data set is clustered according to the levels of the

TREE variable; that is, all observations from the same tree occur sequentially in the input data set.

The output from this analysis is as follows.

The NLMIXED Procedure	
Specifications	
Data Set	WORK.TREE
Dependent Variable	y
Distribution for Dependent Variable	Normal
Random Effects	u1
Distribution for Random Effects	Normal
Subject Variable	tree
Optimization Technique	Dual Quasi-Newton
Integration Method	Adaptive Gaussian Quadrature

The “Specifications” table lists some basic information about the nonlinear mixed model you have specified. Included are the input data set, dependent and subject variables, random effects, relevant distributions, and type of optimization.

The NLMIXED Procedure	
Dimensions	
Observations Used	35
Observations Not Used	0
Total Observations	35
Subjects	5
Max Obs Per Subject	7
Parameters	5
Quadrature Points	1

The “Dimensions” table lists various counts related to the model, including the number of observations, subjects, and parameters. These quantities are useful for checking that you have specified your data set and model correctly. Also listed is the number of quadrature points that PROC NLMIXED has selected based on the evaluation of the log likelihood at the starting values of the parameters. Here, only one quadrature point is necessary because the random-effect parameters u_{i1} enter the model linearly.

The NLMIXED Procedure					
Parameters					
b1	b2	b3	s2u	s2e	NegLogLike
190	700	350	1000	60	132.491787

The “Parameters” table lists the parameters to be estimated, their starting values, and the negative log likelihood evaluated at the starting values.

The NLMIXED Procedure					
Iteration History					
Iter	Calls	NegLogLike	Diff	MaxGrad	Slope
1	4	131.686742	0.805045	0.010269	-0.633
2	6	131.64466	0.042082	0.014783	-0.0182
3	8	131.614077	0.030583	0.009809	-0.02796
4	10	131.572522	0.041555	0.001186	-0.01344
5	11	131.571895	0.000627	0.0002	-0.00121
6	13	131.571889	5.549E-6	0.000092	-7.68E-6
7	15	131.571888	1.096E-6	6.097E-6	-1.29E-6

NOTE: GCONV convergence criterion satisfied.

The “Iterations” table records the history of the minimization of the negative log likelihood. For each iteration of the quasi-Newton optimization, values are listed for the number of function calls, the value of the negative log likelihood, the difference from the previous iteration, the absolute value of the largest gradient, and the slope of the search direction. The note at the bottom of the table indicates that the algorithm has converged successfully according to the GCONV convergence criterion, a standard criterion computed using a quadratic form in the gradient and inverse Hessian.

The NLMIXED Procedure	
Fit Statistics	
-2 Log Likelihood	263.1
AIC (smaller is better)	273.1
AICC (smaller is better)	275.2
BIC (smaller is better)	271.2

The “Fitting Information” table lists the final maximized value of the log likelihood as well as the information criteria of Akaike and Schwarz in two different forms. These statistics can be used to compare different nonlinear mixed models.

The NL MIXED Procedure							
Parameter Estimates							
Parameter	Estimate	Standard Error	DF	t Value	Pr > t	Alpha	Lower
b1	192.05	15.6473	4	12.27	0.0003	0.05	148.61
b2	727.90	35.2472	4	20.65	<.0001	0.05	630.04
b3	348.07	27.0790	4	12.85	0.0002	0.05	272.88
s2u	999.88	647.44	4	1.54	0.1974	0.05	-797.70
s2e	61.5139	15.8831	4	3.87	0.0179	0.05	17.4153

Parameter Estimates			
Parameter	Upper	Gradient	
b1	235.50	1.154E-6	
b2	825.76	5.289E-6	
b3	423.25	-6.1E-6	
s2u	2797.45	-3.84E-6	
s2e	105.61	2.892E-6	

The “Parameter Estimates” table lists the maximum likelihood estimates of the five parameters and their approximate standard errors computed using the final Hessian matrix. Approximate *t*-values and Wald-type confidence limits are also provided, with degrees of freedom equal to the number of subjects minus the number of random effects. You should interpret these statistics cautiously for variance parameters like S2U and S2E. The final column in the output is the gradient vector at the optimization solution. Each element appears to be sufficiently small to indicate a stationary point.

Since the random-effect parameters u_{i1} enter the model linearly, you can obtain equivalent results by using the first-order method (specify METHOD=FIRO in the PROC NL MIXED statement).

Logistic-Normal Model with Binomial Data

This example analyzes the data from Beitler and Landis (1985), which represent results from a multi-center clinical trial investigating the effectiveness of two topical cream treatments (active drug, control) in curing an infection. For each of eight clinics, the number of trials and favorable cures are recorded for each treatment. The SAS data set is as follows.

```

data infection;
  input clinic t x n;
  datalines;
1 1 11 36
1 0 10 37
2 1 16 20
2 0 22 32
3 1 14 19
3 0 7 19
4 1 2 16

```

```

4 0 1 17
5 1 6 17
5 0 0 12
6 1 1 11
6 0 0 10
7 1 1 5
7 0 1 9
8 1 4 6
8 0 6 7
run;

```

Suppose n_{ij} denotes the number of trials for the i th clinic and the j th treatment ($i = 1, \dots, 8$ $j = 0, 1$), and x_{ij} denotes the corresponding number of favorable cures. Then a reasonable model for the preceding data is the following logistic model with random effects:

$$x_{ij}|u_i \sim \text{Binomial}(n_{ij}, p_{ij})$$

and

$$\eta_{ij} = \log \left(\frac{p_{ij}}{(1 - p_{ij})} \right) = \beta_0 + \beta_1 t_j + u_i$$

The notation t_j indicates the j th treatment, and the u_i are assumed to be iid $N(0, \sigma_u^2)$.

The PROC NLMIXED statements to fit this model are as follows:

```

proc nlmixed data=infection;
  parms beta0=-1 beta1=1 s2u=2;
  eta = beta0 + beta1*t + u;
  expeta = exp(eta);
  p = expeta/(1+expeta);
  model x ~ binomial(n,p);
  random u ~ normal(0,s2u) subject=clinic;
  predict eta out=eta;
  estimate '1/beta1' 1/beta1;
run;

```

The PROC NLMIXED statement invokes the procedure, and the PARMS statement defines the parameters and their starting values. The next three statements define p_{ij} , and the MODEL statement defines the conditional distribution of x_{ij} to be binomial. The RANDOM statement defines U to be the random effect with subjects defined by the CLINIC variable.

The PREDICT statement constructs predictions for each observation in the input data set. For this example, predictions of η_{ij} and approximate standard errors of prediction are output to a SAS data set named ETA. These predictions include empirical Bayes estimates of the random effects u_i .

The ESTIMATE statement requests an estimate of the reciprocal of β_1 .

The output for this model is as follows.

The NLMIXED Procedure	
Specifications	
Data Set	WORK.INFECTION
Dependent Variable	x
Distribution for Dependent Variable	Binomial
Random Effects	u
Distribution for Random Effects	Normal
Subject Variable	clinic
Optimization Technique	Dual Quasi-Newton
Integration Method	Adaptive Gaussian Quadrature

The “Specifications” table provides basic information about the nonlinear mixed model.

The NLMIXED Procedure	
Dimensions	
Observations Used	16
Observations Not Used	0
Total Observations	16
Subjects	8
Max Obs Per Subject	2
Parameters	3
Quadrature Points	5

The “Dimensions” table provides counts of various variables. You should check this table to make sure the data set and model have been entered properly. PROC NLMIXED selects five quadrature points to achieve the default accuracy in the likelihood calculations.

The NLMIXED Procedure			
Parameters			
beta0	beta1	s2u	NegLogLike
-1	1	2	37.5945925

The “Parameters” table lists the starting point of the optimization.

The NLMIXED Procedure					
Iteration History					
Iter	Calls	NegLogLike	Diff	MaxGrad	Slope
1	2	37.3622692	0.232323	2.882077	-19.3762
2	3	37.1460375	0.216232	0.921926	-0.82852
3	5	37.0300936	0.115944	0.315897	-0.59175
4	6	37.0223017	0.007792	0.01906	-0.01615
5	7	37.0222472	0.000054	0.001743	-0.00011
6	9	37.0222466	6.57E-7	0.000091	-1.28E-6
7	11	37.0222466	5.38E-10	2.078E-6	-1.1E-9

NOTE: GCONV convergence criterion satisfied.

The “Iterations” table indicates successful convergence in seven iterations.

The NLMIXED Procedure	
Fit Statistics	
-2 Log Likelihood	74.0
AIC (smaller is better)	80.0
AICC (smaller is better)	82.0
BIC (smaller is better)	80.3

The “Fitting Information” table lists some useful statistics based on the maximized value of the log likelihood.

The NLMIXED Procedure							
Parameter Estimates							
Parameter	Estimate	Standard Error	DF	t Value	Pr > t	Alpha	Lower
beta0	-1.1974	0.5561	7	-2.15	0.0683	0.05	-2.5123
beta1	0.7385	0.3004	7	2.46	0.0436	0.05	0.02806
s2u	1.9591	1.1903	7	1.65	0.1438	0.05	-0.8554

Parameter Estimates		
Parameter	Upper	Gradient
beta0	0.1175	-3.1E-7
beta1	1.4488	-2.08E-6
s2u	4.7736	-2.48E-7

The “Parameter Estimates” table indicates marginal significance of the two fixed-effects parameters. The positive value of the estimate of β_1 indicates that the treatment significantly increases the chance of a favorable cure.

The NL MIXED Procedure								
Additional Estimates								
Label	Estimate	Standard Error	DF	t Value	Pr > t	Alpha	Lower	Upper
1/beta1	1.3542	0.5509	7	2.46	0.0436	0.05	0.05146	2.6569

The “Additional Estimates” table displays results from the ESTIMATE statement. The estimate of $1/\beta_1$ equals $1/0.7385 = 1.3541$ and its standard error equals $0.3004/0.7385^2 = 0.5509$ by the delta method (Billingsley 1986, Cox 1998). Note this particular approximation produces a t -statistic identical to that for the estimate of β_1 .

Not shown is the ETA data set, which contains the original 16 observations and predictions of the η_{ij} .

Syntax

The following statements can be used with the NL MIXED procedure:

```

PROC NL MIXED options ;
  ARRAY array specification ;
  BOUNDS boundary constraints ;
  BY variables ;
  CONTRAST 'label' expression <,expression> ;
  ESTIMATE 'label' expression ;
  ID names ;
  MODEL model specification ;
  PARMS parameters and starting values ;
  PREDICT expression ;
  RANDOM random effects specification ;
  REPLICATE variable ;
Program statements ;

```

The following sections provide a detailed description of each of these statements.

PROC NLMIXED Statement

PROC NLMIXED *options* ;

This statement invokes the NLMIXED procedure. A large number of options are available in the PROC NLMIXED statement, and the following table categorizes them according to function.

Table 51.1. PROC NLMIXED statement options

Option	Description
Basic Options	
DATA=	input data set
METHOD=	integration method
Displayed Output Specifications	
START	gradient at starting values
HESS	Hessian matrix
ITDETAILS	iteration details
CORR	correlation matrix
COV	covariance matrix
ECORR	corr matrix of additional estimates
ECOV	cov matrix of additional estimates
EDER	derivatives of additional estimates
ALPHA=	alpha for confidence limits
DF=	degrees of freedom for <i>p</i> values and confidence limits
Debugging Output	
LIST	model program, variables
LISTCODE	compiled model program
LISTDEP	model dependency listing
LISTDER	model derivative
XREF	model cross reference
FLOW	model execution messages
TRACE	detailed model execution messages
Quadrature Options	
NOAD	no adaptive centering
NOADSCALE	no adaptive scaling
OUTQ=	output data set
QFAC=	search factor
QMAX=	maximum points
QPOINTS=	number of points
QSCALEFAC=	scale factor
QTOL=	tolerance
Empirical Bayes Options	
EBSTEPS=	number of Newton steps
EBSUBSTEPS=	number of substeps
EBSSFRAC=	step-shortening fraction
EBSSTOL=	step-shortening tolerance
EBTOL=	convergence tolerance
EBOPT	comprehensive optimization

Table 51.1. (continued)

Option	Description
EBZSTART	zero starting values
Optimization Specifications	
TECHNIQUE=	minimization technique
UPDATE=	update technique
LINESEARCH=	line-search method
LSPRECISION=	line-search precision
HESCAL=	type of Hessian scaling
INHESIAN<=>	start for approximated Hessian
RESTART=	iteration number for update restart
OPTCHECK<=>	check optimality in neighborhood
Derivatives Specifications	
FD<=>	finite-difference derivatives
FDHESSIAN<=>	finite-difference second derivatives
DIAHES	use only diagonal of Hessian
Constraint Specifications	
LCEPSILON=	range for active constraints
LCDEACT=	LM tolerance for deactivating
LCSINGULAR=	tolerance for dependent constraints
Termination Criteria Specifications	
MAXFUNC=	maximum number of function calls
MAXITER=	maximum number of iterations
MINITER=	minimum number of iterations
MAXTIME=	upper limit seconds of CPU time
ABSCONV=	absolute function convergence criterion
ABSFCNV=	absolute function convergence criterion
ABSGCONV=	absolute gradient convergence criterion
ABSXCONV=	absolute parameter convergence criterion
FCONV=	relative function convergence criterion
FCONV2=	relative function convergence criterion
GCONV=	relative gradient convergence criterion
XCONV=	relative parameter convergence criterion
FDIGITS=	number accurate digits in objective function
FSIZE=	used in FCONV, GCONV criterion
XSIZE=	used in XCONV criterion
Step Length Specifications	
DAMPSTEP<=>	damped steps in line search
MAXSTEP=	maximum trust-region radius
INSTEP=	initial trust-region radius
Singularity Tolerances	
SINGCHOL=	tolerance for Cholesky roots
SINGHESS=	tolerance for Hessian
SINGSWEEP=	tolerance for sweep
SINGVAR=	tolerance for variances

Table 51.1. (continued)

Option	Description
Covariance Matrix Tolerances	
ASINGULAR=	absolute singularity for inertia
MSINGULAR=	relative M singularity for inertia
VSINGULAR=	relative V singularity for inertia
G4=	threshold for Moore-Penrose inverse
COVSING=	tolerance for singular COV matrix
CFACTOR=	multiplication factor for COV matrix

These options are described in alphabetical order. For a description of the mathematical notation used in the following sections, see the section “Modeling Assumptions and Notation.”

ABSCONV= r

ABSTOL= r

specifies an absolute function convergence criterion. For minimization, termination requires $f(\theta^{(k)}) \leq r$. The default value of r is the negative square root of the largest double precision value, which serves only as a protection against overflows.

ABSFCONV= $r < [n] >$

ABSFTOL= $r < [n] >$

specifies an absolute function convergence criterion. For all techniques except NMSIMP, termination requires a small change of the function value in successive iterations:

$$|f(\theta^{(k-1)}) - f(\theta^{(k)})| \leq r$$

The same formula is used for the NMSIMP technique, but $\theta^{(k)}$ is defined as the vertex with the lowest function value, and $\theta^{(k-1)}$ is defined as the vertex with the highest function value in the simplex. The default value is $r = 0$. The optional integer value n specifies the number of successive iterations for which the criterion must be satisfied before the process can be terminated.

ABSGCONV= $r < [n] >$

ABSGTOL= $r < [n] >$

specifies an absolute gradient convergence criterion. Termination requires the maximum absolute gradient element to be small:

$$\max_j |g_j(\theta^{(k)})| \leq r$$

This criterion is not used by the NMSIMP technique. The default value is $r = 1\text{E}-5$. The optional integer value n specifies the number of successive iterations for which the criterion must be satisfied before the process can be terminated.

ABSXCONV= $r < [n] >$

ABSXTOL= $r < [n] >$

specifies an absolute parameter convergence criterion. For all techniques except NMSIMP, termination requires a small Euclidean distance between successive parameter vectors,

$$\|\theta^{(k)} - \theta^{(k-1)}\|_2 \leq r$$

For the NMSIMP technique, termination requires either a small length $\alpha^{(k)}$ of the vertices of a restart simplex,

$$\alpha^{(k)} \leq r$$

or a small simplex size,

$$\delta^{(k)} \leq r$$

where the simplex size $\delta^{(k)}$ is defined as the L1 distance from the simplex vertex $\xi^{(k)}$ with the smallest function value to the other n simplex points $\theta_l^{(k)} \neq \xi^{(k)}$:

$$\delta^{(k)} = \sum_{\theta_l \neq y} \|\theta_l^{(k)} - \xi^{(k)}\|_1$$

The default is $r = 1\text{E} - 8$ for the NMSIMP technique and $r = 0$ otherwise. The optional integer value n specifies the number of successive iterations for which the criterion must be satisfied before the process can terminate.

ALPHA= α

specifies the alpha level to be used in computing confidence limits. The default value is 0.05.

ASINGULAR= r

ASING= r

specifies an absolute singularity criterion for the computation of the inertia (number of positive, negative, and zero eigenvalues) of the Hessian and its projected forms. The default value is the square root of the smallest positive double precision value.

CFACTOR= f

specifies a multiplication factor f for the estimated covariance matrix of the parameter estimates.

COV

requests the approximate covariance matrix for the parameter estimates.

CORR

requests the approximate correlation matrix for the parameter estimates.

COVSING= $r > 0$

specifies a nonnegative threshold that determines whether the eigenvalues of a singular Hessian matrix are considered to be zero.

DAMPSTEP $\leq r >$

DS $\leq r >$

specifies that the initial step-size value $\alpha^{(0)}$ for each line search (used by the QUANEW, CONGRA, or NEWRAP technique) cannot be larger than r times the step-size value used in the former iteration. If you specify the DAMPSTEP option without factor r , the default value is $r = 2$. The DAMPSTEP= r option can prevent the line-search algorithm from repeatedly stepping into regions where some objective functions are difficult to compute or where they could lead to floating point overflows during the computation of objective functions and their derivatives. The DAMPSTEP= r option can save time-costly function calls that result in very small

step sizes α . For more details on setting the start values of each line search, see the section “Restricting the Step Length” beginning on page 3096.

DATA=SAS-data-set

specifies the input data set. Observations in this data set are used to compute the log likelihood function that you specify with PROC NLMIXED statements.

NOTE: If you are using a RANDOM statement, the input data set must be clustered according to the SUBJECT= variable. One easy way to accomplish this is to sort your data by the SUBJECT= variable prior to calling PROC NLMIXED. PROC NLMIXED does not sort the input data set for you.

DF=d

specifies the degrees of freedom to be used in computing p values and confidence limits. The default value is the number of subjects minus the number of random effects for random effects models, and the number of observations otherwise.

DIAHES

specifies that only the diagonal of the Hessian is used.

EBOPT

requests that a more comprehensive optimization be carried out if the default empirical Bayes optimization fails to converge.

EBSSFRAC=r > 0

specifies the step-shortening fraction to be used while computing empirical Bayes estimates of the random effects. The default value is 0.8.

EBSTOL=r ≥ 0

specifies the objective function tolerance for determining the cessation of step-shortening while computing empirical Bayes estimates of the random effects. The default value is $r = 1\text{E} - 8$.

EBSTEPS=n ≥ 0

specifies the maximum number of Newton steps for computing empirical Bayes estimates of random effects. The default value is $n = 50$.

EBSUBSTEPS=n ≥ 0

specifies the maximum number of step-shortenings for computing empirical Bayes estimates of random effects. The default value is $n = 20$.

EBTOL=r ≥ 0

specifies the convergence tolerance for empirical Bayes estimation. The default value is $r = \epsilon\text{E}4$, where ϵ is the machine precision. This default value equals approximately $1\text{E} - 12$ on most machines.

EBZSTART

requests that a zero be used as starting values during empirical Bayes estimation. By default, the starting values are set equal to the estimates from the previous iteration (or zero for the first iteration).

ECOV

requests the approximate covariance matrix for all expressions specified in ESTIMATE statements.

ECORR

requests the approximate correlation matrix for all expressions specified in ESTIMATE statements.

EDER

requests the derivatives of all expressions specified in ESTIMATE statements with respect to each of the model parameters.

FCONV= $r < [n] >$

FTOL= $r < [n] >$

specifies a relative function convergence criterion. For all techniques except NMSIMP, termination requires a small relative change of the function value in successive iterations,

$$\frac{|f(\theta^{(k)}) - f(\theta^{(k-1)})|}{\max(|f(\theta^{(k-1)})|, \text{FSIZE})} \leq r$$

where FSIZE is defined by the FSIZE= option. The same formula is used for the NMSIMP technique, but $\theta^{(k)}$ is defined as the vertex with the lowest function value, and $\theta^{(k-1)}$ is defined as the vertex with the highest function value in the simplex. The default is $r=10^{-\text{FDIGITS}}$ where FDIGITS is the value of the FDIGITS= option. The optional integer value n specifies the number of successive iterations for which the criterion must be satisfied before the process can terminate.

FCONV2= $r < [n] >$

FTOL2= $r < [n] >$

specifies another function convergence criterion. For all techniques except NMSIMP, termination requires a small predicted reduction

$$df^{(k)} \approx f(\theta^{(k)}) - f(\theta^{(k)} + s^{(k)})$$

of the objective function. The predicted reduction

$$\begin{aligned} df^{(k)} &= -g^{(k)T} s^{(k)} - \frac{1}{2} s^{(k)T} H^{(k)} s^{(k)} \\ &= -\frac{1}{2} s^{(k)T} g^{(k)} \\ &\leq r \end{aligned}$$

is computed by approximating the objective function f by the first two terms of the Taylor series and substituting the Newton step.

$$s^{(k)} = -[H^{(k)}]^{-1} g^{(k)}$$

For the NMSIMP technique, termination requires a small standard deviation of the function values of the $n + 1$ simplex vertices $\theta_l^{(k)}$, $l = 0, \dots, n$,

$$\sqrt{\frac{1}{n+1} \sum_l [f(\theta_l^{(k)}) - \bar{f}(\theta^{(k)})]^2} \leq r$$

where $\bar{f}(\theta^{(k)}) = \frac{1}{n+1} \sum_l f(\theta_l^{(k)})$. If there are n_{act} boundary constraints active at $\theta^{(k)}$, the mean and standard deviation are computed only for the $n + 1 - n_{act}$ unconstrained vertices. The default value is $r = 1E - 6$ for the NMSIMP technique and $r = 0$ otherwise. The optional integer value n specifies the number of successive iterations for which the criterion must be satisfied before the process can terminate.

FD<=FORWARD | CENTRAL |r >

specifies that all derivatives be computed using finite difference approximations. The following specifications are permitted:

FD is equivalent to FD=100.

FD=CENTRAL uses central differences.

FD=FORWARD uses forward differences.

FD=r uses central differences for the initial and final evaluations of the gradient, and Hessian. During iteration, start with forward differences and switch to a corresponding central-difference formula during the iteration process when one of the following two criteria is satisfied:

- The absolute maximum gradient element is less than or equal to r times the ABSGTOL threshold.
- The normalized predicted function reduction (see the GTOL option on page 3065) is less than or equal to $\max(1E - 6, r * GTOL)$. The $1E - 6$ ensures that the switch is done, even if you set the GTOL threshold to zero.

Note that the FD and FDHESSIAN options cannot apply at the same time. The FDHESSIAN option is ignored when only first-order derivatives are used. See the section [“Finite Difference Approximations of Derivatives”](#) beginning on page 3091 for more information.

FDHESSIAN<=FORWARD | CENTRAL>

FDHES<=FORWARD | CENTRAL>

FDH<=FORWARD | CENTRAL>

specifies that second-order derivatives be computed using finite difference approximations based on evaluations of the gradients.

FDHESSIAN=FORWARD uses forward differences.

FDHESSIAN=CENTRAL uses central differences.

FDHESSIAN uses forward differences for the Hessian except for the initial and final output.

Note that the FD and FDHESSIAN options cannot apply at the same time. See the section [“Finite Difference Approximations of Derivatives”](#) beginning on page 3091 for more information.

FDIGITS=*r*

specifies the number of accurate digits in evaluations of the objective function. Fractional values such as FDIGITS=4.7 are allowed. The default value is $r = -\log_{10} \epsilon$, where ϵ is the machine precision. The value of r is used to compute the interval size h for the computation of finite-difference approximations of the derivatives of the objective function and for the default value of the FCONV= option.

FLOW

displays a message for each statement in the model program as it is executed. This debugging option is very rarely needed and produces voluminous output.

FSIZE=*r*

specifies the FSIZE parameter of the relative function and relative gradient termination criteria. The default value is $r = 0$. For more details, see the FCONV= and GCONV= options.

G4=*n* > 0

specifies a dimension to determine the type of generalized inverse to use when the approximate covariance matrix of the parameter estimates is singular. The default value of n is 60. See the section “Covariance Matrix” beginning on page 3101 for more information.

GCONV=*r* < [*n*] >**GTOL=*r* < [*n*] >**

specifies a relative gradient convergence criterion. For all techniques except CONGRA and NMSIMP, termination requires that the normalized predicted function reduction is small,

$$\frac{g(\theta^{(k)})^T [H^{(k)}]^{-1} g(\theta^{(k)})}{\max(|f(\theta^{(k)})|, \text{FSIZE})} \leq r$$

where FSIZE is defined by the FSIZE= option. For the CONGRA technique (where a reliable Hessian estimate H is not available), the following criterion is used:

$$\frac{\|g(\theta^{(k)})\|_2^2 \|s(\theta^{(k)})\|_2}{\|g(\theta^{(k)}) - g(\theta^{(k-1)})\|_2 \max(|f(\theta^{(k)})|, \text{FSIZE})} \leq r$$

This criterion is not used by the NMSIMP technique. The default value is $r = 1E - 8$. The optional integer value n specifies the number of successive iterations for which the criterion must be satisfied before the process can terminate.

HESCAL=0|1|2|3**HS=0|1|2|3**

specifies the scaling version of the Hessian matrix used in NRRIDG, TRUREG, NEWRAP, or DBLDOG optimization. If HS is not equal to 0, the first iteration and each restart iteration sets the diagonal scaling matrix $D^{(0)} = \text{diag}(d_i^{(0)})$:

$$d_i^{(0)} = \sqrt{\max(|H_{i,i}^{(0)}|, \epsilon)}$$

where $H_{i,i}^{(0)}$ are the diagonal elements of the Hessian. In every other iteration, the diagonal scaling matrix $D^{(0)} = \text{diag}(d_i^{(0)})$ is updated depending on the HS option:

HS=0 specifies that no scaling is done.

HS=1 specifies the Moré (1978) scaling update:

$$d_i^{(k+1)} = \max \left[d_i^{(k)}, \sqrt{\max(|H_{i,i}^{(k)}|, \epsilon)} \right]$$

HS=2 specifies the Dennis, Gay, & Welsch (1981) scaling update:

$$d_i^{(k+1)} = \max \left[0.6 * d_i^{(k)}, \sqrt{\max(|H_{i,i}^{(k)}|, \epsilon)} \right]$$

HS=3 specifies that d_i is reset in each iteration:

$$d_i^{(k+1)} = \sqrt{\max(|H_{i,i}^{(k)}|, \epsilon)}$$

In each scaling update, ϵ is the relative machine precision. The default value is HS=0. Scaling of the Hessian can be time consuming in the case where general linear constraints are active.

HESS

requests the display of the final Hessian matrix after optimization. If you also specify the START option, then the Hessian at the starting values is also printed.

INHESSIAN<=*r*>

INHESS<=*r*>

specifies how the initial estimate of the approximate Hessian is defined for the quasi-Newton techniques QUANEW and DBLDOG. There are two alternatives:

- If you do not use the r specification, the initial estimate of the approximate Hessian is set to the Hessian at $\theta^{(0)}$.
- If you do use the r specification, the initial estimate of the approximate Hessian is set to the multiple of the identity matrix rI .

By default, if you do not specify the option INHESSIAN= r , the initial estimate of the approximate Hessian is set to the multiple of the identity matrix rI , where the scalar r is computed from the magnitude of the initial gradient.

INSTEP= r

reduces the length of the first trial step during the line search of the first iterations. For highly nonlinear objective functions, such as the EXP function, the default initial radius of the trust-region algorithm TRUREG or DBLDOG or the default step length of the line-search algorithms can result in arithmetic overflows. If this occurs, you should specify decreasing values of $0 < r < 1$ such as INSTEP=1E - 1, INSTEP=1E - 2, INSTEP=1E - 4, and so on, until the iteration starts successfully.

- For trust-region algorithms (TRUREG, DBLDOG), the INSTEP= option specifies a factor $r > 0$ for the initial radius $\Delta^{(0)}$ of the trust region. The default initial trust-region radius is the length of the scaled gradient. This step corresponds to the default radius factor of $r = 1$.

- For line-search algorithms (NEWRAP, CONGRA, QUANEW), the INSTEP= option specifies an upper bound for the initial step length for the line search during the first five iterations. The default initial step length is $r = 1$.
- For the Nelder-Mead simplex algorithm, using TECH=NMSIMP, the INSTEP= r option defines the size of the start simplex.

For more details, see the section “[Computational Problems](#)” beginning on page 3098.

ITDETAILS

requests a more complete iteration history, including the current values of the parameter estimates, their gradients, and additional optimization statistics. For further details, see the section “[Iterations](#)” beginning on page 3104.

LCDEACT= r

LCD= r

specifies a threshold r for the Lagrange multiplier that determines whether an active inequality constraint remains active or can be deactivated. During minimization, an active inequality constraint can be deactivated only if its Lagrange multiplier is less than the threshold value $r < 0$. The default value is

$$r = -\min(0.01, \max(0.1 * \text{ABSGCONV}, 0.001 * \text{gmax}^{(k)}))$$

where ABSGCONV is the value of the absolute gradient criterion, and $\text{gmax}^{(k)}$ is the maximum absolute element of the (projected) gradient $g^{(k)}$ or $Z^T g^{(k)}$. (See the section “[Active Set Methods](#)” beginning on page 3093 for a definition of Z .)

LCEPSILON= $r > 0$

LCEPS= $r > 0$

LCE= $r > 0$

specifies the range for active and violated boundary constraints. The default value is $r = 1\text{E} - 8$. During the optimization process, the introduction of rounding errors can force PROC NL MIXED to increase the value of r by a factor of 10, 100, If this happens, it is indicated by a message displayed in the log.

LCSINGULAR= $r > 0$

LCSING= $r > 0$

LCS= $r > 0$

specifies a criterion r , used in the update of the QR decomposition, that determines whether an active constraint is linearly dependent on a set of other active constraints. The default value is $r = 1\text{E} - 8$. The larger r becomes, the more the active constraints are recognized as being linearly dependent. If the value of r is larger than 0.1, it is reset to 0.1.

LINESEARCH= i

LIS= i

specifies the line-search method for the CONGRA, QUANEW, and NEWRAP optimization techniques. Refer to Fletcher (1987) for an introduction to line-search techniques. The value of i can be 1, . . . , 8. For CONGRA, QUANEW and NEWRAP, the default value is $i = 2$.

LIS=1	specifies a line-search method that needs the same number of function and gradient calls for cubic interpolation and cubic extrapolation; this method is similar to one used by the Harwell subroutine library.
LIS=2	specifies a line-search method that needs more function than gradient calls for quadratic and cubic interpolation and cubic extrapolation; this method is implemented as shown in Fletcher (1987) and can be modified to an exact line search by using the LSPRECISION= option.
LIS=3	specifies a line-search method that needs the same number of function and gradient calls for cubic interpolation and cubic extrapolation; this method is implemented as shown in Fletcher (1987) and can be modified to an exact line search by using the LSPRECISION= option.
LIS=4	specifies a line-search method that needs the same number of function and gradient calls for stepwise extrapolation and cubic interpolation.
LIS=5	specifies a line-search method that is a modified version of LIS=4.
LIS=6	specifies golden section line search (Polak 1971), which uses only function values for linear approximation.
LIS=7	specifies bisection line search (Polak 1971), which uses only function values for linear approximation.
LIS=8	specifies the Armijo line-search technique (Polak 1971), which uses only function values for linear approximation.

LIST

displays the model program and variable lists. The LIST option is a debugging feature and is not normally needed.

LISTCODE

displays the derivative tables and the compiled program code. The LISTCODE option is a debugging feature and is not normally needed.

LOGNOTE<=*n*>

writes periodic notes to the log describing the current status of computations. It is designed for use with analyses requiring extensive CPU resources. The optional integer value *n* specifies the desired level of reporting detail. The default is *n* = 1. Choosing *n* = 2 adds information about the objective function values at the end of each iteration. The most detail is obtained with *n* = 3, which also reports the results of function evaluations within iterations.

LSPRECISION=*r***LSP**=*r*

specifies the degree of accuracy that should be obtained by the line-search algorithms LIS=2 and LIS=3. Usually an imprecise line search is inexpensive and successful. For more difficult optimization problems, a more precise and expensive line search may be necessary (Fletcher 1987). The second line-search method (which is the

default for the NEWRAP, QUANEW, and CONGRA techniques) and the third line-search method approach exact line search for small LSPRECISION= values. If you have numerical problems, you should try to decrease the LSPRECISION= value to obtain a more precise line search. The default values are shown in the following table.

TECH=	UPDATE=	LSP default
QUANEW	DBFGS, BFGS	$r = 0.4$
QUANEW	DDFP, DFP	$r = 0.06$
CONGRA	all	$r = 0.1$
NEWRAP	no update	$r = 0.9$

For more details, refer to Fletcher (1987).

MAXFUNC=*i*

MAXFU=*i*

specifies the maximum number *i* of function calls in the optimization process. The default values are

- TRUREG, NRRIDG, NEWRAP: 125
- QUANEW, DBLDOG: 500
- CONGRA: 1000
- NMSIMP: 3000

Note that the optimization can terminate only after completing a full iteration. Therefore, the number of function calls that is actually performed can exceed the number that is specified by the MAXFUNC= option.

MAXITER=*i*

MAXIT=*i*

specifies the maximum number *i* of iterations in the optimization process. The default values are

- TRUREG, NRRIDG, NEWRAP: 50
- QUANEW, DBLDOG: 200
- CONGRA: 400
- NMSIMP: 1000

These default values are also valid when *i* is specified as a missing value.

MAXSTEP=*r* < [*n*] >

specifies an upper bound for the step length of the line-search algorithms during the first *n* iterations. By default, *r* is the largest double precision value and *n* is the largest integer available. Setting this option can improve the speed of convergence for the CONGRA, QUANEW, and NEWRAP techniques.

MAXTIME=*r*

specifies an upper limit of *r* seconds of CPU time for the optimization process. The default value is the largest floating point double representation of your computer. Note that the time specified by the MAXTIME= option is checked only once at the end of each iteration. Therefore, the actual running time can be much longer than that specified by the MAXTIME= option. The actual running time includes the rest of the time needed to finish the iteration and the time needed to generate the output of the results.

METHOD=*value*

specifies the method for approximating the integral of the likelihood over the random effects. Valid values are as follows.

- **FIRO**
specifies the first-order method of Beal and Sheiner (1982). When using METHOD=FIRO, you must specify the NORMAL distribution in the MODEL statement and you must also specify a RANDOM statement.
- **GAUSS**
specifies adaptive Gauss-Hermite quadrature (Pinheiro and Bates 1995). You can prevent the adaptation with the NOAD option or prevent adaptive scaling with the NOADSCALE option. This is the default integration method.
- **HARDY**
specifies Hardy quadrature based on an adaptive trapezoidal rule. This method is available only for one-dimensional integrals; that is, you must specify only one random effect.
- **ISAMP**
specifies adaptive importance sampling (Pinheiro and Bates 1995). You can prevent the adaptation with the NOAD option or prevent adaptive scaling with the NOADSCALE option. You can use the SEED= option to specify a starting seed for the random number generation used in the importance sampling. If you do not specify a seed, or specify a value less than or equal to zero, the seed is generated from reading the time of day from the computer clock.

MINITER=*i***MINIT=*i***

specifies the minimum number of iterations. The default value is 0. If you request more iterations than are actually needed for convergence to a stationary point, the optimization algorithms can behave strangely. For example, the effect of rounding errors can prevent the algorithm from continuing for the required number of iterations.

MSINGULAR=*r* > 0**MSING=*r* > 0**

specifies a relative singularity criterion for the computation of the inertia (number of positive, negative, and zero eigenvalues) of the Hessian and its projected forms. The default value is $1E - 12$ if you do not specify the SINGHESS= option; otherwise, the default value is $\max(10\epsilon, (1E - 4) * SINGHESS)$. See the section “[Covariance Matrix](#)” beginning on page 3101 for more information.

NOAD

requests that the Gaussian quadrature be nonadaptive; that is, the quadrature points are centered at zero for each of the random effects and the current random-effects variance matrix is used as the scale matrix.

NOADSCALE

requests nonadaptive scaling for adaptive Gaussian quadrature; that is, the quadrature points are centered at the empirical Bayes estimates for the random effects, but the current random-effects variance matrix is used as the scale matrix. By default, the observed Hessian from the current empirical Bayes estimates is used as the scale matrix.

OPTCHECK $\langle =r > 0 \rangle$

computes the function values $f(\theta_l)$ of a grid of points θ_l in a ball of radius of r about θ^* . If you specify the OPTCHECK option without factor r , the default value is $r = 0.1$ at the starting point and $r = 0.01$ at the terminating point. If a point θ_l^* is found with a better function value than $f(\theta^*)$, then optimization is restarted at θ_l^* .

OUTQ=SAS-data-set

specifies an output data set containing the quadrature points used for numerical integration.

QFAC= $r > 0$

specifies the additive factor used to adaptively search for the number of quadrature points. For METHOD=GAUSS, the search sequence is 1, 3, 5, 7, 9, 11, $11 + r$, $11 + 2r$, . . . , where the default value of r is 10. For METHOD=ISAMP, the search sequence is 10, $10 + r$, $10 + 2r$, . . . , where the default value of r is 50.

QMAX= $r > 0$

specifies the maximum number of quadrature points permitted before the adaptive search is aborted. The default values are 31 for adaptive Gaussian quadrature, 61 for non-adaptive Gaussian quadrature, 160 for adaptive importance sampling, and 310 for non-adaptive importance sampling.

QPOINTS= $n > 0$

specifies the number of quadrature points to be used during evaluation of integrals. For METHOD=GAUSS, n equals the number of points used in each dimension of the random effects, resulting in a total of n^r points, where r is the number of dimensions. For METHOD=ISAMP, n specifies the total number of quadrature points regardless of the dimension of the random effects. By default, the number of quadrature points is selected adaptively, and this option disables the adaptive search.

QSCALEFAC= $r > 0$

specifies a multiplier for the scale matrix used during quadrature calculations. The default value is 1.0.

QTOL= $r > 0$

specifies the tolerance used to adaptively select the number of quadrature points. When the relative difference between two successive likelihood calculations is less than r , then the search terminates and the lesser number of quadrature points is used during the subsequent optimization process. The default value is $1E - 4$.

RESTART= $i > 0$ **REST= $i > 0$**

specifies that the QUANEW or CONGRA algorithm is restarted with a steepest descent/ascent search direction after, at most, i iterations. Default values are

- CONGRA: UPDATE=PB: restart is performed automatically, i is not used.
- CONGRA: UPDATE \neq PB: $i = \min(10n, 80)$, where n is the number of parameters.
- QUANEW: i is the largest integer available.

SEED= i

specifies the random number seed for METHOD=ISAMP. If you do not specify a seed, or specify a value less than or equal to zero, the seed is generated from reading the time of day from the computer clock. The value must be less than $2^{31} - 1$.

SINGCHOL= $r > 0$

specifies the singularity criterion r for Cholesky roots of the random-effects variance matrix and scale matrix for adaptive Gaussian quadrature. The default value is 1E4 times the machine epsilon; this product is approximately 1E – 12 on most computers.

SINGHESS= $r > 0$

specifies the singularity criterion r for the inversion of the Hessian matrix. The default value is 1E – 8. See the ASINGULAR, MSINGULAR=, and VSINGULAR= options for more information.

SINGSWEEP= $r > 0$

specifies the singularity criterion r for inverting the variance matrix in the first-order method and the empirical Bayes Hessian matrix. The default value is 1E4 times the machine epsilon; this product is approximately 1E – 12 on most computers.

SINGVAR= $r > 0$

specifies the singularity criterion r below which statistical variances are considered to equal zero. The default value is 1E4 times the machine epsilon; this product is approximately 1E – 12 on most computers.

START

requests that the gradient of the log likelihood at the starting values be displayed. If you also specify the HESS option, then the starting Hessian is displayed as well.

TECHNIQUE= $value$ **TECH= $value$**

specifies the optimization technique. Valid values are

- CONGRA
performs a conjugate-gradient optimization, which can be more precisely specified with the UPDATE= option and modified with the LINESEARCH= option. When you specify this option, UPDATE=PB by default.

- **DBLDOG**
performs a version of double dogleg optimization, which can be more precisely specified with the UPDATE= option. When you specify this option, UPDATE=DBFGS by default.
- **NMSIMP**
performs a Nelder-Mead simplex optimization.
- **NONE**
does not perform any optimization. This option can be used
 - to perform a grid search without optimization
 - to compute estimates and predictions that cannot be obtained efficiently with any of the optimization techniques
- **NEWRAP**
performs a Newton-Raphson optimization combining a line-search algorithm with ridging. The line-search algorithm LIS=2 is the default method.
- **NRRIDG**
performs a Newton-Raphson optimization with ridging.
- **QUANEW**
performs a quasi-Newton optimization, which can be defined more precisely with the UPDATE= option and modified with the LINESEARCH= option. This is the default estimation method.
- **TRUREG**
performs a trust region optimization.

TRACE

displays the result of each operation in each statement in the model program as it is executed. This debugging option is very rarely needed, and it produces voluminous output.

UPDATE=method**UPD=method**

specifies the update method for the quasi-Newton, double dogleg, or conjugate-gradient optimization technique. Not every update method can be used with each optimizer. See the section “[Optimization Algorithms](#)” beginning on page 3086 for more information.

Valid methods are

- **BFGS**
performs the original Broyden, Fletcher, Goldfarb, and Shanno (BFGS) update of the inverse Hessian matrix.
- **DBFGS**
performs the dual BFGS update of the Cholesky factor of the Hessian matrix. This is the default update method.
- **DDFP**
performs the dual Davidon, Fletcher, and Powell (DFP) update of the Cholesky factor of the Hessian matrix.

- DFP
performs the original DFP update of the inverse Hessian matrix.
- PB
performs the automatic restart update method of Powell (1977) and Beale (1972).
- FR
performs the Fletcher-Reeves update (Fletcher 1987).
- PR
performs the Polak-Ribiere update (Fletcher 1987).
- CD
performs a conjugate-descent update of Fletcher (1987).

VSINGULAR= $r > 0$

VSING= $r > 0$

specifies a relative singularity criterion for the computation of the inertia (number of positive, negative, and zero eigenvalues) of the Hessian and its projected forms. The default value is $r = 1\text{E} - 8$ if the SINGHESS= option is not specified, and it is the value of SINGHESS= option otherwise. See the section “Covariance Matrix” beginning on page 3101 for more information.

XCONV= $r < [n] > R$

XTOL= $r[n]$

specifies the relative parameter convergence criterion. For all techniques except NMSIMP, termination requires a small relative parameter change in subsequent iterations.

$$\frac{\max_j |\theta_j^{(k)} - \theta_j^{(k-1)}|}{\max(|\theta_j^{(k)}|, |\theta_j^{(k-1)}|, \text{XSIZE})} \leq r$$

For the NMSIMP technique, the same formula is used, but $\theta_j^{(k)}$ is defined as the vertex with the lowest function value and $\theta_j^{(k-1)}$ is defined as the vertex with the highest function value in the simplex. The default value is $r = 1\text{E} - 8$ for the NMSIMP technique and $r = 0$ otherwise. The optional integer value n specifies the number of successive iterations for which the criterion must be satisfied before the process can be terminated.

XSIZE= $r > 0$

specifies the XSIZE parameter of the relative parameter termination criterion. The default value is $r = 0$. For more detail, see the XCONV= option.

ARRAY Statement

ARRAY *arrayname* [{ *dimensions* }] [*\$*] [*variables and constants*];

The ARRAY statement is similar to, but not the same as, the ARRAY statement in the SAS DATA step, and it is the same as the ARRAY statements in the NLIN, NLP, and MODEL procedures. The ARRAY statement is used to associate a name (of no more than eight characters) with a list of variables and constants. The array name

is used with subscripts in the program to refer to the array elements. The following statements illustrate this.

```

array r[8] r1-r8;

do i = 1 to 8;
    r[i] = 0;
end;
    
```

The ARRAY statement does not support all the features of the ARRAY statement in the DATA step. It cannot be used to assign initial values to array elements. Implicit indexing of variables cannot be used; all array references must have explicit subscript expressions. Only exact array dimensions are allowed; lower-bound specifications are not supported. A maximum of six dimensions is allowed.

On the other hand, the ARRAY statement does allow both variables and constants to be used as array elements. (Constant array elements cannot have values assigned to them.) Both dimension specification and the list of elements are optional, but at least one must be specified. When the list of elements is not specified or fewer elements than the size of the array are listed, array variables are created by suffixing element numbers to the array name to complete the element list.

BOUNDS Statement

```
BOUNDS b_con [, b_con... ];
```

where *b_con* := number *operator* parameter_list *operator* number
 or *b_con* := number *operator* parameter_list
 or *b_con* := parameter_list *operator* number
 and *operator* := <=, <, >=, or >

Boundary constraints are specified with a BOUNDS statement. One- or two-sided boundary constraints are allowed. The list of boundary constraints are separated by commas. For example,

```

bounds 0 <= a1-a9 x <= 1, -1 <= c2-c5;
bounds b1-b10 y >= 0;
    
```

You can specify more than one BOUNDS statement. If you specify more than one lower (upper) bound for the same parameter, the maximum (minimum) of these is taken.

If the maximum l_j of all lower bounds is larger than the minimum of all upper bounds u_j for the same variable θ_j , the boundary constraint is replaced by $\theta_j := l_j := \min(u_j)$ defined by the minimum of all upper bounds specified for θ_j .

BY Statement

BY *variables* ;

You can use a BY statement with PROC NLMIXED to obtain separate analyses on DATA= data set observations in groups defined by the BY variables. This means that, unless TECH=NONE, an optimization problem is solved for each BY group separately. When a BY statement appears, the procedure expects the input DATA= data set to be sorted in order of the BY variables. If your input data set is not sorted in ascending order, use one of the following alternatives:

- Use the SORT procedure with a similar BY statement to sort the data.
- Use the BY statement option NOTSORTED or DESCENDING in the BY statement for the NLMIXED procedure. As a cautionary note, the NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Use the DATASETS procedure (in Base SAS software) to create an index on the BY variables.

For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

CONTRAST Statement

CONTRAST *'label'* *expression* <, *expression*> <*options*> ;

The CONTRAST statement enables you to conduct a statistical test that several expressions simultaneously equal zero. The expressions are typically contrasts, that is, differences whose expected values equal zero under the hypothesis of interest.

In the CONTRAST statement you must provide a quoted string to identify the contrast and then a list of valid SAS expressions separated by commas. Multiple CONTRAST statements are permitted, and results from all statements are listed in a common table. PROC NLMIXED constructs approximate F tests for each statement using the delta method (Cox 1998) to approximate the variance-covariance matrix of the constituent expressions.

The following option is available in the CONTRAST statement.

DF=*d*

specifies the denominator degrees of freedom to be used in computing p values for the F statistics. The default value corresponds to the DF= option in the PROC NLMIXED statement.

ESTIMATE Statement

ESTIMATE *'label' expression <options>* ;

The ESTIMATE statement enables you to compute an additional estimate that is a function of the parameter values. You must provide a quoted string to identify the estimate and then a valid SAS expression. Multiple ESTIMATE statements are permitted, and results from all statements are listed in a common table. PROC NL MIXED computes approximate standard errors for the estimates using the delta method (Billingsley 1986). It uses these standard errors to compute corresponding t statistics, p -values, and confidence limits.

The ECOV option in the PROC NL MIXED statement produces a table containing the approximate covariance matrix of all of the additional estimates you specify. The ECORR option produces the corresponding correlation matrix. The EDER option produces a table of the derivatives of the additional estimates with respect to each of the model parameters.

The following options are available in the ESTIMATE statement:

ALPHA= α

specifies the alpha level to be used in computing confidence limits. The default value corresponds to the ALPHA= option in the PROC NL MIXED statement.

DF= d

specifies the degrees of freedom to be used in computing p -values and confidence limits. The default value corresponds to the DF= option in the PROC NL MIXED statement.

ID Statement

ID *names* ;

The ID statement identifies additional quantities to be included in the OUT= data set of the PREDICT statement. These can be any symbols you have defined with SAS programming statements.

MODEL Statement

MODEL *dependent-variable ~ distribution* ;

The MODEL statement is the mechanism for specifying the conditional distribution of the data given the random effects. You must specify a single dependent variable from the input data set, a tilde (~), and then a distribution with its parameters. Valid distributions are as follows.

- *normal*(m,v) specifies a normal (Gaussian) distribution with mean m and variance v .
- *binary*(p) specifies a binary (Bernoulli) distribution with probability p .
- *binomial*(n,p) specifies a binomial distribution with count n and probability p .
- *gamma*(a,b) specifies a gamma distribution with shape a and scale b .

- *negbin(n,p)* specifies a negative binomial distribution with count n and probability p .
- *poisson(m)* specifies a Poisson distribution with mean m .
- *general(ll)* specifies a general log likelihood function that you construct using SAS programming statements.

The MODEL statement must follow any SAS programming statements you specify for computing parameters of the preceding distributions.

PARMS Statement

```
PARMS <name_list [=numbers] [, name_list [=numbers] ... ]>
      </options> ;
```

The PARMS statement lists names of parameters and specifies initial values, possibly over a grid. You can specify the parameters and values either directly in a list or provide the name of a SAS data set that contains them using the DATA= option.

While the PARMS statement is not required, you are encouraged to use it to provide PROC NLMIXED with accurate starting values. Parameters not listed in the PARMS statement are assigned an initial value of 1. PROC NLMIXED considers all symbols not assigned values to be parameters, so you should specify your modeling statements carefully and check the output from the “Parameters” table to make sure the proper parameters are identified.

A list of parameter names in the PARMS statement is not separated by commas and is followed by an equal sign and a list of numbers. If the number list consists of only one number, this number defines the initial value for all the parameters listed to the left of the equal sign.

If the number list consists of more than one number, these numbers specify the grid locations for each of the parameters listed to the left of the equal sign. You can use the TO and BY keywords to specify a number list for a grid search. If you specify a grid of points in a PARMS statement, PROC NLMIXED computes the objective function value at each grid point and chooses the best (feasible) grid point as an initial point for the optimization process. You can use the BEST= option to save memory for the storing and sorting of all grid point information.

The following options are available in the PARMS statement after a slash (/):

BEST= i > 0

specifies the maximum number of points displayed in the “Parameters” table, selected as the points with the maximum likelihood values. By default, all grid values are displayed.

DATA=SAS-data-set

specifies a SAS data set containing parameter names and starting values. The data set should be in one of two forms: narrow or wide. The narrow-form data set contains the variables PARAMETER and ESTIMATE, with parameters and values listed as

distinct observations. The wide-form data set has the parameters themselves as variables, and each observation provides a different set of starting values. BY groups are ignored in this data set, so the same starting grid is evaluated for each BY group.

PREDICT Statement

PREDICT *expression* **OUT=SAS-data-set** *<options>* ;

The PREDICT statement enables you to construct predictions of an expression across all of the observations in the input data set. Any valid SAS programming expression involving the input data set variables, parameters, and random effects is valid. Predicted values are computed using the parameter estimates and empirical Bayes estimates of the random effects. Standard errors of prediction are computed using the delta method (Billingsley 1986, Cox 1998). Results are placed in an output data set that you specify with the OUT= option. Besides all variables from the input data set, the OUT= data set contains the following variables: Pred, StdErrPred, DF, tValue, Probt, Alpha, Lower, Upper. You can also add other computed quantities to this data set with the ID statement.

The following options are available in the PREDICT statement:

ALPHA= α

specifies the alpha level to be used in computing t statistics and intervals. The default value corresponds to the ALPHA= option in the PROC NLMIXED statement.

DER

requests that derivatives of the predicted expression with respect to all parameters be included in the OUT= data set. The variable names for the derivatives are the same as the parameter names with the prefix “Der_” appended. All of the derivatives are evaluated at the final estimates of the parameters and the empirical Bayes estimates of the random effects.

DF= d

specifies the degrees of freedom to be used in computing t statistics and intervals in the OUT= data set. The default value corresponds to the DF= option in the PROC NLMIXED statement.

RANDOM Statement

RANDOM *random-effects* \sim *distribution* **SUBJECT=variable** *<options>* ;

The RANDOM statement defines the random effects and their distribution. The random effects must be represented by symbols that appear in your SAS programming statements. They typically influence the mean value of the distribution specified in the MODEL statement. The RANDOM statement consists of a list of the random effects (usually just one or two symbols), a tilde (~), the distribution for the random effects, and then a SUBJECT= variable.

NOTE: The input data set must be clustered according to the SUBJECT= variable. One easy way to accomplish this is to sort your data by the SUBJECT= variable prior to calling PROC NLMIXED. PROC NLMIXED does not sort the input data set for you; rather, it processes the data sequentially and considers an observation to be

from a new subject whenever the value of its SUBJECT= changes from the previous observation.

The only distribution currently available for the random effects is normal(m,v) with mean m and variance v . This syntax is illustrated as follows for one effect:

```
random u ~ normal(0,s2u) subject=clinic;
```

For multiple effects, you should specify bracketed vectors for m and v , the latter consisting of the lower triangle of the random-effects variance matrix listed in row order. This is illustrated for two and three random effects as follows.

```
random b1 b2 ~ normal([0,0],[g11,g21,g22]) subject=person;
random b1 b2 b3 ~ normal([0,0,0],[g11,g21,g22,g31,g32,g33])
subject=person;
```

The SUBJECT= variable determines when new realizations of the random effects are assumed to occur. PROC NL MIXED assumes that a new realization occurs whenever the SUBJECT= variable changes from the previous observation, so your input data set should be clustered according to this variable. One easy way to accomplish this is to run PROC SORT prior to calling PROC NL MIXED using the SUBJECT= variable as the BY variable.

Only one RANDOM statement is permitted, so multilevel nonlinear mixed models are not currently accommodated.

The following options are available in the RANDOM statement:

ALPHA= α

specifies the alpha level to be used in computing t statistics and intervals. The default value corresponds to the ALPHA= option in the PROC NL MIXED statement.

DF= d

specifies the degrees of freedom to be used in computing t statistics and intervals in the OUT= data set. The default value corresponds to the DF= option in the PROC NL MIXED statement.

OUT=*SAS-data-set*

requests an output data set containing empirical Bayes estimates of the random effects and their approximate standard errors of prediction.

REPLICATE Statement

```
REPLICATE variable ;
```

The REPLICATE statement provides a way to accommodate models in which different subjects have identical data. This occurs most commonly when the dependent variable is binary. When you specify a REPLICATE variable, PROC NL MIXED assumes that its value indicates the number of subjects having data identical to those for the current value of the SUBJECT= variable (specified in the RANDOM statement). Only the last observation of the REPLICATE variable for each subject is used, and the replicate variable must have only positive integer values.

Programming Statements

This section lists the programming statements used to code the log likelihood function in PROC NLMIXED. It also documents the differences between programming statements in PROC NLMIXED and programming statements in the DATA step. The syntax of programming statements used in PROC NLMIXED is identical to that used in the CALIS and GENMOD procedures (see [Chapter 19](#) and [Chapter 31](#), respectively), and the MODEL procedure (refer to the *SAS/ETS User's Guide*). Most of the programming statements that can be used in the SAS DATA step can also be used in the NLMIXED procedure. Refer to *SAS Language Reference: Dictionary* for a description of SAS programming statements. The following are valid statements:

```

ABORT;
CALL name [ ( expression [, expression ... ] ) ];
DELETE;
DO [ variable = expression
      [ TO expression ] [ BY expression ]
      [, expression [ TO expression ] [ BY expression ] ... ]
      ]
      [ WHILE expression ] [ UNTIL expression ];
END;
GOTO statement_label;
IF expression;
IF expression THEN program_statement;
      ELSE program_statement;
variable = expression;
variable + expression;
LINK statement_label;
PUT [ variable ] [=] [...] ;
RETURN;
SELECT [( expression )];
STOP;
SUBSTR( variable, index, length ) = expression;
WHEN ( expression ) program_statement;
      OTHERWISE program_statement;

```

For the most part, the SAS programming statements work the same as they do in the SAS DATA step, as documented in *SAS Language Reference: Concepts*; however, there are several differences.

- The ABORT statement does not allow any arguments.
- The DO statement does not allow a character index variable. Thus

```
do i = 1, 2, 3;
```

is supported; however, the following statement is not supported.

```
do i = 'A', 'B', 'C' ;
```

- The LAG function does work appropriately with PROC NLMIXED, but you can use the ZLAG function instead.
- The PUT statement, used mostly for program debugging in PROC NLMIXED, supports only some of the features of the DATA step PUT statement, and it has some new features that the DATA step PUT statement does not.
 - The PROC NLMIXED PUT statement does not support line pointers, factored lists, iteration factors, overprinting, `_INFILE_`, the colon (`:`) format modifier, or `“$”`.
 - The PROC NLMIXED PUT statement does support expressions, but the expression must be enclosed in parentheses. For example, the following statement displays the square root of `x`:

```
put (sqrt(x));
```
 - The PROC NLMIXED PUT statement supports the item `_PDV_` to display a formatted listing of all variables in the program. For example, the following statement displays a much more readable listing of the variables than the `_ALL_` print item:

```
put _pdv_;
```
- The WHEN and OTHERWISE statements enable you to specify more than one target statement. That is, DO/END groups are not necessary for multiple statement WHENs. For example, the following syntax is valid.

```
select;
when ( exp1 ) stmt1;
      stmt2;
when ( exp2 ) stmt3;
      stmt4;
end;
```

When coding your programming statements, you should avoid defining variables that begin with an underscore (`_`), as they may conflict with internal variables created by PROC NLMIXED. The MODEL statement must come after any SAS programming statements you specify for computing parameters of the modeling distribution.

Details

This section contains details about the underlying theory and computations of PROC NL MIXED.

Modeling Assumptions and Notation

PROC NL MIXED operates under the following general framework for nonlinear mixed models. Assume that you have an observed data vector y_i for each of i subjects, $i = 1, \dots, s$. The y_i are assumed to be independent across i , but within-subject covariance is likely to exist because each of the elements of y_i are measured on the same subject. As a statistical mechanism for modeling this within-subject covariance, assume that there exist latent random-effect vectors u_i of small dimension (typically one or two) that are also independent across i . Assume also that an appropriate model linking y_i and u_i exists, leading to the joint probability density function

$$p(y_i|X_i, \phi, u_i)q(u_i|\xi)$$

where X_i is a matrix of observed explanatory variables and ϕ and ξ are vectors of unknown parameters.

Let $\theta = (\phi, \xi)$ and assume that it is of dimension n . Then inferences about θ are based on the marginal likelihood function

$$m(\theta) = \prod_{i=1}^s \int p(y_i|X_i, \phi, u_i)q(u_i|\xi)du_i$$

In particular, the function

$$f(\theta) = -\log m(\theta)$$

is minimized over θ numerically in order to estimate θ , and the inverse Hessian (second derivative) matrix at the estimates provides an approximate variance-covariance matrix for the estimate of θ . The function $f(\theta)$ is referred to both as the negative log likelihood function and as the objective function for optimization.

As an example of the preceding general framework, consider the nonlinear growth curve example in the “Getting Started” section. Here, the conditional distribution $p(y_i|X_i, \phi, u_i)$ is normal with mean

$$\frac{b_1 + u_{i1}}{1 + \exp[-(d_{ij} - b_2)/b_3]}$$

and variance σ_e^2 ; thus $\phi = (b_1, b_2, b_3, \sigma_e^2)$. Also, u_i is a scalar and $q(u_i|\xi)$ is normal with mean 0 and variance σ_u^2 ; thus $\xi = \sigma_u^2$.

The following additional notation is also found in this chapter. The quantity $\theta^{(k)}$ refers to the parameter vector at the k th iteration, the function $g(\theta)$ refers to the gradient vector $\nabla f(\theta)$, and the matrix $H(\theta)$ refers to the Hessian $\nabla^2 f(\theta)$. Other symbols are used to denote various constants or option values.

Integral Approximations

An important part of the marginal maximum likelihood method described previously is the computation of the integral over the random effects. The default method in PROC NLMIXED for computing this integral is adaptive Gaussian quadrature as described in Pinheiro and Bates (1995). Another approximation method is the first-order method of Beal and Sheiner (1982, 1988). A description of these two methods follows.

Adaptive Gaussian Quadrature

A quadrature method approximates a given integral by a weighted sum over predefined abscissas for the random effects. A good approximation can usually be obtained with an adequate number of quadrature points as well as appropriate centering and scaling of the abscissas. Adaptive Gaussian quadrature for the integral over u_i centers the integral at the empirical Bayes estimate of u_i , defined as the vector \hat{u}_i that minimizes

$$-\log [p(y_i|X_i, \phi, u_i)q(u_i|\xi)]$$

with ϕ and ξ set equal to their current estimates. The final Hessian matrix from this optimization can be used to scale the quadrature abscissas.

Suppose $(z_j, w_j; j = 1, \dots, p)$ denote the standard Gauss-Hermite abscissas and weights (Golub and Welsch 1969, or Table 25.10 of Abramowitz and Stegun 1972). The adaptive Gaussian quadrature integral approximation is as follows.

$$\int p(y_i|X_i, \phi, u_i)q(u_i|\xi)du_i \approx 2^{r/2} |\Gamma(X_i, \theta)|^{-1/2} \sum_{j_1=1}^p \cdots \sum_{j_r=1}^p \left[p(y_i|X_i, \phi, a_{j_1, \dots, j_r})q(a_{j_1, \dots, j_r}|\xi) \prod_{k=1}^r w_{j_k} \exp z_{j_k}^2 \right]$$

where r is the dimension of u_i , $\Gamma(X_i, \theta)$ is the Hessian matrix from the empirical Bayes minimization, z_{j_1, \dots, j_r} is a vector with elements $(z_{j_1}, \dots, z_{j_r})$, and

$$a_{j_1, \dots, j_r} = \hat{u}_i + 2^{1/2} \Gamma(X_i, \theta)^{-1/2} z_{j_1, \dots, j_r}$$

PROC NLMIXED selects the number of quadrature points adaptively by evaluating the log likelihood function at the starting values of the parameters until two successive evaluations have a relative difference less than the value of the QTOL= option. The specific search sequence is described under the QFAC= option. Using the QPOINTS= option, you can adjust the number of quadrature points p to obtain different levels of accuracy. Setting $p = 1$ results in the Laplacian approximation as described in Beal and Sheiner (1992), Wolfinger (1993), Vonesh (1992, 1996), Vonesh and Chinchilli (1997), and Wolfinger and Lin (1997).

The NOAD option in the PROC NLMIXED statement requests nonadaptive Gaussian quadrature. Here all \hat{u}_i are set equal to zero, and the Cholesky root of the estimated variance matrix of the random effects is substituted for $\Gamma(X_i, \theta)^{-1/2}$ in the preceding

expression for a_{j_1, \dots, j_r} . In this case derivatives are computed using the algorithm of Smith (1995). The NOADSCALE option requests the same scaling substitution but with the empirical Bayes \hat{u}_i .

PROC NLMIXED computes the derivatives of the adaptive Gaussian quadrature approximation when carrying out the default dual quasi-Newton optimization.

First-Order Method

Another integral approximation available in PROC NLMIXED is the first-order method of Beal and Sheiner (1982, 1988) and Sheiner and Beal (1985). This approximation is used only in the case where $p(y_i|X_i, \phi, u_i)$ is normal, that is,

$$p(y_i|X_i, \phi, u_i) = (2\pi)^{-n_i/2} |R_i(X_i, \phi)|^{-1/2} \exp \left\{ -(1/2) [y_i - m_i(X_i, \phi, u_i)]^T R_i(X_i, \phi)^{-1} [y_i - m_i(X_i, \phi, u_i)] \right\}$$

where n_i is the dimension of y_i , R_i is a diagonal variance matrix, and m_i is the conditional mean vector of y_i .

The first-order approximation is obtained by expanding $m(X_i, \phi, u_i)$ with a one-term Taylor series expansion about $u_i = 0$, resulting in the approximation

$$p(y_i|X_i, \phi, u_i) \approx (2\pi)^{-n_i/2} |R_i(X_i, \phi)|^{-1/2} \exp \left(-(1/2) [y_i - m_i(X_i, \phi, 0) - Z_i(X_i, \phi)u_i]^T R_i(X_i, \phi)^{-1} [y_i - m_i(X_i, \phi, 0) - Z_i(X_i, \phi)u_i] \right)$$

where $Z_i(X_i, \phi)$ is the Jacobian matrix $\partial m_i(X_i, \phi, u_i)/\partial u_i$ evaluated at $u_i = 0$.

Assuming that $q(u_i|\xi)$ is normal with mean 0 and variance matrix $G(\xi)$, the first-order integral approximation is computable in closed form after completing the square:

$$\int p(y_i|X_i, \phi, u_i)q(u_i|\xi)du_i \approx (2\pi)^{-n_i/2} |V_i(X_i, \theta)|^{-1/2} \exp \left(-(1/2) [y_i - m_i(X_i, \phi, 0)]^T V_i(X_i, \theta)^{-1} [y_i - m_i(X_i, \phi, 0)] \right)$$

where $V_i(X_i, \theta) = Z_i(X_i, \phi)G(\xi)Z_i(X_i, \phi)^T + R_i(X_i, \phi)$. The resulting approximation for $f(\theta)$ is then minimized over $\theta = (\phi, \xi)$ to obtain the first-order estimates. PROC NLMIXED uses finite-difference derivatives of the first-order integral approximation when carrying out the default dual quasi-Newton optimization.

Optimization Algorithms

There are several optimization techniques available in PROC NLMIXED. You can choose a particular optimizer with the `TECH=name` option in the PROC NLMIXED statement.

Algorithm	TECH=
trust region Method	TRUREG
Newton-Raphson method with line search	NEWRAP
Newton-Raphson method with ridging	NRRIDG
quasi-Newton methods (DBFGS, DDFP, BFGS, DFP)	QUANEW
double-dogleg method (DBFGS, DDFP)	DBLDOG
conjugate gradient methods (PB, FR, PR, CD)	CONGRA
Nelder-Mead simplex method	NMSIMP

No algorithm for optimizing general nonlinear functions exists that always finds the global optimum for a general nonlinear minimization problem in a reasonable amount of time. Since no single optimization technique is invariably superior to others, PROC NLMIXED provides a variety of optimization techniques that work well in various circumstances. However, you can devise problems for which none of the techniques in PROC NLMIXED can find the correct solution. Moreover, nonlinear optimization can be computationally expensive in terms of time and memory, so you must be careful when matching an algorithm to a problem.

All optimization techniques in PROC NLMIXED use $O(n^2)$ memory except the conjugate gradient methods, which use only $O(n)$ of memory and are designed to optimize problems with many parameters. Since the techniques are iterative, they require the repeated computation of

- the function value (optimization criterion)
- the gradient vector (first-order partial derivatives)
- for some techniques, the (approximate) Hessian matrix (second-order partial derivatives)

However, since each of the optimizers requires different derivatives, some computational efficiencies can be gained. The following table shows, for each optimization technique, which derivatives are required (FOD: first-order derivatives; SOD: second-order derivatives).

Algorithm	FOD	SOD
TRUREG	x	x
NEWRAP	x	x
NRRIDG	x	x
QUANEW	x	-
DBLDOG	x	-
CONGRA	x	-
NMSIMP	-	-

Each optimization method employs one or more convergence criteria that determine when it has converged. The various termination criteria are listed and described in the “PROC NLMIXED Statement” section. An algorithm is considered to have converged when any one of the convergence criterion is satisfied. For example, under the default settings, the QUANEW algorithm will converge if $ABSGCONV < 1E - 5$, $FCONV < 10^{-FDIGITS}$, or $GCONV < 1E - 8$.

Choosing an Optimization Algorithm

The factors that go into choosing a particular optimization technique for a particular problem are complex and may involve trial and error.

For many optimization problems, computing the gradient takes more computer time than computing the function value, and computing the Hessian sometimes takes *much* more computer time and memory than computing the gradient, especially when there are many decision variables. Unfortunately, optimization techniques that do not use some kind of Hessian approximation usually require many more iterations than techniques that do use a Hessian matrix, and as a result the total run time of these techniques is often longer. Techniques that do not use the Hessian also tend to be less reliable. For example, they can more easily terminate at stationary points rather than at global optima.

A few general remarks about the various optimization techniques are as follows.

- The second-derivative methods TRUREG, NEWRAP, and NRRIDG are best for small problems where the Hessian matrix is not expensive to compute. Sometimes the NRRIDG algorithm can be faster than the TRUREG algorithm, but TRUREG can be more stable. The NRRIDG algorithm requires only one matrix with $n(n + 1)/2$ double words; TRUREG and NEWRAP require two such matrices.
- The first-derivative methods QUANEW and DBLDOG are best for medium-sized problems where the objective function and the gradient are much faster to evaluate than the Hessian. The QUANEW and DBLDOG algorithms, in general, require more iterations than TRUREG, NRRIDG, and NEWRAP, but each iteration can be much faster. The QUANEW and DBLDOG algorithms require only the gradient to update an approximate Hessian, and they require slightly less memory than TRUREG or NEWRAP (essentially one matrix with $n(n + 1)/2$ double words). QUANEW is the default optimization method.
- The first-derivative method CONGRA is best for large problems where the objective function and the gradient can be computed much faster than the Hessian and where too much memory is required to store the (approximate) Hessian. The CONGRA algorithm, in general, requires more iterations than QUANEW or DBLDOG, but each iteration can be much faster. Since CONGRA requires only a factor of n double-word memory, many large applications of PROC NLMIXED can be solved only by CONGRA.
- The no-derivative method NMSIMP is best for small problems where derivatives are not continuous or are very difficult to compute.

Algorithm Descriptions

Some details about the optimization techniques are as follows.

Trust Region Optimization (TRUREG)

The trust region method uses the gradient $g(\theta_{(k)})$ and the Hessian matrix $H(\theta_{(k)})$; thus, it requires that the objective function $f(\theta)$ have continuous first- and second-order derivatives inside the feasible region.

The trust region method iteratively optimizes a quadratic approximation to the nonlinear objective function within a hyper-elliptic trust region with radius Δ that constrains the step size corresponding to the quality of the quadratic approximation. The trust region method is implemented using Dennis, Gay, and Welsch (1981), Gay (1983), and Moré and Sorensen (1983).

The trust region method performs well for small- to medium-sized problems, and it does not need many function, gradient, and Hessian calls. However, if the computation of the Hessian matrix is computationally expensive, one of the (dual) quasi-Newton or conjugate gradient algorithms may be more efficient.

Newton-Raphson Optimization with Line Search (NEWRAP)

The NEWRAP technique uses the gradient $g(\theta_{(k)})$ and the Hessian matrix $H(\theta_{(k)})$; thus, it requires that the objective function have continuous first- and second-order derivatives inside the feasible region. If second-order derivatives are computed efficiently and precisely, the NEWRAP method may perform well for medium-sized to large problems, and it does not need many function, gradient, and Hessian calls.

This algorithm uses a pure Newton step when the Hessian is positive definite and when the Newton step reduces the value of the objective function successfully. Otherwise, a combination of ridging and line search is performed to compute successful steps. If the Hessian is not positive definite, a multiple of the identity matrix is added to the Hessian matrix to make it positive definite (Eskow and Schnabel 1991).

In each iteration, a line search is performed along the search direction to find an approximate optimum of the objective function. The default line-search method uses quadratic interpolation and cubic extrapolation (LIS=2).

Newton-Raphson Ridge Optimization (NRRIDG)

The NRRIDG technique uses the gradient $g(\theta_{(k)})$ and the Hessian matrix $H(\theta_{(k)})$; thus, it requires that the objective function have continuous first- and second-order derivatives inside the feasible region.

This algorithm uses a pure Newton step when the Hessian is positive definite and when the Newton step reduces the value of the objective function successfully. If at least one of these two conditions is not satisfied, a multiple of the identity matrix is added to the Hessian matrix.

The NRRIDG method performs well for small- to medium-sized problems, and it does not require many function, gradient, and Hessian calls. However, if the computation of the Hessian matrix is computationally expensive, one of the (dual) quasi-Newton or conjugate gradient algorithms may be more efficient.

Since the NRRIDG technique uses an orthogonal decomposition of the approximate Hessian, each iteration of NRRIDG can be slower than that of the NEWRAP technique, which works with Cholesky decomposition. Usually, however, NRRIDG requires fewer iterations than NEWRAP.

Quasi-Newton Optimization (QUANEW)

The (dual) quasi-Newton method uses the gradient $g(\theta_{(k)})$, and it does not need to compute second-order derivatives since they are approximated. It works well for medium to moderately large optimization problems where the objective function and the gradient are much faster to compute than the Hessian; but, in general, it requires more iterations than the TRUREG, NEWRAP, and NRRIDG techniques, which compute second-order derivatives. QUANEW is the default optimization algorithm because it provides an appropriate balance between the speed and stability required for most nonlinear mixed model applications.

The QUANEW technique is one of the following, depending upon the value of the UPDATE= option.

- the original quasi-Newton algorithm, which updates an approximation of the inverse Hessian
- the dual quasi-Newton algorithm, which updates the Cholesky factor of an approximate Hessian (default)

You can specify four update formulas with the UPDATE= option:

- DBFGS performs the dual Broyden, Fletcher, Goldfarb, and Shanno (BFGS) update of the Cholesky factor of the Hessian matrix. This is the default.
- DDFP performs the dual Davidon, Fletcher, and Powell (DFP) update of the Cholesky factor of the Hessian matrix.
- BFGS performs the original BFGS update of the inverse Hessian matrix.
- DFP performs the original DFP update of the inverse Hessian matrix.

In each iteration, a line search is performed along the search direction to find an approximate optimum. The default line-search method uses quadratic interpolation and cubic extrapolation to obtain a step size α satisfying the Goldstein conditions. One of the Goldstein conditions can be violated if the feasible region defines an upper limit of the step size. Violating the left-side Goldstein condition can affect the positive definiteness of the quasi-Newton update. In that case, either the update is skipped or the iterations are restarted with an identity matrix, resulting in the steepest descent or ascent search direction. You can specify line-search algorithms other than the default with the LIS= option.

The QUANEW algorithm performs its own line-search technique. All options and parameters (except the INSTEP= option) controlling the line search in the other algorithms do not apply here. In several applications, large steps in the first iterations are troublesome. You can use the INSTEP= option to impose an upper bound for the step

size α during the first five iterations. You can also use the `INHESIAN[=r]` option to specify a different starting approximation for the Hessian. If you specify only the `INHESIAN` option, the Cholesky factor of a (possibly ridged) finite difference approximation of the Hessian is used to initialize the quasi-Newton update process. The values of the `LCSINGULAR=`, `LCEPSILON=`, and `LCDEACT=` options, which control the processing of linear and boundary constraints, are valid only for the quadratic programming subroutine used in each iteration of the `QUANEW` algorithm.

Double Dogleg Optimization (DBLDOG)

The double dogleg optimization method combines the ideas of the quasi-Newton and trust region methods. In each iteration, the double dogleg algorithm computes the step $s^{(k)}$ as the linear combination of the steepest descent or ascent search direction $s_1^{(k)}$ and a quasi-Newton search direction $s_2^{(k)}$.

$$s^{(k)} = \alpha_1 s_1^{(k)} + \alpha_2 s_2^{(k)}$$

The step is requested to remain within a prespecified trust region radius; refer to Fletcher (1987, p. 107). Thus, the `DBLDOG` subroutine uses the dual quasi-Newton update but does not perform a line search. You can specify two update formulas with the `UPDATE=` option:

- `DBFGS` performs the dual Broyden, Fletcher, Goldfarb, and Shanno update of the Cholesky factor of the Hessian matrix. This is the default.
- `DDFP` performs the dual Davidon, Fletcher, and Powell update of the Cholesky factor of the Hessian matrix.

The double dogleg optimization technique works well for medium to moderately large optimization problems where the objective function and the gradient are much faster to compute than the Hessian. The implementation is based on Dennis and Mei (1979) and Gay (1983), but it is extended for dealing with boundary and linear constraints. The `DBLDOG` technique generally requires more iterations than the `TRUREG`, `NEWRAP`, or `NRRIDG` technique, which requires second-order derivatives; however, each of the `DBLDOG` iterations is computationally cheap. Furthermore, the `DBLDOG` technique requires only gradient calls for the update of the Cholesky factor of an approximate Hessian.

Conjugate Gradient Optimization (CONGRA)

Second-order derivatives are not required by the `CONGRA` algorithm and are not even approximated. The `CONGRA` algorithm can be expensive in function and gradient calls, but it requires only $O(n)$ memory for unconstrained optimization. In general, many iterations are required to obtain a precise solution, but each of the `CONGRA` iterations is computationally cheap. You can specify four different update formulas for generating the conjugate directions by using the `UPDATE=` option:

- `PB` performs the automatic restart update method of Powell (1977) and Beale (1972). This is the default.

- FR performs the Fletcher-Reeves update (Fletcher 1987).
- PR performs the Polak-Ribiere update (Fletcher 1987).
- CD performs a conjugate-descent update of Fletcher (1987).

The default, UPDATE=PB, behaved best in most test examples. You are advised to avoid the option UPDATE=CD, which behaved worst in most test examples.

The CONGRA subroutine should be used for optimization problems with large n . For the unconstrained or boundary constrained case, CONGRA requires only $O(n)$ bytes of working memory, whereas all other optimization methods require order $O(n^2)$ bytes of working memory. During n successive iterations, uninterrupted by restarts or changes in the working set, the conjugate gradient algorithm computes a cycle of n conjugate search directions. In each iteration, a line search is performed along the search direction to find an approximate optimum of the objective function. The default line-search method uses quadratic interpolation and cubic extrapolation to obtain a step size α satisfying the Goldstein conditions. One of the Goldstein conditions can be violated if the feasible region defines an upper limit for the step size. Other line-search algorithms can be specified with the LIS= option.

Nelder-Mead Simplex Optimization (NMSIMP)

The Nelder-Mead simplex method does not use any derivatives and does not assume that the objective function has continuous derivatives. The objective function itself needs to be continuous. This technique is quite expensive in the number of function calls, and it may be unable to generate precise results for $n \gg 40$.

The original Nelder-Mead simplex algorithm is implemented and extended to boundary constraints. This algorithm does not compute the objective for infeasible points, but it changes the shape of the simplex adapting to the nonlinearities of the objective function, which contributes to an increased speed of convergence. It uses a special termination criteria.

Finite Difference Approximations of Derivatives

The FD= and FDHESSIAN= options specify the use of finite difference approximations of the derivatives. The FD= option specifies that all derivatives are approximated using function evaluations, and the FDHESSIAN= option specifies that second-order derivatives are approximated using gradient evaluations.

Computing derivatives by finite difference approximations can be very time consuming, especially for second-order derivatives based only on values of the objective function (FD= option). If analytical derivatives are difficult to obtain (for example, if a function is computed by an iterative process), you might consider one of the optimization techniques that uses first-order derivatives only (QUANEW, DBLDOG, or CONGRA).

Forward Difference Approximations

The forward difference derivative approximations consume less computer time, but they are usually not as precise as approximations that use central difference formulas.

- For first-order derivatives, n additional function calls are required:

$$g_i = \frac{\partial f}{\partial \theta_i} \approx \frac{f(\theta + h_i e_i) - f(\theta)}{h_i}$$

- For second-order derivatives based on function calls only (Dennis and Schnabel 1983, p. 80), $n + n^2/2$ additional function calls are required for dense Hessian:

$$\frac{\partial^2 f}{\partial \theta_i \partial \theta_j} \approx \frac{f(\theta + h_i e_i + h_j e_j) - f(\theta + h_i e_i) - f(\theta + h_j e_j) + f(\theta)}{h_i h_j}$$

- For second-order derivatives based on gradient calls (Dennis and Schnabel 1983, p. 103), n additional gradient calls are required:

$$\frac{\partial^2 f}{\partial \theta_i \partial \theta_j} \approx \frac{g_i(\theta + h_j e_j) - g_i(\theta)}{2h_j} + \frac{g_j(\theta + h_i e_i) - g_j(\theta)}{2h_i}$$

Central Difference Approximations

Central difference approximations are usually more precise, but they consume more computer time than approximations that use forward difference derivative formulas.

- For first-order derivatives, $2n$ additional function calls are required:

$$g_i = \frac{\partial f}{\partial \theta_i} \approx \frac{f(\theta + h_i e_i) - f(\theta - h_i e_i)}{2h_i}$$

- For second-order derivatives based on function calls only (Abramowitz and Stegun 1972, p. 884), $2n + 4n^2/2$ additional function calls are required.

$$\frac{\partial^2 f}{\partial \theta_i^2} \approx \frac{-f(\theta + 2h_i e_i) + 16f(\theta + h_i e_i) - 30f(\theta) + 16f(\theta - h_i e_i) - f(\theta - 2h_i e_i)}{12h_i^2}$$

$$\frac{\partial^2 f}{\partial \theta_i \partial \theta_j} \approx \frac{f(\theta + h_i e_i + h_j e_j) - f(\theta + h_i e_i - h_j e_j) - f(\theta - h_i e_i + h_j e_j) + f(\theta - h_i e_i - h_j e_j)}{4h_i h_j}$$

- For second-order derivatives based on gradient calls, $2n$ additional gradient calls are required:

$$\frac{\partial^2 f}{\partial \theta_i \partial \theta_j} \approx \frac{g_i(\theta + h_j e_j) - g_i(\theta - h_j e_j)}{4h_j} + \frac{g_j(\theta + h_i e_i) - g_j(\theta - h_i e_i)}{4h_i}$$

You can use the `FDIGITS==` option to specify the number of accurate digits in the evaluation of the objective function. This specification is helpful in determining an appropriate interval size h to be used in the finite difference formulas.

The step sizes h_j , $j = 1, \dots, n$ are defined as follows.

- For the forward difference approximation of first-order derivatives using function calls and second-order derivatives using gradient calls, $h_j = \sqrt[2]{\eta}(1 + |\theta_j|)$.

- For the forward difference approximation of second-order derivatives using only function calls and all central difference formulas, $h_j = \sqrt[3]{\eta}(1 + |\theta_j|)$.

The value of η is defined by the FDIGITS= option:

- If you specify the number of accurate digits using FDIGITS= r , η is set to 10^{-r} .
- If you do not specify the FDIGITS= option, η is set to the machine precision ϵ .

Hessian Scaling

The rows and columns of the Hessian matrix can be scaled when you use the trust region, Newton-Raphson, and double dogleg optimization techniques. Each element $H_{i,j}$, $i, j = 1, \dots, n$ is divided by the scaling factor $d_i d_j$, where the scaling vector $d = (d_1, \dots, d_n)$ is iteratively updated in a way specified by the HESCAL= i option, as follows.

$i = 0$: No scaling is done (equivalent to $d_i = 1$).

$i \neq 0$: First iteration and each restart iteration sets:

$$d_i^{(0)} = \sqrt{\max(|H_{i,i}^{(0)}|, \epsilon)}$$

$i = 1$: Refer to Moré (1978):

$$d_i^{(k+1)} = \max \left[d_i^{(k)}, \sqrt{\max(|H_{i,i}^{(k)}|, \epsilon)} \right]$$

$i = 2$: Refer to Dennis, Gay, and Welsch (1981):

$$d_i^{(k+1)} = \max \left[.6d_i^{(k)}, \sqrt{\max(|H_{i,i}^{(k)}|, \epsilon)} \right]$$

$i = 3$: d_i is reset in each iteration:

$$d_i^{(k+1)} = \sqrt{\max(|H_{i,i}^{(k)}|, \epsilon)}$$

In the preceding equations, ϵ is the relative machine precision or, equivalently, the largest double precision value that, when added to 1, results in 1.

Active Set Methods

The parameter vector $\theta \in \mathcal{R}^n$ can be subject to a set of m linear equality and inequality constraints:

$$\sum_{j=1}^n a_{ij}\theta_j = b_i \quad i = 1, \dots, m_e$$

$$\sum_{j=1}^n a_{ij}\theta_j \geq b_i \quad i = m_e + 1, \dots, m$$

The coefficients a_{ij} and right-hand sides b_i of the equality and inequality constraints are collected in the $m \times n$ matrix A and the m vector b .

The m linear constraints define a feasible region \mathcal{G} in \mathcal{R}^n that must contain the point θ_* that minimizes the problem. If the feasible region \mathcal{G} is empty, no solution to the optimization problem exists.

In PROC NLMIXED, all optimization techniques use *active set methods*. The iteration starts with a feasible point $\theta_{(0)}$, which you can provide or which can be computed by the Schittkowski and Stoer (1979) algorithm implemented in PROC NLMIXED. The algorithm then moves from one feasible point $\theta_{(k-1)}$ to a better feasible point $\theta_{(k)}$ along a feasible search direction $s^{(k)}$,

$$\theta_{(k)} = \theta_{(k-1)} + \alpha^{(k)} s^{(k)} \quad , \quad \alpha^{(k)} > 0$$

Theoretically, the path of points $\theta_{(k)}$ never leaves the feasible region \mathcal{G} of the optimization problem, but it can reach its boundaries. The active set $\mathcal{A}^{(k)}$ of point $\theta_{(k)}$ is defined as the index set of all linear equality constraints and those inequality constraints that are satisfied at $\theta_{(k)}$. If no constraint is active at $\theta_{(k)}$, the point is located in the interior of \mathcal{G} , and the active set $\mathcal{A}^{(k)} = \emptyset$ is empty. If the point $\theta_{(k)}$ in iteration k hits the boundary of inequality constraint i , this constraint i becomes active and is added to $\mathcal{A}^{(k)}$. Each equality constraint and each active inequality constraint reduce the dimension (degrees of freedom) of the optimization problem.

In practice, the active constraints can be satisfied only with finite precision. The LCEPSILON= r option specifies the range for active and violated linear constraints. If the point $\theta_{(k)}$ satisfies the condition

$$\left| \sum_{j=1}^n a_{ij} \theta_j^{(k)} - b_i \right| \leq t$$

where $t = r(|b_i| + 1)$, the constraint i is recognized as an active constraint. Otherwise, the constraint i is either an inactive inequality or a violated inequality or equality constraint. Due to rounding errors in computing the projected search direction, error can be accumulated so that an iterate $\theta_{(k)}$ steps out of the feasible region.

In those cases, PROC NLMIXED may try to pull the iterate $\theta_{(k)}$ back into the feasible region. However, in some cases the algorithm needs to increase the feasible region by increasing the LCEPSILON= r value. If this happens, a message is displayed in the log output.

If the algorithm cannot improve the value of the objective function by moving from an active constraint back into the interior of the feasible region, it makes this inequality constraint an equality constraint in the next iteration. This means that the active set $\mathcal{A}^{(k+1)}$ still contains the constraint i . Otherwise, it releases the active inequality constraint and increases the dimension of the optimization problem in the next iteration.

A serious numerical problem can arise when some of the active constraints become (nearly) linearly dependent. PROC NLMIXED removes linearly dependent equality constraints before starting optimization. You can use the LCSINGULAR= option to specify a criterion r used in the update of the QR decomposition that determines whether an active constraint is linearly dependent relative to a set of other active constraints.

If the solution θ_* is subjected to n_{act} linear equality or active inequality constraints, the QR decomposition of the $n \times n_{act}$ matrix \hat{A}^T of the linear constraints is computed by $\hat{A}^T = QR$, where Q is an $n \times n$ orthogonal matrix and R is an $n \times n_{act}$ upper triangular matrix. The n columns of matrix Q can be separated into two matrices, $Q = [Y, Z]$, where Y contains the first n_{act} orthogonal columns of Q and Z contains the last $n - n_{act}$ orthogonal columns of Q . The $n \times (n - n_{act})$ column-orthogonal matrix Z is also called the *nullspace matrix* of the active linear constraints \hat{A}^T . The $n - n_{act}$ columns of the $n \times (n - n_{act})$ matrix Z form a basis orthogonal to the rows of the $n_{act} \times n$ matrix \hat{A} .

At the end of the iterating, PROC NLMIXED computes the *projected gradient* g_Z ,

$$g_Z = Z^T g$$

In the case of boundary-constrained optimization, the elements of the projected gradient correspond to the gradient elements of the free parameters. A necessary condition for θ_* to be a local minimum of the optimization problem is

$$g_Z(\theta_*) = Z^T g(\theta_*) = 0$$

The symmetric $n_{act} \times n_{act}$ matrix G_Z ,

$$G_Z = Z^T G Z$$

is called a *projected Hessian matrix*. A second-order necessary condition for θ_* to be a local minimizer requires that the projected Hessian matrix is positive semidefinite.

Those elements of the n_{act} vector of first-order estimates of *Lagrange multipliers*,

$$\lambda = (\hat{A}\hat{A}^T)^{-1} \hat{A} Z Z^T g$$

that correspond to active inequality constraints indicate whether an improvement of the objective function can be obtained by releasing this active constraint. For minimization, a significant negative Lagrange multiplier indicates that a possible reduction of the objective function can be achieved by releasing this active linear constraint. The LCDEACT= r option specifies a threshold r for the Lagrange multiplier that determines whether an active inequality constraint remains active or can be deactivated. (In the case of boundary-constrained optimization, the Lagrange multipliers for active lower (upper) constraints are the negative (positive) gradient elements corresponding to the active parameters.)

Line-Search Methods

In each iteration k , the (dual) quasi-Newton, conjugate gradient, and Newton-Raphson minimization techniques use iterative line-search algorithms that try to optimize a linear, quadratic, or cubic approximation of f along a feasible descent search direction $s^{(k)}$

$$\theta_{(k+1)} = \theta_{(k)} + \alpha^{(k)} s^{(k)}, \quad \alpha^{(k)} > 0$$

by computing an approximately optimal scalar $\alpha^{(k)}$.

Therefore, a line-search algorithm is an iterative process that optimizes a nonlinear function $f(\alpha)$ of one parameter (α) within each iteration k of the optimization technique. Since the outside iteration process is based only on the approximation of the objective function, the inside iteration of the line-search algorithm does not have to be perfect. Usually, it is satisfactory that the choice of α significantly reduces (in a minimization) the objective function. Criteria often used for termination of line-search algorithms are the Goldstein conditions (refer to Fletcher 1987).

You can select various line-search algorithms by specifying the LIS= option. The line-search method LIS=2 seems to be superior when function evaluation consumes significantly less computation time than gradient evaluation. Therefore, LIS=2 is the default method for Newton-Raphson, (dual) quasi-Newton, and conjugate gradient optimizations.

You can modify the line-search methods LIS=2 and LIS=3 to be exact line searches by using the LSPRECISION= option and specifying the σ parameter described in Fletcher (1987). The line-search methods LIS=1, LIS=2, and LIS=3 satisfy the left-hand side and right-hand side Goldstein conditions (refer to Fletcher 1987). When derivatives are available, the line-search methods LIS=6, LIS=7, and LIS=8 try to satisfy the right-hand side Goldstein condition; if derivatives are not available, these line-search algorithms use only function calls.

Restricting the Step Length

Almost all line-search algorithms use iterative extrapolation techniques that can easily lead them to (feasible) points where the objective function f is no longer defined or difficult to compute. Therefore, PROC NLMIXED provides options restricting the step length α or trust region radius Δ , especially during the first main iterations.

The inner product $g^T s$ of the gradient g and the search direction s is the slope of $f(\alpha) = f(\theta + \alpha s)$ along the search direction s . The default starting value $\alpha^{(0)} = \alpha^{(k,0)}$ in each line-search algorithm ($\min_{\alpha > 0} f(\theta + \alpha s)$) during the main iteration k is computed in three steps:

1. The first step uses either the difference $df = |f^{(k)} - f^{(k-1)}|$ of the function values during the last two consecutive iterations or the final step-size value α of the last iteration $k - 1$ to compute a first value of $\alpha_1^{(0)}$.

- If the DAMPSTEPoption is not used,

$$\alpha_1^{(0)} = \begin{cases} step & \text{if } 0.1 \leq step \leq 10 \\ 10 & \text{if } step > 10 \\ 0.1 & \text{if } step < 0.1 \end{cases}$$

with

$$step = \begin{cases} df/|g^T s| & \text{if } |g^T s| \geq \epsilon \max(100df, 1) \\ 1 & \text{otherwise} \end{cases}$$

This value of $\alpha_1^{(0)}$ can be too large and can lead to a difficult or impossible function evaluation, especially for highly nonlinear functions such as the EXP function.

- If the DAMPSTEP[=r] option is used,

$$\alpha_1^{(0)} = \min(1, r\alpha^-)$$

The initial value for the new step length can be no larger than r times the final step length α^- of the former iteration. The default value is $r = 2$.

2. During the first five iterations, the second step enables you to reduce $\alpha_1^{(0)}$ to a smaller starting value $\alpha_2^{(0)}$ using the INSTEP= r option:

$$\alpha_2^{(0)} = \min(\alpha_1^{(0)}, r)$$

After more than five iterations, $\alpha_2^{(0)}$ is set to $\alpha_1^{(0)}$.

3. The third step can further reduce the step length by

$$\alpha_3^{(0)} = \min(\alpha_2^{(0)}, \min(10, u))$$

where u is the maximum length of a step inside the feasible region.

The INSTEP= r option enables you to specify a smaller or larger radius Δ of the trust region used in the first iteration of the trust region and double dogleg algorithms. The default initial trust region radius $\Delta^{(0)}$ is the length of the scaled gradient (Moré 1978). This step corresponds to the default radius factor of $r = 1$. In most practical applications of the TRUREG and DBLDOG algorithms, this choice is successful. However, for bad initial values and highly nonlinear objective functions (such as the EXP function), the default start radius can result in arithmetic overflows. If this happens, you can try decreasing values of INSTEP= r , $0 < r < 1$, until the iteration starts successfully. A small factor r also affects the trust region radius $\Delta^{(k+1)}$ of the next steps because the radius is changed in each iteration by a factor $0 < c \leq 4$, depending on the ratio ρ expressing the goodness of quadratic function approximation. Reducing the radius Δ corresponds to increasing the ridge parameter λ , producing smaller steps directed more closely toward the (negative) gradient direction.

Computational Problems

Floating Point Errors and Overflows

Numerical optimization of a numerically integrated function is a difficult task, and the computation of the objective function and its derivatives can lead to arithmetic exceptions and overflows. A typical cause of these problems is parameters with widely varying scales. If the scaling of your parameters varies by more than a few orders of magnitude, the numerical stability of the optimization problem can be seriously reduced and result in computational difficulties. A simple remedy is to rescale each parameter so that its final estimated value has a magnitude near 1.

If parameter rescaling does not help, consider the following actions:

- Specify the ITDETAILS option in the PROC NLMIXED statement to obtain more detailed information about when and where the problem is occurring.
- Provide different initial values or try a grid search of values.
- Use boundary constraints to avoid the region where overflows may happen.
- Delete outlying observations or subjects from the input data, if this is reasonable.
- Change the algorithm (specified in programming statements) that computes the objective function.

The line-search algorithms that work with cubic extrapolation are especially sensitive to arithmetic overflows. If an overflow occurs during a line search, you can use the INSTEP= option to reduce the length of the first trial step during the first five iterations, or you can use the DAMPSTEP or MAXSTEP option to restrict the step length of the initial α in subsequent iterations. If an arithmetic overflow occurs in the first iteration of the trust region or double dogleg algorithms, you can use the INSTEP= option to reduce the default trust region radius of the first iteration. You can also change the optimization technique or the line-search method.

Long Run Times

PROC NLMIXED can take a long time to run for problems with complex models, many parameters, or large input data sets. Although the optimization techniques used by PROC NLMIXED are some of the best ones available, they are not guaranteed to converge quickly for all problems. Ill-posed or misspecified models can cause the algorithms to use more extensive calculations designed to achieve convergence, and this can result in longer run times. So first make sure that your model is specified correctly, that your parameters are scaled to be of the same order of magnitude, and that your data reasonably match the model you are contemplating.

If you are using the default adaptive Gaussian quadrature algorithm and no iteration history is printing at all, then PROC NLMIXED may be bogged down trying to determine the number of quadrature points at the first set of starting values. Specifying the QPOINTS= option will bypass this stage and proceed directly to iterations; however, be aware that the likelihood approximation may not be accurate if there are too few quadrature points.

PROC NLMIXED may also have difficulty determining the number of quadrature points if the initial starting values are far from the optimum values. To obtain more accurate starting values for the model parameters, one easy method is to fit a model with no RANDOM statement. You can then use these estimates as starting values, although you will still need to specify values for the random-effects distribution. For normal-normal models, another strategy is to use METHOD=FIRO. If you can obtain estimates using this approximate method, then they can be used as starting values for more accurate likelihood approximations.

If you are running PROC NLMIXED multiple times, you will probably want to include a statement like the following in your program:

```
ods output ParameterEstimates=pe;
```

This statement creates a SAS data set named PE upon completion of the run. In your next invocation of PROC NLMIXED, you can then specify

```
parms / data=pe;
```

to read in the previous estimates as starting values.

To speed general computations, you should check over your programming statements to minimize the number of floating point operations. Using auxiliary variables and factoring amenable expressions can be useful changes in this regard.

Problems Evaluating Code for Objective Function

The starting point $\theta^{(0)}$ must be a point for which the programming statements can be evaluated. However, during optimization, the optimizer may iterate to a point $\theta^{(k)}$ where the objective function or its derivatives cannot be evaluated. In some cases, the specification of boundary for parameters can avoid such situations. In many other cases, you can indicate that the point $\theta^{(0)}$ is a bad point simply by returning an extremely large value for the objective function. In these cases, the optimization algorithm reduces the step length and stays closer to the point that has been evaluated successfully in the former iteration.

No Convergence

There are a number of things to try if the optimizer fails to converge.

- Change the initial values by using a grid search specification to obtain a set of good feasible starting values.
- Change or modify the update technique or the line-search algorithm.

This method applies only to TECH=QUANEW and TECH=CONGRA. For example, if you use the default update formula and the default line-search algorithm, you can

- change the update formula with the UPDATE= option

- change the line-search algorithm with the LIS= option
- specify a more precise line search with the LSPRECISION= option, if you use LIS=2 or LIS=3
- Change the optimization technique.
For example, if you use the default option, TECH=QUANEW, you can try one of the second-derivative methods if your problem is small or the conjugate gradient method if it is large.
- Adjust finite difference derivatives.
The forward difference derivatives specified with the FD[=] or FDHESSIAN[=] option may not be precise enough to satisfy strong gradient termination criteria. You may need to specify the more expensive central difference formulas. The finite difference intervals may be too small or too big, and the finite difference derivatives may be erroneous.
- Double-check the data entry and program specification.

Convergence to Stationary Point

The gradient at a stationary point is the null vector, which always leads to a zero search direction. This point satisfies the first-order termination criterion. Search directions that are based on the gradient are zero, so the algorithm terminates. There are two ways to avoid this situation:

- Use the PARMS statement to specify a grid of feasible initial points.
- Use the OPTCHECK[=*r*] option to avoid terminating at the stationary point.

The signs of the eigenvalues of the (reduced) Hessian matrix contain information regarding a stationary point.

- If all of the eigenvalues are positive, the Hessian matrix is positive definite, and the point is a minimum point.
- If some of the eigenvalues are positive and all remaining eigenvalues are zero, the Hessian matrix is positive semidefinite, and the point is a minimum or saddle point.
- If all of the eigenvalues are negative, the Hessian matrix is negative definite, and the point is a maximum point.
- If some of the eigenvalues are negative and all of the remaining eigenvalues are zero, the Hessian matrix is negative semidefinite, and the point is a maximum or saddle point.
- If all of the eigenvalues are zero, the point can be a minimum, maximum, or saddle point.

Precision of Solution

In some applications, PROC NLMIXED may result in parameter values that are not precise enough. Usually, this means that the procedure terminated at a point too far from the optimal point. The termination criteria define the size of the termination region around the optimal point. Any point inside this region can be accepted for terminating the optimization process. The default values of the termination criteria are set to satisfy a reasonable compromise between the computational effort (computer time) and the precision of the computed estimates for the most common applications. However, there are a number of circumstances in which the default values of the termination criteria specify a region that is either too large or too small.

If the termination region is too large, then it can contain points with low precision. In such cases, you should determine which termination criterion stopped the optimization process. In many applications, you can obtain a solution with higher precision simply by using the old parameter estimates as starting values in a subsequent run in which you specify a smaller value for the termination criterion that was satisfied at the former run.

If the termination region is too small, the optimization process may take longer to find a point inside such a region, or it may not even find such a point due to rounding errors in function values and derivatives. This can easily happen in applications in which finite difference approximations of derivatives are used and the GCONV and ABSGCONV termination criteria are too small to respect rounding errors in the gradient values.

Covariance Matrix

The estimated covariance matrix of the parameter estimates is computed as the inverse Hessian matrix, and for unconstrained problems it should be positive definite. If the final parameter estimates are subjected to $n_{act} > 0$ active linear inequality constraints, the formulas of the covariance matrices are modified similar to Gallant (1987) and Cramer (1986, p. 38) and additionally generalized for applications with singular matrices.

There are several steps available that enable you to tune the rank calculations of the covariance matrix.

1. You can use the ASINGULAR=, MSINGULAR=, and VSINGULAR= options to set three singularity criteria for the inversion of the Hessian matrix H . The singularity criterion used for the inversion is

$$|d_{j,j}| \leq \max(\text{ASING}, \text{VSING} * |H_{j,j}|, \text{MSING} * \max(|H_{1,1}|, \dots, |H_{n,n}|))$$

where $d_{j,j}$ is the diagonal pivot of the matrix H , and ASING, VSING, and MSING are the specified values of the ASINGULAR=, VSINGULAR=, and MSINGULAR= options. The default values are

- ASING: the square root of the smallest positive double precision value
- MSING: 1E – 12 if you do not specify the SINGHESS= option and $\max(10\epsilon, 1\text{E-}4 * \text{SINGHESS})$ otherwise, where ϵ is the machine precision

- VSING: 1E – 8 if you do not specify the SINGHESS= option and the value of SINGHESS otherwise

Note that, in many cases, a normalized matrix $D^{-1}AD^{-1}$ is decomposed, and the singularity criteria are modified correspondingly.

2. If the matrix H is found to be singular in the first step, a generalized inverse is computed. Depending on the G4= option, either a generalized inverse satisfying all four Moore-Penrose conditions is computed or a generalized inverse satisfying only two Moore-Penrose conditions is computed. If the number of parameters n of the application is less than or equal to G4= i , a G4 inverse is computed; otherwise, only a G2 inverse is computed. The G4 inverse is computed by the (computationally very expensive but numerically stable) eigenvalue decomposition, and the G2 inverse is computed by Gauss transformation. The G4 inverse is computed using the eigenvalue decomposition $A = Z\Lambda Z^T$, where Z is the orthogonal matrix of eigenvectors and Λ is the diagonal matrix of eigenvalues, $\Lambda = \text{diag}(\lambda_1, \dots, \lambda_n)$. The G4 inverse of H is set to

$$A^- = Z\Lambda^-Z^T$$

where the diagonal matrix $\Lambda^- = \text{diag}(\lambda_1^-, \dots, \lambda_n^-)$ is defined using the COVSING= option.

$$\lambda_i^- = \begin{cases} 1/\lambda_i & \text{if } |\lambda_i| > \text{COVSING} \\ 0 & \text{if } |\lambda_i| \leq \text{COVSING} \end{cases}$$

If you do not specify the COVSING= option, the nr smallest eigenvalues are set to zero, where nr is the number of rank deficiencies found in the first step.

For optimization techniques that do not use second-order derivatives, the covariance matrix is computed using finite difference approximations of the derivatives.

Prediction

The nonlinear mixed model is a useful tool for statistical prediction. Assuming a prediction is to be made regarding the i th subject, suppose that $f(\theta, u_i)$ is a differentiable function predicting some quantity of interest. Recall that θ denotes the vector of unknown parameters and u_i denotes the vector of random effects for the i th subject. A natural point prediction is $f(\hat{\theta}, \hat{u}_i)$, where $\hat{\theta}$ is the maximum likelihood estimate of θ and \hat{u}_i is the empirical Bayes estimate of u_i described previously in “Integral Approximations.”

An approximate prediction variance matrix for $(\hat{\theta}, \hat{u}_i)$ is

$$P = \begin{bmatrix} \hat{H}^{-1} & \hat{H}^{-1} \left(\frac{\partial \hat{u}_i}{\partial \theta} \right)^T \\ \left(\frac{\partial \hat{u}_i}{\partial \theta} \right) \hat{H}^{-1} & \hat{\Gamma}^{-1} + \left(\frac{\partial \hat{u}_i}{\partial \theta} \right) \hat{H}^{-1} \left(\frac{\partial \hat{u}_i}{\partial \theta} \right)^T \end{bmatrix}$$

where \hat{H} is the approximate Hessian matrix from the optimization for $\hat{\theta}$, $\hat{\Gamma}$ is the approximate Hessian matrix from the optimization for \hat{u}_i , and $(\partial \hat{u}_i / \partial \theta)$ is the derivative

of \hat{u}_i with respect to θ , evaluated at $(\hat{\theta}, \hat{u}_i)$. The approximate variance matrix for $\hat{\theta}$ is the standard one discussed in the previous section, and that for \hat{u}_i is an approximation to the conditional mean squared error of prediction described by Booth and Hobert (1998).

The prediction variance for a general scalar function $f(\theta, u_i)$ is defined as the expected squared difference $E[f(\hat{\theta}, \hat{u}_i) - f(\theta, u_i)]^2$. PROC NLMIXED computes an approximation to it as follows. The derivative of $f(\theta, u_i)$ is computed with respect to each element of (θ, u_i) and evaluated at $(\hat{\theta}, \hat{u}_i)$. If a_i is the resulting vector, then the approximate prediction variance is $a_i^T P a_i$. This approximation is known as the delta method (Billingsley, 1986; Cox, 1998).

Computational Resources

Since nonlinear optimization is an iterative process that depends on many factors, it is difficult to estimate how much computer time is necessary to find an optimal solution satisfying one of the termination criteria. You can use the MAXTIME=, MAXITER=, and MAXFU= options to restrict the amount of CPU time, the number of iterations, and the number of function calls in a single run of PROC NLMIXED.

In each iteration k , the NRRIDG technique uses a symmetric Householder transformation to decompose the $n \times n$ Hessian matrix H

$$H = V^T T V, \quad V: \text{orthogonal}, \quad T: \text{tridiagonal}$$

to compute the (Newton) search direction s

$$s^{(k)} = -[H^{(k)}]^{-1} g^{(k)} \quad k = 1, 2, 3, \dots$$

The TRUREG and NEWRAP techniques use the Cholesky decomposition to solve the same linear system while computing the search direction. The QUANEW, DBLDOG, CONGRA, and NMSIMP techniques do not need to invert or decompose a Hessian matrix; thus, they require less computational resources than the other techniques.

The larger the problem, the more time is needed to compute function values and derivatives. Therefore, you may want to compare optimization techniques by counting and comparing the respective numbers of function, gradient, and Hessian evaluations.

Finite difference approximations of the derivatives are expensive because they require additional function or gradient calls:

- forward difference formulas
 - For first-order derivatives, n additional function calls are required.
 - For second-order derivatives based on function calls only, for a dense Hessian, $n + n^2/2$ additional function calls are required.
 - For second-order derivatives based on gradient calls, n additional gradient calls are required.

- central difference formulas
 - For first-order derivatives, $2n$ additional function calls are required.
 - For second-order derivatives based on function calls only, for a dense Hessian, $2n + 2n^2$ additional function calls are required.
 - For second-order derivatives based on gradient calls, $2n$ additional gradient calls are required.

Many applications need considerably more time for computing second-order derivatives (Hessian matrix) than for computing first-order derivatives (gradient). In such cases, a dual quasi-Newton technique is recommended, which does not require second-order derivatives.

Displayed Output

This section describes the displayed output from PROC NLMIXED. See the section “ODS Table Names” on page 3107 for details about how this output interfaces with the Output Delivery System.

Specifications

The NLMIXED procedure first displays the “Specifications” table, listing basic information about the nonlinear mixed model that you have specified. It includes the principal variables and estimation methods.

Dimensions

The “Dimensions” table lists counts of important quantities in your nonlinear mixed model, including the number of observations, subjects, parameters, and quadrature points.

Parameters

The “Parameters” table displays the information you provided with the PARMs statement and the value of the negative log likelihood function evaluated at the starting values.

Starting Gradient and Hessian

The START option in the PROC NLMIXED statement displays the gradient of the negative log likelihood function at the starting values of the parameters. If you also specify the HESS option, then the starting Hessian is displayed as well.

Iterations

The iteration history consists of one line of output for each iteration in the optimization process. The iteration history is displayed by default because it is important that you check for possible convergence problems. The default iteration history includes the following variables:

- Iter, the iteration number
- Calls, the number of function calls

- NegLogLike, the value of the objective function
- Diff, the difference between adjacent function values
- MaxGrad, the maximum of the absolute (projected) gradient components (except NMSIMP)
- Slope, the slope $g^T s$ of the search direction s at the current parameter iterate $\theta_{(k)}$ (QUANEW only)
- Rho, the ratio between the achieved and predicted value of Diff (NRRIDG only)
- Radius, the radius of the trust region (TRUREG only)
- StdDev, the standard deviation of the simplex values (NMSIMP only)
- Delta, the vertex length of the simplex (NMSIMP only)
- Size, the size of the simplex (NMSIMP only)

For the QUANEW method, the value of Slope should be significantly negative. Otherwise, the line-search algorithm has difficulty reducing the function value sufficiently. If this difficulty is encountered, an asterisk (*) appears after the iteration number. If there is a tilde (~) after the iteration number, the BFGS update is skipped, and very high values of the Lagrange function are produced. A backslash (\) after the iteration number indicates that Powell's correction for the BFGS update is used.

For methods using second derivatives, an asterisk (*) after the iteration number means that the computed Hessian approximation was singular and had to be ridged with a positive value.

For the NMSIMP method, only one line is displayed for several internal iterations. This technique skips the output for some iterations because some of the termination tests (StdDev and Size) are rather time consuming compared to the simplex operations, and they are performed only every five simplex operations.

The ITDETAILS option in the PROC NLMIXED statement provides a more detailed iteration history. Besides listing the current values of the parameters and their gradients, the following values are provided in addition to the default output:

- Restart, the number of iteration restarts
- Active, the number of active constraints
- Lambda, the value of the Lagrange multiplier (TRUREG and DBLDOG only)
- Ridge, the ridge value (NRRIDG only)
- Alpha, the line-search step size (QUANEW only)

An apostrophe (') trailing the number of active constraints indicates that at least one of the active constraints was released from the active set due to a significant Lagrange multiplier.

Fitting Information

The “Fitting Information” table lists the final minimized value of -2 times the log likelihood as well as the information criteria of Akaike (AIC) and Schwarz (BIC), as well as a finite-sample corrected version of AIC (AICC). The criteria are computed as follows:

$$\begin{aligned} AIC &= 2f(\hat{\theta}) + 2p \\ AICC &= 2f(\hat{\theta}) + 2pn/(n - p - 1) \\ BIC &= 2f(\hat{\theta}) + p \log(s) \end{aligned}$$

where $f()$ is the negative of the marginal log likelihood function, $\hat{\theta}$ is the vector of parameter estimates, p is the number of parameters, n is the number of observations, and s is the number of subjects. Refer to Hurvich and Tsai (1989) and Burnham and Anderson (1998) for additional details.

Parameter Estimates

The “Parameter Estimates” table lists the estimates of the parameter values after successful convergence of the optimization problem or the final values of the parameters under nonconvergence. If the problem did converge, standard errors are computed from the final Hessian matrix. The ratio of the estimate with its standard error produces a t value, with approximate degrees of freedom computed as the number of subjects minus the number of random effects. A p -value and confidence limits based on this t distribution are also provided. Finally, the gradient of the negative log likelihood function is displayed for each parameter, and you should verify that they each are sufficiently small for non-constrained parameters.

Covariance and Correlation Matrices

Following standard maximum likelihood theory (for example, Serfling 1980), the asymptotic variance-covariance matrix of the parameter estimates equals the inverse of the Hessian matrix. You can display this matrix with the COV option in the PROC NLMIXED statement. The corresponding correlation form is available with the CORR option.

Additional Estimates

The “Additional Estimates” table displays the results of all ESTIMATE statements that you specify, with the same columns as the “Parameter Estimates” table. The ECOV and ECORR options in the PROC NLMIXED statement produce tables displaying the approximate covariance and correlation matrices of the additional estimates. They are computed using the delta method (Billingsley 1986; Cox 1998). The EDER option in the PROC NLMIXED statement produces a table displaying the derivatives of the additional estimates with respect to the model parameters evaluated at their final estimated values.

ODS Table Names

PROC NL MIXED assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

Table 51.2. ODS Tables Produced in PROC NL MIXED

ODS Table Name	Description	Statement or Option
AdditionalEstimates	Results from ESTIMATE statements	ESTIMATE
ConvergenceStatus	Convergence status	default
CorrMatAddEst	Correlation matrix of additional estimates	ECORR
CorrMatParmEst	Correlation matrix of parameter estimates	CORR
CovMatAddEst	Covariance matrix of additional estimates	ECOV
CovMatParmEst	Covariance matrix of parameter estimates	COV
DerAddEst	Derivatives of additional estimates	EDER
Dimensions	Dimensions of the problem	default
FitStatistics	Fit statistics	default
Hessian	Second derivative matrix	HESS
IterHistory	Iteration history	default
Parameters	Parameters	default
ParameterEstimates	Parameter estimates	default
Specifications	Model specifications	default
StartingHessian	Starting hessian matrix	START HESS
StartingValues	Starting values and gradient	START

Examples

Example 51.1. One-Compartment Model with Pharmacokinetic Data

A popular application of nonlinear mixed models is in the field of pharmacokinetics, which studies how a drug disperses through a living individual. This example considers the theophylline data from Pinheiro and Bates (1995). Serum concentrations of the drug theophylline are measured in 12 subjects over a 25-hour period after oral administration. The data are as follows.

```
data theoph;
  input subject time conc dose wt;
  datalines;
1 0.00 0.74 4.02 79.6
1 0.25 2.84 4.02 79.6

Pinheiro and Bates (1995) consider the following first-order compartment model for these data:

$$C_{it} = \frac{Dk_{e_i}k_{a_i}}{Cl_i(k_{a_i} - k_{e_i})} [\exp(-k_{e_i}t) - \exp(-k_{a_i}t)] + e_{it}$$

where C_{it} is the observed concentration of the i th subject at time t , D is the dose of theophylline, k_{e_i} is the elimination rate constant for subject i , k_{a_i} is the absorption rate constant for subject i , Cl_i is the clearance for subject i , and e_{it} are normal errors. To allow for random variability between subjects, they assume

$$\begin{aligned} Cl_i &= \exp(\beta_1 + b_{i1}) \\ k_{a_i} &= \exp(\beta_2 + b_{i2}) \\ k_{e_i} &= \exp(\beta_3) \end{aligned}$$

where the β s denote fixed-effects parameters and the b_i s denote random-effects parameters with an unknown covariance matrix.

The PROC NLMIXED statements to fit this model are as follows.

```

proc nlmixed data=theoph;
  parms beta1=-3.22 beta2=0.47 beta3=-2.45
        s2b1=0.03 cb12=0 s2b2=0.4 s2=0.5;
  cl = exp(beta1 + b1);
  ka = exp(beta2 + b2);
  ke = exp(beta3);
  pred = dose*ke*ka*(exp(-ke*time)-exp(-ka*time))/cl/(ka-ke);
  model conc ~ normal(pred,s2);
  random b1 b2 ~ normal([0,0],[s2b1,cb12,s2b2]) subject=subject;
run;

```

The PARMs statement specifies starting values for the three β s and four variance-covariance parameters. The clearance and rate constants are defined using SAS programming statements, and the conditional model for the data is defined to be normal

with mean PRED and variance S2. The two random effects are B1 and B2, and their joint distribution is defined in the RANDOM statement. Brackets are used in defining their mean vector (two zeroes) and the lower triangle of their variance-covariance matrix (a general 2×2 matrix). The SUBJECT= variable is SUBJECT.

The results from this analysis are as follows.

The NL MIXED Procedure	
Specifications	
Data Set	WORK.THEOPH
Dependent Variable	conc
Distribution for Dependent Variable	Normal
Random Effects	b1 b2
Distribution for Random Effects	Normal
Subject Variable	subject
Optimization Technique	Dual Quasi-Newton
Integration Method	Adaptive Gaussian Quadrature

The “Specifications” table lists the set up of the model.

The NL MIXED Procedure	
Dimensions	
Observations Used	132
Observations Not Used	0
Total Observations	132
Subjects	12
Max Obs Per Subject	11
Parameters	7
Quadrature Points	5

The “Dimensions” table indicates that there are 132 observations, 12 subjects, and 7 parameters. PROC NL MIXED selects 5 quadrature points for each random effect, producing a total grid of 25 points over which quadrature is performed.

The NLMIXED Procedure

s2b2	0.8798	-6.98E-6	
s2	0.6540	6.133E-6	

The “Parameter Estimates” table contains the maximum likelihood estimates of the parameters. Both S2B1 and S2B2 are marginally significant, indicating between-subject variability in the clearances and absorption rate constants, respectively. There does not appear to be a significant covariance between them, as seen by the estimate of CB12.

The estimates of β_1 , β_2 , and β_3 are close to the adaptive quadrature estimates listed in Table 3 of Pinheiro and Bates (1995). However, Pinheiro and Bates use a Cholesky-root parameterization for the random-effects variance matrix and a logarithmic parameterization for the residual variance. The PROC NL MIXED statements using their parameterization are as follows, and results are similar.

```
proc nlmixed data=theoph;
  parms l11=-1.5 l12=0 l13=-0.1 beta1=-3 beta2=0.5 beta3=-2.5
    ls2=-0.7;
  s2 = exp(ls2);
  l1 = exp(l11);
  l3 = exp(l13);
  s2b1 = l1*l1*s2;
  cb12 = l2*l1*s2;
  s2b2 = (l2*l12 + l3*l13)*s2;
  c1 = exp(beta1 + b1);
  ka = exp(beta2 + b2);
  ke = exp(beta3);
  pred = dose*ke*ka*(exp(-ke*time)-exp(-ka*time))/c1/(ka-ke);
  model conc ~ normal(pred,s2);
  random b1 b2 ~ normal([0,0],[s2b1,cb12,s2b2]) subject=subject;
run;
```

Example 51.2. Probit-Normal Model with Binomial Data

For this example, consider the data from Weil (1970), also studied by Williams (1975), Ochi and Prentice (1984), and McCulloch (1994). In this experiment 16 pregnant rats receive a control diet and 16 receive a chemically treated diet, and the litter size for each rat is recorded after 4 and 21 days. The SAS data set is as follows.

```
data rats;
  input trt$ m x;
  if (trt='c') then do;
    x1 = 1;
    x2 = 0;
  end;
  else do;
    x1 = 0;
    x2 = 1;
  end;
  litter = _n_;
  datalines;

c 12 12
c 9 9
c 9 9
c 8 8
c 8 8
c 13 12
c 12 11
c 10 9
c 10 9
c 9 8
c 13 11
c 5 4
c 7 5
c 10 7
c 10 7
t 12 12
t 11 11
t 10 10
t 9 9
t 11 10
t 10 9
t 10 9
t 9 8
t 9 8
t 5 4
t 9 7
t 7 4
t 10 5
t 6 3
t 10 3
t 7 0
run;
```

Here, M represents the size of the litter after 4 days, and X represents the size of the litter after 21 days. Also, indicator variables X_1 and X_2 are constructed for the two treatment levels.

Following McCulloch (1994), assume a latent survival model of the form

$$y_{ijk} = t_i + \alpha_{ij} + e_{ijk}$$

where i indexes treatment, j indexes litter, and k indexes newborn rats within a litter. The t_i represent treatment means, the α_{ij} represent random litter effects assumed to be iid $N(0, s_i^2)$, and the e_{ijk} represent iid residual errors, all on the latent scale.

Instead of observing the survival times y_{ijk} , assume that only the binary variable indicating whether y_{ijk} exceeds 0 is observed. If x_{ij} denotes the sum of these binary variables for the i th treatment and the j th litter, then the preceding assumptions lead to the following generalized linear mixed model:

$$x_{ij} | \alpha_{ij} \sim \text{Binomial}(m_{ij}, p_{ij})$$

where m_{ij} is the size of each litter after 4 days and

$$p_{ij} = \Phi(t_i + \alpha_{ij})$$

The PROC NLMIXED statements to fit this model are as follows.

```
proc nlmixed data=rats;
  parms t1=1 t2=1 s1=.05 s2=1;
  eta = x1*t1 + x2*t2 + alpha;
  p = probnorm(eta);
  model x ~ binomial(m,p);
  random alpha ~ normal(0,x1*s1*s1+x2*s2*s2) subject=litter;
  estimate 'gamma2' t2/sqrt(1+s2*s2);
  predict p out=p;
run;
```

As in the previous example, the PROC NLMIXED statement invokes the procedure and the PARMs statement defines the parameters. The parameters for this example are the two treatment means, T_1 and T_2 , and the two random-effect standard deviations, S_1 and S_2 .

The indicator variables X_1 and X_2 are used in the program to assign the proper mean to each observation in the input data set as well as the proper variance to the random effects. Note that programming expressions are permitted inside the distributional specifications, as illustrated by the random-effects variance specified here.

The ESTIMATE statement requests an estimate of $\gamma_2 = t_2 / \sqrt{1 + s_2^2}$, which is a location-scale parameter from Ochi and Prentice (1984).

The PREDICT statement constructs predictions for each observation in the input data set. For this example, predictions of P and approximate standard errors of prediction are output to a SAS data set named P . These predictions are functions of the parameter estimates and the empirical Bayes estimates of the random effects α_i .

The output for this model is as follows.

The NLMIXED Procedure	
Specifications	
Data Set	WORK.RATS
Dependent Variable	x
Distribution for Dependent Variable	Binomial
Random Effects	alpha
Distribution for Random Effects	Normal
Subject Variable	litter
Optimization Technique	Dual Quasi-Newton

Parameter	Upper	Gradient
t1	1.6499	-0.00002
t2	1.5705	9.283E-6
s1	0.8552	0.000014
s2	1.6385	-3.16E-6

The “Parameter Estimates” table indicates significance of all of the parameters except S1.

The NLMIXED Procedure								
Additional Estimates								
Label	Estimate	Standard Error	DF	t Value	Pr > t	Alpha	Lower	Upper
gamma2	0.6603	0.2165	31	3.05	0.0047	0.05	0.2186	1.1019

The “Additional Estimates” table displays results from the ESTIMATE statement. The estimate of γ_2 equals 0.66, agreeing with that obtained by McCulloch (1994). The standard error 0.22 is computed using the delta method (Billingsley 1986; Cox, 1998).

Not shown is the P data set, which contains the original 32 observations and predictions of the p_{ij} .

Example 51.3. Probit-Normal Model with Ordinal Data

The data for this example are from Ezzet and Whitehead (1991), who describe a crossover experiment on two groups of patients using two different inhaler devices (A and B). Patients from group 1 used device A for one week and then device B for another week. Patients from group 2 used the devices in reverse order. The data entered as a SAS data set are as follows.

```

data inhaler;
  input clarity group time freq;
  gt = group*time;
  sub = floor((_n_+1)/2);
  datalines;

4 1 0 2
1 1 1 2
4 1 0 1
3 1 1 1
run;

```

The response measurement, CLARITY, is the patients' assessment on the clarity of the leaflet instructions for the devices. The CLARITY variable is on an ordinal scale, with 1=easy, 2=only clear after rereading, 3=not very clear, and 4=confusing. The GROUP variable indicates the treatment group and the TIME variable indicates the time of measurement. The FREQ variable indicates the number of patients with exactly the same responses. A variable GT is created to indicate a group by time interaction, and a variable SUB is created to indicate patients.

As in the previous example and in Hedeker and Gibbons (1994), assume an underlying latent continuous variable, here with the form

$$y_{ij} = \beta_0 + \beta_1 g_i + \beta_2 t_j + \beta_3 g_i t_j + u_i + e_{ij}$$

where i indexes patient and j indexes the time period, g_i indicates groups, t_j indicates time, u_i is a patient-level normal random effect, and e_{ij} are iid normal errors. The β s are unknown coefficients to be estimated.

Instead of observing y_{ij} , though, you observe only whether it falls in one of the four intervals: $(-\infty, 0)$, $(0, I_1)$, $(I_1, I_1 + I_2)$, or $(I_1 + I_2, \infty)$, where I_1 and I_2 are both positive. The resulting category is the value assigned to the CLARITY variable.

The following code sets up and fits this ordinal probit model:

```

proc nlmixed data=inhaler corr ecorr;
  parms b0=0 b1=0 b2=0 b3=0 sd=1 i1=1 i2=1;
  bounds i1 > 0, i2 > 0;
  eta = b0 + b1*group + b2*time + b3*gt + u;
  if (clarity=1) then p = probnorm(-eta);
  else if (clarity=2) then
    p = probnorm(i1-eta) - probnorm(-eta);
  else if (clarity=3) then
    p = probnorm(i1+i2-eta) - probnorm(i1-eta);
  else p = 1 - probnorm(i1+i2-eta);
  if (p > 1e-8) then ll = log(p);
  else ll = -1e100;
  model clarity ~ general(ll);
  random u ~ normal(0,sd*sd) subject=sub;
  replicate freq;
  estimate 'thresh2' i1;
  estimate 'thresh3' i1 + i2;
  estimate 'icc' sd*sd/(1+sd*sd);
run;

```

The PROC statement specifies the input data set and requests correlations both for the parameter estimates (CORR option) and the additional estimates specified with ESTIMATE statements (ECORR option).

The parameters as defined in the PARMs statement are as follows. B0 (overall intercept), B1 (group main effect), B2 (time main effect), B3 (group by time interaction), SD (standard deviation of the random effect), I1 (increment between first and second thresholds), and I2 (increment between second and third thresholds). The BOUNDS statement restricts I1 and I2 to be positive.

The SAS programming statements begin by defining the linear predictor ETA, which is a linear combination of the B parameters and a single random effect U. The next statements define the ordinal likelihood according to the CLARITY variable, ETA, and the increment variables. An error trap is included in case the likelihood becomes too small.

A general log likelihood specification is used in the MODEL statement, and the RANDOM statement defines the random effect U to have standard deviation SD and subject variable SUB. The REPLICATE statement indicates that data for each subject should be replicated according to the FREQ variable.

The ESTIMATE statements specify the second and third thresholds in terms of the increment variables (the first threshold is assumed to equal zero for model identifiability). Also computed is the intraclass correlation.

The output is as follows.

The NL MIXED Procedure	
Specifications	
Data Set	WORK.INHALER
Dependent Variable	clarity
Distribution for Dependent Variable	General
Random Effects	u
Distribution for Random Effects	Normal
Subject Variable	sub
Replicate Variable	freq
Optimization Technique	Dual Quasi-Newton
Integration Method	Adaptive Gaussian Quadrature

The “Specifications” table echoes some primary information specified for this non-linear mixed model.

The NL MIXED Procedure	
Dimensions	
Observations Used	38
Observations Not Used	0
Total Observations	38
Subjects	286
Max Obs Per Subject	2
Parameters	7
Quadrature Points	5

The “Dimensions” table reveals a total of 286 subjects, which is the sum of the values of the FREQ variable. Five quadrature points are selected for log likelihood evaluation.

Example 51.4. Poisson-Normal Model with Count Data

This example uses the pump failure data of Gaver and O’Muircheartaigh (1987). The number of failures and the time of operation are recorded for 10 pumps. Each of the pumps is classified into one of two groups corresponding to either continuous or intermittent operation. The data are as follows.

```
data pump;
  input y t group;
  pump = _n_;
  logtstd = log(t) - 2.4564900;
  datalines;
5  94.320 1
1  15.720 2
5  62.880 1
14 125.760 1
3   5.240 2
19 31.440 1
1   1.048 2
1   1.048 2
4   2.096 2
22 10.480 2
run;
```

Each row denotes data for a single pump, and the variable LOGTSTD contains the centered operation times.

Letting y_{ij} denote the number of failures for the j th pump in the i th group, Draper (1996) considers the following hierarchical model for these data:

$$\begin{aligned} y_{ij} | \lambda_{ij} &\sim \text{Poisson}(\lambda_{ij}) \\ \log \lambda_{ij} &= \alpha_i + \beta_i (\log t_{ij} - \overline{\log t}) + e_{ij} \\ e_{ij} | \sigma^2 &\sim \text{Normal}(0, \sigma^2) \end{aligned}$$

The model specifies different intercepts and slopes for each group, and the random effect is a mechanism for accounting for overdispersion.

The corresponding PROC NLMIXED statements are as follows.

```
proc nlmixed data=pump;
  parms logsig 0 beta1 1 beta2 1 alpha1 1 alpha2 1;
  if (group = 1) then eta = alpha1 + beta1*logtstd + e;
  else eta = alpha2 + beta2*logtstd + e;
  lambda = exp(eta);
  model y ~ poisson(lambda);
  random e ~ normal(0,exp(2*logsig)) subject=pump;
  estimate 'alpha1-alpha2' alpha1-alpha2;
  estimate 'beta1-beta2' beta1-beta2;
run;
```

The output is as follows.

The “Parameter Estimates” and “Additional Estimates” tables list the maximum likelihood estimates for each of the parameters and two differences. The point estimates for the mean parameters agree fairly closely with the Bayesian posterior means reported by Draper (1996); however, the likelihood-based standard errors are roughly half the Bayesian posterior standard deviations. This is most likely due to the fact that the Bayesian standard deviations account for the uncertainty in estimating σ^2 , whereas the likelihood values plug in its estimated value. This downward bias can be corrected somewhat by using the t_9 distribution shown here.

Example 51.5. Failure Time and Frailty Model

In this example an accelerated failure time model with proportional hazard is fitted with and without random effects. The data are from the “Getting Started” example of PROC LIFEREG, see Chapter 39, “The LIFEREG Procedure.” Thirty-eight patients are divided into two groups of equal size, and different pain relievers are assigned to each group. The outcome reported is the time in minutes until headache relief. The variable `sensor` indicates whether relief was observed during the course of the observation period (`sensor = 0`) or whether the observation is censored (`sensor = 1`).

```
data headache;
  input minutes group sensor @@;
  patient = _n_;
  datalines;
11 1 0 12 1 0 19 1 0 19 1 0
19 1 0 19 1 0 21 1 0 20 1 0
21 1 0 21 1 0 20 1 0 21 1 0
20 1 0 21 1 0 25 1 0 27 1 0
30 1 0 21 1 1 24 1 1 14 2 0
16 2 0 16 2 0 21 2 0 21 2 0
23 2 0 23 2 0 23 2 0 23 2 0
25 2 1 23 2 0 24 2 0 24 2 0
26 2 1 32 2 1 30 2 1 30 2 0
32 2 1 20 2 1
;
```

In modeling survival data, censoring of observations must be taken into account carefully. In this example, only right censoring occurs. If $g(t, \beta)$, $h(t, \beta)$, and $G(t, \beta)$ denote the density of failure, hazard function, and survival distribution function at time t , respectively, the log-likelihood can be written as

$$\begin{aligned} l(\beta; \mathbf{t}) &= \sum_{i \in U_u} \log f(t_i, \beta) + \sum_{i \in U_c} \log G(t_i, \beta) \\ &= \sum_{i \in U_u} \log h(t_i, \beta) + \sum_{i=1}^n \log G(t_i, \beta) \end{aligned}$$

Refer to Cox and Oakes (1984, ch. 3). In these expressions U_u is the set of uncensored observations, U_c is the set of censored observations, and n denotes the total sample size.

The proportional hazards specification expresses the hazard in terms of a baseline hazard, multiplied by a constant. In this example the hazard is that of a Weibull model and is parameterized as $h(t, \beta) = \gamma\alpha(\alpha t)^{\gamma-1}$ and $\alpha = \exp\{-\mathbf{x}'\beta\}$.

The linear predictor is set equal to the intercept in the reference group (`group = 2`); this defines the baseline hazard. The corresponding distribution of survival past time t is $G(t, \beta) = \exp\{-(\alpha t)^\gamma\}$. Refer to Cox and Oakes (1984, Table 2.1) and the

section “Supported Distributions” in Chapter 39, “The LIFEREG Procedure,” for this and other survival distribution models and various parameterizations.

The following NLMIXED statements fit this accelerated failure time model and estimate the cumulative distribution function of time to headache relief.

```
proc nlmixed data=headache;
  bounds gamma > 0;
  linp = b0 - b1*(group-2);
  alpha = exp(-linp);
  G_t = exp(-(alpha*minutes)**gamma);
  g = gamma*alpha*((alpha*minutes)**(gamma-1))*G_t;
  ll = (censor=0)*log(g) + (censor=1)*log(G_t);
  model minutes ~ general(ll);
  predict 1-G_t out=cdf;
run;
proc print data=cdf;
  var group censor patient minutes pred;
run;
```

BIC (smaller is better)	210.7

After 17 iterations and 34 evaluations of the objective function, the procedure converges.

The NLMIXED Procedure							
Parameter Estimates							
Parameter	Estimate	Standard Error	DF	t Value	Pr > t	Alpha	Lower
gamma	4.7128	0.6742	38	6.99	<.0001	0.05	3.3479
b0	3.3091	0.05885	38	56.23	<.0001	0.05	3.1900
b1	-0.1933	0.07856	38	-2.46	0.0185	0.05	-0.3523

Parameter Estimates		
Parameter	Upper	Gradient
gamma	6.0777	5.327E-8
b0	3.4283	-4.77E-6
b1	-0.03426	-1.22E-6

The parameter estimates and their standard errors are identical to those obtained with the LIFEREG procedure and the statements

```
proc lifereg data=headache;
  class group;
  model minutes*censor(1) = group / dist=weibull;
run;
```

The t statistic and confidence limits are based on 38 degrees of freedom. The LIFEREG procedure computes z -intervals for the parameter estimates.

For the two groups you obtain

$$\hat{\alpha}(\text{group} = 1) = \exp\{-3.3091 + 0.1933\} = 0.04434$$

$$\hat{\alpha}(\text{group} = 2) = \exp\{-3.3091\} = 0.03655$$

The probabilities of headache relief by t minutes are estimated as

$$1 - G(t, \text{group} = 1) = 1 - \exp\{-(0.04434 * t)^{4.7128}\}$$

$$1 - G(t, \text{group} = 2) = 1 - \exp\{-(0.03655 * t)^{4.7128}\}$$

These probabilities, calculated at the observed times, are shown for the two groups in [Output 51.5.2](#).

Output 51.5.2. Estimated Cumulative Distribution Function

37	2	1	37	32	0.87656
38	2	1	38	20	0.20414

Since the slope estimate is negative with p -value of 0.0185, you can infer that pain reliever 1 leads to overall significantly faster relief, but the estimated probabilities give no information about patient-to-patient variation within and between groups. For example, while pain reliever 1 provides faster relief overall, some patients in group 2 may respond more quickly than other patients in group 1. A frailty model enables you to accommodate and estimate patient-to-patient variation in health status by introducing random effects into a subject's hazard function.

The following statements model the hazard for patient i in terms of $\alpha_i = \exp\{-\mathbf{x}'_i\beta - z_i\}$, where z_i is a (normal) random patient effect. Notice that the only difference from the previous NLMIXED statements are the RANDOM statement and the addition of z in the linear predictor. The empirical Bayes estimates of the random effect (RANDOM statement), the parameter estimates (ODS OUTPUT statement), and the estimated cumulative distribution function (PREDICT statement) are saved to subsequently graph the patient-specific distribution functions.

```

ods output ParameterEstimates=est;
proc nlmixed data=headache;
  bounds gamma > 0;
  linp = b0 - b1*(group-2) + z;
  alpha = exp(-linp);
  G_t = exp(-(alpha*minutes)**gamma);
  g = gamma*alpha*((alpha*minutes)**(gamma-1))*G_t;
  ll = (censor=0)*log(g) + (censor=1)*log(G_t);
  model minutes ~ general(ll);
  random z ~ normal(0,exp(2*logsig)) subject=patient out=EB;
  predict 1-G_t out=cdf;
run;
proc print data=eb;
  var patient effect estimate stderrpred;
run;

```

Output 51.5.3. Analysis Results for Frailty Model

NOTE: GCONV convergence criterion satisfied.

The procedure converges after 15 iterations. The achieved -2 log likelihood is only 1.2 less than that in the model without random effects. Compared to a chi-square distribution with one degree of freedom, the addition of the random effect appears not to improve the model significantly. Care must be exercised, however, in the interpretation of likelihood ratio tests when the value under the null hypothesis falls on the boundary of the parameter space (refer to, for example, Self and Liang 1987).

The NLMIXED Procedure	
Fit Statistics	
-2 Log Likelihood	198.5
AIC (smaller is better)	206.5
AICC (smaller is better)	207.7
BIC (smaller is better)	213.0

The NLMIXED Procedure

The estimate of the Weibull parameter has changed drastically from the model without random effects. The variance of the patient random effect is $\exp\{-2 * 1.9027\} = 0.02225$. The next listing shows the empirical Bayes estimates of the random effects. These are the adjustments made to the linear predictor in order to obtain a patient's survival distribution.

The predicted values and patient-specific survival distributions can be plotted with the SAS code that follows.

```

data cdf; set cdf; symbolid = int((patient-1)/19);
proc transpose data=est(keep=estimate) out=trest;
data trest; set trest; rename coll=gamma col2=b0 col3=b1;
data pred; merge eb(keep=estimate)
                headache(keep=patient group);
if _n_ = 1 then merge trest(keep=gamma b0 b1);
do minutes=11 to 32;
  linp      = b0 - b1*(group-2) + estimate;
  pred      = 1-exp(- (exp(-linp)*minutes)**gamma);
  symbolid = patient+1;
  output;
end;
keep pred minutes symbolid;
run;

```

```

data pred; set cdf(keep=pred minutes symbolid) pred;
run;

axis1 label=(angle=90 rotate=0
             'Estimated Patient-specific CDF')
       minor=none;
axis2 label=('Minutes to Headache Relief' )
       minor=none order=(10 to 35 by 5);

symbol1 value=dot      c=black h=0.15in i=none r=1;
symbol2 value=circle   c=black h=0.15in i=none r=1;
symbol3 value=none     c=black l=1      i=join r=19;
symbol4 value=none     c=black l=2      i=join r=19;
proc gplot data=pred;
  plot pred*minutes=symbolid / frame cframe=ligr
       nolegend vaxis=axis1 haxis=axis2;
run;

```

The separation of the distribution functions by groups is evident in [Output 51.5.4](#). Most of the distributions of patients in the first group are to the left of the distributions in the second group. The separation is not complete, however. Several patients assigned the second pain reliever experience headache relief more quickly than patients assigned to the first group.

Output 51.5.4. Patient-Specific CDFs and Predicted Values. Pain Reliever 1: Solid Line, Closed Circles. Pain Reliever 2: Dashed Lines, Open Circles.

Chapter 52

The NPAR1WAY Procedure

Overview

The NPAR1WAY procedure performs nonparametric tests for location and scale differences across a one-way classification. PROC NPAR1WAY also provides a standard analysis of variance on the raw data and tests based on the empirical distribution function.

PROC NPAR1WAY performs tests for location and scale differences based on the following scores of a response variable: Wilcoxon, median, Van der Waerden, Savage, Siegel-Tukey, Ansari-Bradley, Klotz, and Mood scores. Additionally, PROC NPAR1WAY provides tests using the raw input data as scores. When the data are classified into two samples, tests are based on simple linear rank statistics. When the data are classified into more than two samples, tests are based on one-way ANOVA statistics. Both asymptotic and exact p -values are available for these tests.

PROC NPAR1WAY also provides empirical distribution function (EDF) statistics, which test whether the distribution of a variable is the same across different groups. These include the Kolmogorov-Smirnov test, the Cramer-von Mises test, and, when the data are classified into only two samples, the Kuiper test. Exact p -values are available for the two-sample Kolmogorov-Smirnov test.

Getting Started

This example illustrates how you can use PROC NPAR1WAY to perform a one-way nonparametric analysis. The data from Halverson and Sherwood (1932) consist of weight gain measurements for five different levels of gossypol additive. Gossypol is a substance contained in cottonseed shells, and these data were collected to study the effect of gossypol on animal nutrition.

The following DATA step statements create the SAS data set Gossypol:

```
data Gossypol;
  input Dose n;
  do i=1 to n;
    input Gain @@;
    output;
  end;
  datalines;
0 16
  228 229 218 216 224 208 235 229 233 219 224 220 232 200 208 232
.04 11
  186 229 220 208 228 198 222 273 216 198 213
.07 12
  179 193 183 180 143 204 114 188 178 134 208 196
.10 17
  130 87 135 116 118 165 151 59 126 64 78 94 150 160 122 110 178
```

```
.13 11
    154 130 130 118 118 104 112 134 98 100 104
;
```

The data set `Gossypol` contains the variable `Dose`, which represents the amount of gossypol additive, and the variable `Gain`, which represents the weight gain.

Researchers are interested in whether there is a difference in weight gain among the different dose levels of gossypol. The following statements invoke the `NPAR1WAY` procedure to perform a nonparametric analysis of this problem:

```
proc npar1way data=Gossypol;
    class Dose;
    var Gain;
run;
```

The variable `Dose` is the `CLASS` variable, and the `VAR` statement specifies the variable `Gain` is the response variable. The `CLASS` statement is required, and you must name only one `CLASS` variable. You may name one or more analysis variables in the `VAR` statement. If you omit the `VAR` statement, `PROC NPAR1WAY` analyzes all numeric variables in the data set except for the `CLASS` variable, the `FREQ` variable, and the `BY` variables.

Since no analysis options are specified in the `PROC NPAR1WAY` statement, the `ANOVA`, `WILCOXON`, `MEDIAN`, `VW`, `SAVAGE`, and `EDF` options are invoked by default. The following tables show the results of these analyses.

The tables in [Figure 52.1](#) are produced with the `ANOVA` option. For each level of the `CLASS` variable `Dose`, `PROC NPAR1WAY` displays the number of observations and the mean of the analysis variable `Gain`. `PROC NPAR1WAY` displays a standard analysis of variance on the raw data. This gives the same results as the `GLM` and `ANOVA` procedures. The p -value for the F test is $<.0001$, which indicates that `Dose` accounts for a significant portion of the variability in the dependent variable `Gain`.

Average scores were used for ties.					

Figure 52.1. Analysis of Variance

The WILCOXON option produces the output in [Figure 52.2](#). PROC NPAR1WAY first provides a summary of the Wilcoxon scores for the analysis variable Gain by class level. For each level of the CLASS variable Dose, PROC NPAR1WAY displays the following information: number of observations, sum of the Wilcoxon scores, expected sum under the null hypothesis of no difference among class levels, standard deviation under the null hypothesis, and mean score.

Next PROC NPAR1WAY displays the one-way ANOVA statistic, which for Wilcoxon scores is known as the Kruskal-Wallis test. The statistic equals 52.6656, with four degrees of freedom, which is the number of class levels minus one. The p -value, or probability of a larger statistic under the null hypothesis, is $<.0001$. This leads to rejection of the null hypothesis that there is no difference in location for Gain among the levels of Dose. This p -value is asymptotic, computed from the asymptotic chi-square distribution of the test statistic. For certain data sets it may also be useful to compute the exact p -value; for example, for small data sets, or data sets that are sparse, skewed, or heavily tied. You can use the EXACT statement to request exact p -values for any of the location or scale tests available in PROC NPAR1WAY.

Wilcoxon Scores (Rank Sums) for Variable Gain Classified by Variable Dose					
Dose	N	Sum of Scores	Expected Under H0	Std Dev Under H0	Mean Score
0	16	890.50	544.0	67.978966	55.656250
0.04	11	555.00	374.0	59.063588	50.454545

Figure 52.2. Wilcoxon Score Analysis

[Figure 52.3](#) through [Figure 52.5](#) display the analyses produced by the MEDIAN, VW, and SAVAGE options. For each score type, PROC NPAR1WAY provides a summary of scores and the one-way ANOVA statistic, as previously described for Wilcoxon scores. Other score types available in PROC NPAR1WAY are Siegel-Tukey, Ansari-Bradley, Klotz, and Mood, which are used to test for scale differences. Additionally, you can request the SCORES=DATA option, which uses the input data as scores. This option gives you the flexibility to construct any scores for your data with the DATA step and then analyze these scores with PROC NPAR1WAY.

Median Scores (Number of Points Above Median) for Variable Gain Classified by Variable Dose

Figure 52.6. Empirical Distribution Function Analysis

The tables in [Figure 52.6](#) display the empirical distribution function statistics, comparing the distribution of `Gain` for the different levels of `Dose`. These tables are produced by the `EDF` option, and they include Kolmogorov-Smirnov statistics and Cramer-von Mises statistics.

In the preceding example, the `CLASS` variable `Dose` has five levels, and the analyses examine possible differences among these five levels, or samples. The following statements invoke the `NPAR1WAY` procedure to perform a nonparametric analysis of the two lowest levels of `Dose`:

```
proc npar1way data=Gossypol;
  where Dose <= .04;
  class Dose;
  var Gain;
run;
```

The following tables show the results of this two-sample analysis. The tables in [Figure 52.7](#) are produced by the `ANOVA` option.

The NPAR1WAY Procedure

Figure 52.8. Wilcoxon Two-Sample Analysis

Figure 52.8 displays the output produced by the WILCOXON option. PROC NPAR1WAY provides a summary of the Wilcoxon scores for the analysis variable Gain for each of the two class levels. Since there are only two levels, PROC NPAR1WAY displays the two-sample test, based on the simple linear rank statistic with Wilcoxon scores. The normal approximation includes a continuity correction. To remove this, you can specify the CORRECT=NO option. PROC NPAR1WAY also gives a *t* approximation for the Wilcoxon two-sample test. And as for the multisample analysis, PROC NPAR1WAY computes a one-way ANOVA statistic, which for Wilcoxon scores is known as the Kruskal-Wallis test. All these *p*-values show no difference in Gain for the two Dose levels at the .05 level of significance.

Figure 52.9 through Figure 52.11 display the two-sample analyses produced by the MEDIAN, VW, and SAVAGE options.

Figure 52.12. Two-Sample EDF Tests

The tables in [Figure 52.12](#) display the empirical distribution function statistics, comparing the distribution of **Gain** for the two levels of **Dose**. The p -value for the Kolmogorov-Smirnov two-sample test is 0.6199, which indicates no rejection of the null hypothesis that the **Gain** distributions are identical for the two levels of **Dose**.

Syntax

The following statements are available in PROC NPAR1WAY:

```

PROC NPAR1WAY < options > ;
  BY variables ;
  CLASS variable ;
  EXACT statistic-options < / computation-options > ;
  FREQ variable ;
  OUTPUT < OUT=SAS-data-set > < options > ;
  VAR variables ;

```

Both the PROC NPAR1WAY statement and the CLASS statement are required for the NPAR1WAY procedure. The rest of this section gives detailed syntax information for the BY, CLASS, EXACT, FREQ, OUTPUT, and VAR statements in alphabetical order after the description of the PROC NPAR1WAY statement. [Table 52.1](#) summarizes the basic function of each PROC NPAR1WAY statement.

Table 52.1. Summary of PROC NPAR1WAY Statements

Statement	Description
BY	provides separate analyses for each BY group
CLASS	identifies the classification variable
EXACT	requests exact tests
FREQ	identifies a frequency variable
OUTPUT	requests an output data set
VAR	identifies analysis variables

PROC NPAR1WAY Statement

```

PROC NPAR1WAY < options > ;

```

The PROC NPAR1WAY statement invokes the procedure and optionally identifies the input data set or requests particular analyses. By default, the procedure uses the most recently created SAS data set and omits missing values from the analysis. If you do not specify any analysis options, PROC NPAR1WAY performs an analysis of variance (option ANOVA), tests for location differences (options WILCOXON, MEDIAN, SAVAGE, and VW), and performs empirical distribution function tests (option EDF).

The following table lists the options available with the PROC NPAR1WAY statement. Descriptions follow in alphabetical order.

Table 52.2. PROC NPAR1WAY Statement Options

Task	Options
Specify the input data set	DATA=
Include missing CLASS values	MISSING
Suppress all displayed output	NOPRINT
Request analyses	AB ANOVA D EDF KLOTZ MEDIAN MOOD SAVAGE SCORES=DATA ST VW WILCOXON
Suppress continuity correction	CORRECT=NO

You can specify the following options in the PROC NPAR1WAY statement:

AB

requests an analysis using Ansari-Bradley scores. See the section “[Ansari-Bradley Scores](#)” on page 3168 for more information.

ANOVA

requests a standard analysis of variance on the raw data.

CORRECT=NO

suppresses the continuity correction for the Wilcoxon two-sample test and the Siegel-Tukey two-sample test. See the section “[Simple Linear Rank Tests for Two-Sample Data](#)” on page 3163 for more information.

D

requests the one-sided Kolmogorov-Smirnov $D+$ and $D-$ statistics and their asymptotic p -values, in addition to the two-sided D statistic produced by the EDF option for two-sample data. The D option invokes the EDF option. The statistics $D+$ and $D-$ are provided automatically if you request exact Kolmogorov-Smirnov statistics with the KS option in the EXACT statement for two-sample data. See the section “[Tests Based on the Empirical Distribution Function](#)” on page 3168 for details on Kolmogorov-Smirnov statistics.

DATA=SAS-data-set

names the SAS data set to be analyzed by PROC NPAR1WAY. If you omit the DATA= option, the procedure uses the most recently created SAS data set.

EDF

requests statistics based on the empirical distribution function. These include the Kolmogorov-Smirnov and Cramer-von Mises tests and, if there are only two classification levels, the Kuiper test. See the section [“Tests Based on the Empirical Distribution Function”](#) on page 3168 for more information.

The EDF option produces the Kolmogorov-Smirnov D statistic for two-sample data. You can also request the one-sided $D+$ and $D-$ statistics for two-sample data with the **D** option.

KLOTZ

requests an analysis using Klotz scores. See the section [“Klotz Scores”](#) on page 3168 for more information.

MEDIAN

requests an analysis using median scores. When there are two classification levels, or two samples, this option produces the two-sample median test. When there are more than two samples, this option produces the multisample median test, which is also known as the Brown-Mood test. See the section [“Median Scores”](#) on page 3167 for more information.

MISSING

treats missing values of the CLASS variable as a valid class level.

MOOD

requests an analysis using Mood scores. See the section [“Mood Scores”](#) on page 3168 for more information.

NOPRINT

suppresses the display of all output. You can use the NOPRINT option when you only want to create an output data set. Note that this option temporarily disables the Output Delivery System (ODS). For more information, see [Chapter 14, “Using the Output Delivery System.”](#)

SAVAGE

requests an analysis using Savage scores. See the section [“Savage Scores”](#) on page 3167 for more information.

SCORES=DATA

requests an analysis using input data as scores. This option gives you the flexibility to construct any scores for your data with the DATA step and then analyze these scores with PROC NPAR1WAY. See the section [“Scores for Linear Rank and One-Way ANOVA Tests”](#) on page 3166 for more information. Using the SCORES=DATA option for raw (unscored) two-sample data produces a permutation test known as Pitman’s test.

ST

requests an analysis using Siegel-Tukey scores. See the section [“Siegel-Tukey Scores”](#) on page 3167 for more information.

VW

requests an analysis using Van der Waerden scores. See the section “[Van der Waerden Scores](#)” on page 3167 for more information.

WILCOXON

requests an analysis using Wilcoxon scores. When there are two classification levels, or two samples, this option produces the Wilcoxon rank-sum test. For any number of classification levels, this option produces the Kruskal-Wallis test. See the section “[Wilcoxon Scores](#)” on page 3166 for more information.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC NPAR1WAY to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the NPAR1WAY procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure.

For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

CLASS Statement

CLASS *variable* ;

The CLASS statement, which is required, names one and only one classification variable. The variable can be character or numeric. The CLASS variable identifies groups (or samples) in the data, and PROC NPAR1WAY provides analyses to examine differences among these groups. There may be two or more groups in the data.

EXACT Statement

EXACT *statistic-options* < / *computation-options* > ;

The EXACT statement requests exact tests for the specified statistics. Optionally, PROC NPAR1WAY computes Monte Carlo estimates of the exact p -values. The *statistic-options* specify the statistics for which to provide exact tests, and the *computation-options* specify options for the computation of exact statistics.

CAUTION: PROC NPAR1WAY computes exact tests with fast and efficient algorithms that are superior to direct enumeration. Exact tests are appropriate when a data set is small, sparse, skewed, or heavily tied. For some large problems, computation of exact tests may require a large amount of time and memory. Consider using asymptotic tests for such problems. Alternatively, when asymptotic methods may not be sufficient for such large problems, consider using Monte Carlo estimation of exact p -values. See the section “[Computational Resources](#)” on page 3173 for more information.

Statistic-Options

The *statistic-options* specify the statistics for which to provide exact tests.

Exact p -values are available for all nonparametric tests of location and scale differences produced by PROC NPAR1WAY. These include tests based on the following scores: Wilcoxon, median, Van der Waerden, Savage, Siegel-Tukey, Ansari-Bradley, Klotz, and Mood scores. Additionally, exact p -values are available for tests using the raw input data as scores. The procedure computes exact p -values when the data are classified into two levels (two-sample tests) and when the data are classified into more than two levels (multisample tests). Two-sample tests are based on simple linear rank statistics. Multisample tests are based on one-way ANOVA statistics. Exact p -values are also available for the two-sample Kolmogorov-Smirnov test. See the section “[Exact Tests](#)” on page 3171 for details.

[Table 52.3](#) lists the available *statistic-options* and the exact tests computed. The option names are identical to the corresponding options in the PROC NPAR1WAY statement and the OUTPUT statement.

If you list no *statistic-options* in the EXACT statement, then PROC NPAR1WAY computes all the available exact p -values for those tests requested in the PROC NPAR1WAY statement.

Table 52.3. EXACT Statement Statistic-Options

Option	Exact Test Computed
AB	Ansari-Bradley Test
KLOTZ	Klotz Test
KS	Two-Sample Kolmogorov-Smirnov Test
MEDIAN	Median Test
MOOD	Mood Test
SAVAGE	Savage Test
SCORES=DATA	Test Using Input Data as Scores
ST	Siegel-Tukey Test
WILCOXON	Wilcoxon Test for Two-Sample Data
	Kruskal-Wallis Test for Multisample Data
VW	Van der Waerden Test

Computation-Options

The *computation-options* specify options for computation of exact statistics. You can specify the following *computation-options* in the EXACT statement:

ALPHA= α

specifies the level of the confidence limits for Monte Carlo p -value estimates. The value of the ALPHA= option must be between 0 and 1, and the default is 0.01. A confidence level of α produces $100(1 - \alpha)\%$ confidence limits. The default of ALPHA=0.01 produces 99% confidence limits for the Monte Carlo estimates. The ALPHA= option invokes the MC option.

MAXTIME=*value*

specifies the maximum clock time (in seconds) that PROC NPAR1WAY can use to compute an exact p -value. If the procedure does not complete the computation within the specified time, the computation terminates. The value of the MAXTIME= option must be a positive number. The MAXTIME= option is valid for Monte Carlo estimation of exact p -values, as well as for direct exact p -value computation.

See the section “[Computational Resources](#)” on page 3173 for more information.

MC

requests Monte Carlo estimation of exact p -values, instead of direct exact p -value computation. Monte Carlo estimation can be useful for large problems that require a great amount of time and memory for exact computations but for which asymptotic approximations may not be sufficient. See the section “[Monte Carlo Estimation](#)” on page 3174 for more information.

The MC option is available for all the EXACT statement *statistic-options*. The ALPHA=, N=, and SEED= options also invoke the MC option.

N= n

specifies the number of samples for Monte Carlo estimation. The value of the N= option must be a positive integer, and the default is 10,000 samples. Larger values of n produce more precise estimates of exact p -values. Because larger values of n generate more samples, the computation time increases. The N= option invokes the MC option.

POINT

requests exact point probabilities for the test statistics.

The POINT option is available for all the EXACT statement *statistic-options*. The POINT option is not available with the MC option.

SEED=number

specifies the initial seed for random number generation for Monte Carlo estimation. The value of the SEED= option must be an integer. If you do not specify the SEED= option, or if the SEED= value is negative or zero, PROC NPAR1WAY uses the time of day from the computer's clock to obtain the initial seed. The SEED= option invokes the MC option.

FREQ Statement

FREQ *variable* ;

The FREQ statement names a numeric variable that provides a frequency for each observation in the DATA= data set. If you use a FREQ statement, PROC NPAR1WAY assumes that an observation occurs n times, where n is the value of the FREQ variable for that observation. The sum of the FREQ variable values represents the total number of observations, and the analysis is based on this expanded number of observations.

If the value of the FREQ variable is missing or is less than one, PROC NPAR1WAY does not use that observation in the analysis. If the value of the FREQ variable is not an integer, PROC NPAR1WAY uses only the integer portion as the frequency of the observation.

OUTPUT Statement

OUTPUT < **OUT=SAS-data-set** > < *options* > ;

The OUTPUT statement creates a SAS data set containing statistics computed by PROC NPAR1WAY. You specify which statistics to store in the output data set, using options identical to those used in the PROC NPAR1WAY statement. The output data set contains one observation for each analysis variable named in the VAR statement. For more information on the contents of the output data set, see the section “[Output Data Set](#)” on page 3175.

Note that you can use the Output Delivery System (ODS) to create a SAS data set from any piece of PROC NPAR1WAY output. For more information, see [Table 52.6](#) on page 3184 and [Chapter 14](#), “Using the Output Delivery System.”

You can specify the following options in the OUTPUT statement:

OUT=SAS-data-set

names the output data set. If you omit the OUT= option, the data set is named DATA n , where n is the smallest integer that makes the name unique.

options

specifies the statistics you want in the new data set. The options are identical to those used in the PROC NPAR1WAY statement to request analyses. [Table 52.4](#) shows the available options. When you specify one of these options in the OUTPUT statement,

the output data set contains statistics from that analysis. See the section “[Output Data Set](#)” on page 3175 for a list of the output data set variables corresponding to each option.

If you do not specify any statistics options in the OUTPUT statement, then the output data set includes statistics from all analyses specified in the PROC NPAR1WAY statement.

Table 52.4. OUTPUT Statement Options

Option	Output Data Set Statistics
AB	Ansari-Bradley Test
ANOVA	Standard analysis of variance
EDF	Kolmogorov-Smirnov Test
	Cramer-von Mises Test
	Kuiper Test for Two-Sample Data
KLOTZ	Klotz Test
MEDIAN	Median Test
MOOD	Mood Test
SAVAGE	Savage Test
SCORES=DATA	Test Using Input Data as Scores
ST	Siegel-Tukey Test
WILCOXON	Wilcoxon Test for Two-Sample Data
	Kruskal-Wallis Test
VW	Van der Waerden Test

VAR Statement

VAR *variables* ;

The VAR statement names the response or dependent variables to be analyzed. These variables must be numeric. If the VAR statement is omitted, the procedure analyzes all numeric variables in the data set except for the CLASS variable, the FREQ variable, and the BY variables.

Details

Missing Values

If an observation has a missing value for a response variable, PROC NPAR1WAY excludes that observation from the analysis.

By default, PROC NPAR1WAY excludes observations with missing values of the CLASS variable. If you specify the [MISSING](#) option, PROC NPAR1WAY treats missing values of the CLASS variable as a valid class level and includes these observations in the analysis.

PROC NPAR1WAY treats missing BY variable values like any other BY variable value. The missing values form a separate BY group. When a value of the FREQ variable is missing, PROC NPAR1WAY excludes the observation from the analysis.

Tied Values

Tied values occur when two or more observations are equal, whether the observations occur in the same sample or in different samples. In theory, nonparametric tests were developed for continuous distributions where the probability of a tie is zero. In practice, however, ties often occur. PROC NPAR1WAY uses the same method to handle ties for all score types. The procedure computes the scores as if there were no ties, averages the scores for tied observations, and assigns this average score to each observation with the same value.

When there are tied values, PROC NPAR1WAY first sorts the observations in ascending order and assigns ranks as if there were no ties. Then the procedure computes the scores based on these ranks, using the formula for the specified score type. The procedure averages the scores for tied observations and assigns this average score to each of the tied observations. Thus, all equal data values have the same score value. PROC NPAR1WAY then computes the test statistic from these scores.

Note that the asymptotic tests may be less accurate when the distribution of the data is heavily tied. For such data, it may be appropriate to use the exact tests provided by PROC NPAR1WAY as described in the section “[Exact Tests](#)” on page 3171.

When computing empirical distribution function statistics for data with ties, PROC NPAR1WAY uses the formulas given in the section “[Tests Based on the Empirical Distribution Function](#)” on page 3168. No special handling of ties is necessary.

Note that PROC NPAR1WAY bases its computations on the internal numeric values of the analysis variables; the procedure does not format or round these values before analysis. When values differ in their internal representation, even slightly, PROC NPAR1WAY does not treat them as tied values. If this is a concern for your data, then round the analysis variables by an appropriate amount before invoking PROC NPAR1WAY. For information on the ROUND function, refer to the discussion in *SAS Language Reference: Dictionary*.

Statistical Computations

Simple Linear Rank Tests for Two-Sample Data

Statistics of the form

$$S = \sum_{j=1}^n c_j a(R_j)$$

are called *simple linear rank statistics*, where

R_j is the rank of the observation j

$a(R_j)$ is the score based on that rank

c_j is an indicator variable denoting the class to which the j th observation belongs

n is the total number of observations

For two-sample data (where the observations are classified into two levels), PROC NPAR1WAY calculates simple linear rank statistics for the scores that you specify. The section “[Scores for Linear Rank and One-Way ANOVA Tests](#)” on page 3166 describes the available scores, which you can use to test for differences in location and differences in scale.

To compute S , PROC NPAR1WAY sums the scores of the observations in the smaller of the two samples. If both samples have the same number of observations, PROC NPAR1WAY sums those scores for the sample that appears first in the input data set.

For each score that you specify, PROC NPAR1WAY computes an asymptotic test of the null hypothesis of no difference between the two classification levels. Exact tests are also available for these two-sample linear rank statistics. PROC NPAR1WAY computes exact tests for each score type that you specify in the **EXACT** statement. See the section “[Exact Tests](#)” on page 3171 for details.

To compute an asymptotic test for a linear rank sum statistic, PROC NPAR1WAY uses a standardized test statistic z , which has an asymptotic standard normal distribution under the null hypothesis. The standardized test statistic is computed as

$$z = \frac{S - E_0(S)}{\sqrt{Var_0(S)}}$$

where $E_0(S)$ is the expected value of S under the null hypothesis, and $Var_0(S)$ is the variance under the null hypothesis. As shown in Randles and Wolfe (1979),

$$E_0(S) = \frac{n_1}{n} \sum_{j=1}^n a(R_j)$$

where n_1 is the number of observations in the first (smaller) class level or sample, n_2 is the number of observations in the other class level, and

$$Var_0(S) = \frac{1}{(n-1)} \frac{n_1 n_2}{n} \left[\sum_{j=1}^n (a(R_j) - \bar{a})^2 \right]$$

where \bar{a} is the average score,

$$\bar{a} = \sum_{j=1}^n a(R_j) / n$$

PROC NPAR1WAY computes one-sided and two-sided asymptotic p -values for each two-sample linear rank test. When the test statistic z is greater than its null hypothesis expected value of zero, PROC NPAR1WAY computes the right-sided p -value, which is the probability of a larger value of the statistic occurring under the null hypothesis. When the test statistic is less than or equal to zero, PROC NPAR1WAY computes the

left-sided p -value, which is the probability of a smaller value of the statistic occurring under the null hypothesis. The one-sided p -value P_1 can be expressed as

$$P_1 = \text{Prob} (Z > z) \quad \text{if } z > 0$$

$$P_1 = \text{Prob} (Z < z) \quad \text{if } z \leq 0$$

where Z has a standard normal distribution. The two-sided p -value P_2 is computed as

$$P_2 = \text{Prob} (|Z| > |z|)$$

For Wilcoxon scores and Siegel-Tukey scores, PROC NPAR1WAY incorporates a continuity correction when computing the standardized test statistic z , unless you specify the **CORRECT=NO** option. PROC NPAR1WAY applies the continuity correction by subtracting 0.5 from the numerator $S - E_0(S)$ if it is greater than zero. If the numerator is less than zero, PROC NPAR1WAY adds 0.5. Some sources recommend a continuity correction for nonparametric tests that use a continuous distribution to approximate a discrete distribution. Refer to Sheskin (1997). If you specify **CORRECT=NO**, PROC NPAR1WAY does not use a continuity correction for any test.

One-Way ANOVA Tests

PROC NPAR1WAY computes a one-way ANOVA test for each score type that you specify. Under the null hypothesis of no difference among class levels (or samples), this test statistic has an asymptotic chi-square distribution with $r - 1$ degrees of freedom, where r is the number of class levels. For Wilcoxon scores, this test is known as the Kruskal-Wallis test.

Exact one-way ANOVA tests are also available for multisample data (where the data are classified into more than two levels). For two-sample data, exact simple linear rank tests are available. PROC NPAR1WAY computes exact tests for each score type that you specify in the **EXACT** statement. See the section “Exact Tests” on page 3171 for details on exact tests.

PROC NPAR1WAY computes the one-way ANOVA test statistic as

$$C = \left(\sum_{i=1}^r (T_i - E_0(T_i))^2 / n_i \right) / S^2$$

where T_i is the total of scores for the class level i , $E_0(T_i)$ is the expected total for level i under the null hypothesis of no difference among levels, n_i is the number of observations in level i , and S^2 is the sample variance of the scores.

$$T_i = \sum_{j=1}^n c_{ij} a(R_j)$$

where $a(R_j)$ is the score for observation j , and c_{ij} indicates whether observation j is in level i .

$$E_0(T_i) = \frac{n_i}{n} \sum_{j=1}^n a(R_j)$$

$$S^2 = \frac{1}{(n-1)} \left[\sum_{j=1}^n (a(R_j) - \bar{a})^2 \right]$$

where \bar{a} is the average score,

$$\bar{a} = \sum_{j=1}^n a(R_j) / n$$

Scores for Linear Rank and One-Way ANOVA Tests

For each score type that you specify, PROC NPAR1WAY computes a one-way ANOVA statistic and also a linear rank statistic for two-sample data. The following score types are used primarily to test for differences in location: Wilcoxon, median, Van der Waerden, and Savage. The following scores types are used to test for scale differences: Siegel-Tukey, Ansari-Bradley, Klotz, and Mood. This section gives formulas for the score types. For further information on the formulas and the applicability of each score, refer to Randles and Wolfe (1979), Gibbons and Chakraborti (1992), Conover (1999), and Hollander and Wolfe (1999).

In addition to the score types described in this section, you can specify the `SCORES=DATA` option to use the input data observations as scores. This enables you to produce a very wide variety of tests. You can construct any scores using the `DATA` step, and then PROC NPAR1WAY computes the corresponding linear rank and one-way ANOVA tests. You can also analyze the raw data with the `SCORES=DATA` option; for two-sample data, this permutation test is known as Pitman's test.

Wilcoxon Scores

Wilcoxon scores are the ranks of the observations.

$$a(R_j) = R_j$$

Using Wilcoxon scores in the linear rank statistic for two-sample data produces the rank sum statistic of the Mann-Whitney-Wilcoxon test. Using Wilcoxon scores in the one-way ANOVA statistic produces the Kruskal-Wallis test. Wilcoxon scores are locally most powerful for location shifts of a logistic distribution.

When computing the asymptotic Wilcoxon two-sample test, PROC NPAR1WAY uses a continuity correction by default, as described in the section “[Simple Linear Rank Tests for Two-Sample Data](#)” on page 3163. If you specify `CORRECT=NO` in the PROC NPAR1WAY statement, the procedure does not use a continuity correction.

Median Scores

Median scores equal 1 for observations greater than the median, and 0 otherwise.

$$a(R_j) = \begin{cases} 1 & \text{if } R_j > \frac{n+1}{2} \\ 0 & \text{if } R_j \leq \frac{n+1}{2} \end{cases}$$

Using median scores in the linear rank statistic for two-sample data produces the two-sample median test. The one-way ANOVA statistic with median scores is equivalent to the Brown-Mood test. Median scores are particularly powerful for distributions that are symmetric and heavy-tailed.

Van der Waerden Scores

Van der Waerden scores are the quantiles of a standard normal distribution. These scores are also known as *quantile normal scores*.

$$a(R_j) = \Phi^{-1} \left(\frac{R_j}{n+1} \right)$$

where Φ is the cumulative distribution function of a standard normal distribution. These scores are powerful for normal distributions.

Savage Scores

Savage scores are expected values of order statistics from the exponential distribution, with 1 subtracted to center the scores around 0.

$$a(R_j) = \sum_{i=1}^{R_j} \frac{1}{n-i+1} - 1$$

Savage scores are powerful for comparing scale differences in exponential distributions or location shifts in extreme value distributions (Hajek 1969, p. 83).

Siegel-Tukey Scores

Siegel-Tukey scores are computed as

$$\begin{aligned} a(1) &= 1, & a(n) &= 2, & a(n-1) &= 3, & a(2) &= 4, \\ a(3) &= 5, & a(n-2) &= 6, & a(n-3) &= 7, & a(4) &= 8, \dots \end{aligned}$$

where the score values continue to increase in this pattern towards the middle ranks until all observations have been assigned a score.

Ansari-Bradley Scores

Ansari-Bradley scores are similar to Siegel-Tukey scores, but Ansari-Bradley assigns the same scores to corresponding extreme ranks. (Siegel Tukey scores are just a permutation of the ranks $1, 2, \dots, n$.)

$$\begin{aligned} a(1) &= 1, & a(n) &= 1, \\ a(2) &= 2, & a(n-1) &= 2, \dots \end{aligned}$$

Equivalently, Ansari-Bradley scores are defined as

$$a(R_j) = \frac{n+1}{2} - \left| R_j - \frac{n+1}{2} \right|$$

Klotz Scores

Klotz scores are the squares of the Van der Waerden (or quantile normal) scores.

$$a(R_j) = \left[\Phi^{-1} \left(\frac{R_j}{n+1} \right) \right]^2$$

where Φ is the cumulative distribution function of a standard normal distribution.

Mood Scores

Mood scores are computed as the square of the difference between each rank and the average rank.

$$a(R_j) = \left[R_j - \frac{n+1}{2} \right]^2$$

Tests Based on the Empirical Distribution Function

If you specify the **EDF** option, PROC NPAR1WAY computes tests based on the empirical distribution function. These include the Kolmogorov-Smirnov and Cramer-von Mises tests, and also the Kuiper test for two-sample data. This section gives formulas for these test statistics. For further information on the formulas and the interpretation of EDF statistics, refer to Hollander and Wolfe (1999) and Gibbons and Chakraborti (1992). For details on the k -sample analogues of the Kolmogorov-Smirnov and Cramer-von Mises statistics used by NPAR1WAY, refer to Kiefer (1959).

The *empirical distribution function* (EDF) of a sample $\{x_j\}$, $j = 1, 2, \dots, n$, is defined as the following function:

$$F(x) = \frac{1}{n} (\text{number of } x_j \leq x) = \frac{1}{n} \sum_{j=1}^n I(x_j \leq x)$$

where $I(\cdot)$ is an indicator function. PROC NPAR1WAY uses the subsample of values within the i th class level to generate an EDF for the class, F_i . The EDF for the overall sample, pooled over classes, can also be expressed as

$$F = \frac{1}{n} \sum_i (n_i F_i)$$

where n_i is the number of observations in the i th class level, and n is the total number of observations.

Kolmogorov-Smirnov Test

The Kolmogorov-Smirnov statistic measures the maximum deviation of the EDF within the classes from the pooled EDF. PROC NPAR1WAY computes the Kolmogorov-Smirnov statistic as

$$KS = \max_j \sqrt{\frac{1}{n} \sum_i n_i (F_i(x_j) - F(x_j))^2} \quad \text{where } j = 1, 2, \dots, n$$

The asymptotic Kolmogorov-Smirnov statistic is computed as

$$KS_a = KS \times \sqrt{n}$$

For each class level i and overall, PROC NPAR1WAY displays the value of F_i at the maximum deviation from F and the value $(F_i - F) \sqrt{n_i}$ at the maximum deviation from F . PROC NPAR1WAY also gives the observation where the maximum deviation occurs.

If there are only two class levels, PROC NPAR1WAY computes the two-sample Kolmogorov-Smirnov test statistic D as

$$D = \max_j |F_1(x_j) - F_2(x_j)| \quad \text{where } j = 1, 2, \dots, n$$

The p -value for this test is the probability that D is greater than the observed value d under the null hypothesis of no difference between class levels or samples. PROC NPAR1WAY computes the asymptotic p -value for D with the approximation

$$\text{Prob}(D > d) = 1 - 2 \sum_{i=1}^{\infty} (-1)^{(i-1)} e^{-2i^2 z^2}$$

where

$$z = d \sqrt{\left(\frac{n_1 n_2}{n}\right)}$$

The quality of this approximation has been studied by Hodges (1957).

If you specify the **D** option, or if you request exact Kolmogorov-Smirnov p -values with the KS option in the **EXACT** statement, PROC NPAR1WAY also computes the one-sided Kolmogorov-Smirnov statistics $D+$ and $D-$ for two-sample data.

$$D+ = \max_j (F_1(x_j) - F_2(x_j)) \quad \text{where } j = 1, 2, \dots, n$$

$$D- = \max_j (F_2(x_j) - F_1(x_j)) \quad \text{where } j = 1, 2, \dots, n$$

The asymptotic probability that $D+$ is greater than the observed value d^+ , under the null hypothesis of no difference between the two class levels, is computed as

$$\text{Prob} (D+ > d^+) = e^{-2z^2}, \quad \text{where } z = d^+ \sqrt{\left(\frac{n_1 n_2}{n} \right)}$$

Similarly, the asymptotic probability that $D-$ is greater than the observed value d^- is computed as

$$\text{Prob} (D- > d^-) = e^{-2z^2}, \quad \text{where } z = d^- \sqrt{\left(\frac{n_1 n_2}{n} \right)}$$

To request exact p -values for the Kolmogorov-Smirnov statistics, you can specify the KS option in the **EXACT** statement. See the section “Exact Tests” on page 3171 for more information.

Cramer-von Mises Test

The Cramer-von Mises statistic is defined as

$$\text{CM} = \frac{1}{n^2} \sum_i \left(n_i \sum_{j=1}^p t_j (F_i(x_j) - F(x_j))^2 \right)$$

where t_j is the number of ties at the j th distinct value and p is the number of distinct values. The asymptotic value is computed as

$$\text{CM}_a = \text{CM} \times n$$

PROC NPAR1WAY displays the contribution of each class level to the sum CM_a .

Kuiper Test

For data with two class levels, PROC NPAR1WAY computes the Kuiper statistic, its scaled value for the asymptotic distribution, and the asymptotic p -value. The Kuiper statistic is computed as

$$K = \max_j (F_1(x_j) - F_2(x_j)) - \min_j (F_1(x_j) - F_2(x_j)) \quad \text{where } j = 1, 2, \dots, n$$

The asymptotic value is

$$K_a = K \sqrt{\frac{n_1 n_2}{n}}$$

PROC NPAR1WAY displays $\max_j |F_1(x_j) - F_2(x_j)|$ for each class level.

The p -value for the Kuiper test is the probability of observing a larger value of K_a under the null hypothesis of no difference between the two classes. PROC NPAR1WAY computes this p -value according to Owen (1962), p. 441.

Exact Tests

PROC NPAR1WAY provides exact p -values for tests for location and scale differences based on the following scores: Wilcoxon, median, van der Waerden, Savage, Siegel-Tukey, Ansari-Bradley, Klotz, and Mood scores. Additionally, PROC NPAR1WAY provides exact p -values for tests using the raw data as scores. Exact tests are available for two-sample and multisample data. When the data are classified into two samples, tests are based on simple linear rank statistics. When the data are classified into more than two samples, tests are based on one-way ANOVA statistics.

Exact tests can be useful in situations where the asymptotic assumptions are not met and the asymptotic p -values are not close approximations for the true p -values. Standard asymptotic methods involve the assumption that the test statistic follows a particular distribution when the sample size is sufficiently large. When the sample size is not large, asymptotic results may not be valid, with the asymptotic p -values differing perhaps substantially from the exact p -values. Asymptotic results may also be unreliable when the distribution of the data is sparse, skewed, or heavily tied. Refer to Agresti (1996) and Bishop, Fienberg, and Holland (1975). Exact computations are based on the statistical theory of exact conditional inference for contingency tables, reviewed by Agresti (1992).

In addition to computation of exact p -values, PROC NPAR1WAY provides the option of estimating exact p -values by Monte Carlo simulation. This can be useful for problems that are so large that exact computations require a great amount of time and memory, but for which asymptotic approximations may not be sufficient.

The following sections summarize the exact computational algorithms, define the exact p -values that PROC NPAR1WAY computes, discuss the computational resource requirements, and describe the Monte Carlo estimation option.

Computational Algorithms

PROC NPAR1WAY computes exact p -values using the network algorithm developed by Mehta and Patel (1983). This algorithm provides a substantial advantage over direct enumeration, which can be very time consuming and feasible only for small problems. Refer to Agresti (1992) for a review of algorithms for computation of exact p -values, and refer to Mehta, Patel, and Tsiatis (1984) and Mehta, Patel, and Senchaudhuri (1991) for information on the performance of the network algorithm.

PROC NPAR1WAY constructs a contingency table from the input data, with rows formed by the levels of the classification variable and columns formed by the response variable values. The reference set for a given contingency table is the set of all contingency tables with the observed marginal row and column sums. Corresponding to this reference set, the network algorithm forms a directed acyclic network consisting of nodes in a number of stages. A path through the network corresponds to a distinct table in the reference set. The distances between nodes are defined so that the total distance of a path through the network is the corresponding value of the test statistic. At each node, the algorithm computes the shortest and longest path distances for all the paths that pass through that node. For the two-sample linear rank statistics, which can be expressed as a linear combination of cell frequencies multiplied by increasing row and column scores, PROC NPAR1WAY computes shortest and longest path distances using the algorithm given in Agresti, Mehta, and Patel (1990). For the multisample one-way test statistics, PROC NPAR1WAY computes an upper bound for the longest path and a lower bound for the shortest path, following the approach of Valz and Thompson (1994).

The longest and shortest path distances or bounds for a node are compared to the value of the test statistic to determine whether all paths through the node contribute to the p -value, none of the paths through the node contribute to the p -value, or neither of these situations occur. If all paths through the node contribute, the p -value is incremented accordingly, and these paths are eliminated from further analysis. If no paths contribute, these paths are eliminated from the analysis. Otherwise, the algorithm continues, still processing this node and the associated paths. The algorithm finishes when all nodes have been accounted for.

In applying the network algorithm, PROC NPAR1WAY uses full precision to represent all statistics, row and column scores, and other quantities involved in the computations. Although it is possible to use rounding to improve the speed and memory requirements of the algorithm, PROC NPAR1WAY does not do this since it can result in reduced accuracy of the p -values.

Definition of p -Values

For two-sample linear rank tests, PROC NPAR1WAY computes exact one-sided and two-sided p -values for each test specified in the EXACT statement. For the one-sided test, PROC NPAR1WAY displays the right-sided p -value when the observed value of the test statistic is greater than its expected value. The right-sided p -value is the sum of probabilities for those tables having a test statistic greater than or equal to the observed test statistic. Otherwise, when the test statistic is less than or equal to its expected value, PROC NPAR1WAY displays the left-sided p -value. The left-sided

p -value is the sum of probabilities for those tables having a test statistic less than or equal to the one observed. The one-sided p -value P_1 can be expressed as

$$P_1 = \text{Prob} (\text{Test Statistic} \geq S) \quad \text{if } S > \text{Mean}$$

$$P_1 = \text{Prob} (\text{Test Statistic} \leq S) \quad \text{if } S \leq \text{Mean}$$

where S is the observed value of the test statistic and Mean is the expected value of the test statistic under the null hypothesis. PROC NPAR1WAY computes the two-sided p -value as the sum of the one-sided p -value and the corresponding area in the opposite tail of the distribution of the statistic, equidistant from the expected value. The two-sided p -value P_2 can be expressed as

$$P_2 = \text{Prob} (| \text{Test Statistic} - \text{Mean} | \geq | S - \text{Mean} |)$$

For multisample data, the tests are based on one-way ANOVA statistics. For a test of this form, large values of the test statistic indicate a departure from the null hypothesis; the test is inherently two-sided. The exact p -value is the sum of probabilities for those tables having a test statistic greater than or equal to the value of the observed test statistic.

If you specify the **POINT** option in the EXACT statement, PROC NPAR1WAY also displays exact point probabilities for the test statistics. The exact point probability is the exact probability that the test statistic equals the observed value.

Computational Resources

PROC NPAR1WAY uses relatively fast and efficient algorithms for exact computations. These recently developed algorithms, together with improvements in computer power, make it feasible now to perform exact computations for data sets where previously only asymptotic methods could be applied. Nevertheless, there are still large problems that may require a prohibitive amount of time and memory for exact computations, depending on the speed and memory available on your computer. For large problems, consider whether exact methods are really needed or whether asymptotic methods might give results quite close to the exact results while requiring much less computer time and memory. When asymptotic methods may not be sufficient for such large problems, consider using Monte Carlo estimation of exact p -values, as described in the section “[Monte Carlo Estimation](#)” on page 3174.

A formula does not exist that can predict in advance how much time and memory are needed to compute an exact p -value for a certain problem. The time and memory required depend on several factors, including which test is being performed, the total sample size, the number of rows and columns, and the specific arrangement of the observations into table cells. Generally, larger problems (in terms of total sample size, number of rows, and number of columns) tend to require more time and memory. Additionally, for a fixed total sample size, time and memory requirements tend to increase as the number of rows and columns increase, since this corresponds to an increase in the number of tables in the reference set. Also for a fixed sample size, time

and memory requirements increase as the marginal row and column totals become more homogeneous. Refer to Agresti, Mehta, and Patel (1990) and Gail and Mantel (1977).

At any time while PROC NPAR1WAY is computing exact p -values, you can terminate the computations by pressing the system interrupt key sequence (refer to the *SAS Companion* for your system) and choosing to stop computations. After you terminate exact computations, PROC NPAR1WAY completes all other remaining tasks. The procedure produces the requested output and reports missing values for any exact p -values not computed by the time of termination.

You can also use the `MAXTIME=` option in the EXACT statement to limit the amount of time PROC NPAR1WAY uses for exact computations. You specify a `MAXTIME=` value that is the maximum amount of time (in seconds) that PROC NPAR1WAY can use to compute an exact p -value. If PROC NPAR1WAY does not finish computing an exact p -value within that time, it terminates the computation and completes all other remaining tasks.

Monte Carlo Estimation

If you specify the `MC` option in the EXACT statement, PROC NPAR1WAY computes Monte Carlo estimates of the exact p -values instead of directly computing the exact p -values. Monte Carlo estimation can be useful for large problems that require a great amount of time and memory for exact computations but for which asymptotic approximations may not be sufficient. To describe the precision of each Monte Carlo estimate, PROC NPAR1WAY provides the asymptotic standard error and $100(1 - \alpha)\%$ confidence limits. The confidence level α is determined by the `ALPHA=` option in the EXACT statement, which, by default, equals 0.01, and produces 99% confidence limits. The `N=` option in the EXACT statement specifies the number of samples PROC NPAR1WAY uses for Monte Carlo estimation; the default is 10,000 samples. You can specify a larger value for n to improve the precision of the Monte Carlo estimates. Because larger values of n generate more samples, the computation time increases. Or you can specify a smaller value of n to reduce the computation time.

To compute a Monte Carlo estimate of an exact p -value, PROC NPAR1WAY generates a random sample of tables with the same total sample size, row totals, and column totals as the observed table. PROC NPAR1WAY uses the algorithm of Agresti, Wackerly, and Boyett (1979), which generates tables in proportion to their hypergeometric probabilities conditional on the marginal frequencies. For each sample table, PROC NPAR1WAY computes the value of the test statistic and compares it to the value for the observed table. When estimating a right-sided p -value, PROC NPAR1WAY counts all sample tables for which the test statistic is greater than or equal to the observed test statistic. Then the p -value estimate equals the number of these tables divided by the total number of tables sampled.

$$\begin{aligned}\hat{P}_{MC} &= M / N \\ M &= \text{number of samples with (Test Statistic} \geq t) \\ N &= \text{total number of samples} \\ t &= \text{observed Test Statistic}\end{aligned}$$

PROC NPAR1WAY computes left-sided and two-sided p -value estimates in a similar manner. For left-sided p -values, PROC NPAR1WAY evaluates whether the test statistic for each sampled table is less than or equal to the observed test statistic. For two-sided p -values, PROC NPAR1WAY examines the sample test statistics according to the expression for P_2 given in the section “Definition of p -Values” on page 3172.

The variable M is a binomial variable with N trials and success probability p . It follows that the asymptotic standard error of the Monte Carlo estimate is

$$se(\hat{P}_{MC}) = \sqrt{\hat{P}_{MC} (1 - \hat{P}_{MC}) / (N - 1)}$$

PROC NPAR1WAY constructs asymptotic confidence limits for the p -values according to

$$\hat{P}_{MC} \pm z_{\alpha/2} \times se(\hat{P}_{MC})$$

where $z_{\alpha/2}$ is the $100(1 - \alpha/2)$ percentile of the standard normal distribution, and the confidence level α is determined by the ALPHA= option in the EXACT statement.

When the Monte Carlo estimate \hat{P}_{MC} equals 0, then PROC NPAR1WAY computes the confidence limits for the p -value as

$$(0, 1 - \alpha^{(1/N)})$$

When the Monte Carlo estimate \hat{P}_{MC} equals 1, then PROC NPAR1WAY computes the confidence limits as

$$(\alpha^{(1/N)}, 1)$$

Output Data Set

The OUTPUT statement creates a SAS data set that contains statistics computed by PROC NPAR1WAY. You specify which statistics to store in the output data set, using options identical to those used in the PROC NPAR1WAY statement. When you specify one of these options in the OUTPUT statement, PROC NPAR1WAY includes all available statistics from that analysis in the output data set.

The output data set contains one observation for each analysis variable within a BY-group. The OUTPUT data set can include the following variables:

- BY variables
- `_VAR_`, which identifies the analysis variable
- variables containing the specified statistics

The following table lists the variable names and descriptions for all available statistics. Note that some statistics are available only for the two-sample case (where the classification variable groups the data into two classes). Other statistics are available only for the multisample case.

When you request exact p -values for certain analyses using the EXACT statement, PROC NPAR1WAY also includes those p -values in the output data set if you specify the corresponding analysis options in the OUTPUT statement. If you do not request exact p -values, then they do not appear in the output data set.

Monte Carlo estimates of exact p -values are not available in this output data set, but you can use the Output Delivery System (ODS) to store Monte Carlo estimates in a SAS data set. You can use the Output Delivery System to create a SAS data set from any piece of PROC NPAR1WAY output. For more information, see [Table 52.6](#) on page 3184 and [Chapter 14](#), “Using the Output Delivery System.”

Table 52.5. Output Data Set Variable Names and Descriptions

Option	Output Variables	Variable Descriptions	
ANOVA	_MSA_	ANOVA Effect Mean Square, Among MS	
	MSE	ANOVA Error Mean Square, Within MS	
	F	F Statistic for ANOVA	
	P_F	p -value, F Statistic for ANOVA	
WILCOXON	_WIL_	* Two-sample Wilcoxon Statistic	
	Z_WIL	* Wilcoxon Statistic, Standardized

Displayed Output

If you specify the [ANOVA](#) option, PROC NPAR1WAY displays a Class Means table and an Analysis of Variance table for each response variable. The Class Means table includes the following information for each [CLASS](#) variable value, or level:

- N, the number of observations
- the Mean of the response variable

The Analysis of Variance table includes the following information for each Source of variation (Among classes, and Within classes):

- DF, the degrees of freedom associated with the source
- the Sum of Squares
- the Mean Square, the sum of squares divided by the degrees of freedom

The Analysis of Variance table also includes the following:

- the F Value for testing the hypothesis that the group means are equal. This is computed by dividing the Mean Square (Among) by the Mean Square (Within).
- $Pr > F$, the significance probability corresponding to the F Value

For each score type that you specify, PROC NPAR1WAY displays a Class Scores table. The available score types include Wilcoxon, median, Van der Waerden, Savage, Siegel-Tukey, Ansari-Bradley, Klotz, Mood, and raw data scores. PROC NPAR1WAY assigns the specified scores to the response variable values, and classifies then according to the [CLASS](#) variable values. The Class Scores table includes the following information for each class:

- N, the number of observations
- Sum of Scores
- Expected Under H_0 , the expected sum of scores under the null hypothesis of no difference among classes
- Std Dev Under H_0 , the standard deviation under the null hypothesis
- Mean Score

When there are only two levels of the [CLASS](#) variable, PROC NPAR1WAY displays the following Two-Sample Test results for each analysis of scores:

- Statistic, which is the sum of scores for the class with the smaller sample size
- Z, the standardized test statistic, which has an asymptotic standard normal distribution under the null hypothesis
- One-Sided $Pr < Z$, or One-Sided $Pr > Z$, the asymptotic one-sided p -value, displayed as $Pr < Z$ or $Pr > Z$, depending on whether Z is ≤ 0 or > 0
- Two-Sided $Pr > |Z|$, the asymptotic two-sided p -value

For Wilcoxon scores, PROC NPAR1WAY also displays a t -approximation for the two-sample test.

If you request an exact test by specifying the score type in the EXACT statement, PROC NPAR1WAY displays the following exact p -values for two-sample data:

- One-Sided Pr $\leq S$, or One-Sided Pr $\geq S$, the one-sided exact p -value, displayed as Pr $\leq S$ or Pr $\geq S$, depending on whether $S \leq \text{Mean}$ or $S > \text{Mean}$, where S is the test statistic and Mean is its expected value under the null hypothesis
- Point Pr = S , the point probability, if you specify the POINT option in the EXACT statement
- Two-Sided Pr $\geq |S - \text{Mean}|$, the two-sided exact p -value

If you request Monte Carlo estimates for the exact test by specifying the MC option in the EXACT statement, PROC NPAR1WAY displays the following information for two-sample data:

- Estimate of One-Sided Pr $\leq S$ or One-Sided Pr $\geq S$, the one-sided exact p -value, together with its Lower and Upper Confidence Limits
- Estimate of Two-Sided Pr $\geq |S - \text{Mean}|$, the two-sided exact p -value, together with its Lower and Upper Confidence Limits
- Number of Samples used to compute the Monte Carlo estimates
- Initial Seed used to compute the Monte Carlo estimates

For both two-sample and multisample data, PROC NPAR1WAY displays the following One-Way Analysis for each score type:

- Chi-Square, the one-way ANOVA statistic for testing the null hypothesis of no difference among classes
- DF, the degrees of freedom
- Pr > Chi-Square, the asymptotic p -value

For multisample data, if you request an exact test by specifying the score type in the EXACT statement, PROC NPAR1WAY also displays the exact p -value as follows:

- Exact Pr \geq Chi-Square
- Exact Pr = Chi-Square, the point probability, if you specify the POINT option in the EXACT statement

For multisample data, if you request a Monte Carlo estimate for the exact test by specifying the **MC** option in the EXACT statement, PROC NPAR1WAY displays the following information:

- Estimate of $\Pr \geq \text{Chi-Square}$, together with its Lower and Upper Confidence Limits
- Number of Samples used to compute the Monte Carlo estimate
- Initial Seed used to compute the Monte Carlo estimate

If you specify the **EDF** option, PROC NPAR1WAY produces tables for the Kolmogorov-Smirnov Test, the Cramer-von Mises Test, and for two-sample data only, the Kuiper Test. The Kolmogorov-Smirnov Test table includes the following information for each **CLASS** variable value, or level:

- N, the number of observations
- EDF at Maximum, the value of the class EDF (empirical distribution function) at its maximum deviation from the pooled EDF
- Deviation from Mean at Maximum, the value of $\sqrt{n_i} \sqrt{F_i - F}$ at its maximum, where n_i is the class sample size, F_i is the class EDF, and F is the pooled EDF

PROC NPAR1WAY displays the following Kolmogorov-Smirnov statistics:

- KS, the Kolmogorov-Smirnov statistic
- KSa, the asymptotic Kolmogorov-Smirnov statistic, where $\text{KSa} = \sqrt{n} \text{KS}$

For two-sample data, PROC NPAR1WAY displays the following Kolmogorov-Smirnov statistics:

- $\Pr > \text{KSa}$, the asymptotic p -value for KSa, which equals $\Pr > D$
- $D = \max |F_1 - F_2|$, the two-sample Kolmogorov-Smirnov statistic

For two-sample data, if you specify the **D** option, PROC NPAR1WAY also displays the following one-sided Kolmogorov-Smirnov statistics and their asymptotic p -values:

- $D^+ = \max (F_1 - F_2)$
- $\Pr > D^+$
- $D^- = \max (F_2 - F_1)$
- $\Pr > D^-$

For two-sample data, if you request an exact Kolmogorov-Smirnov test by specifying the KS option in the **EXACT** statement, PROC NPAR1WAY displays the following exact *p*-values:

- Exact Pr >= D
- Exact Pr >= D+
- Exact Pr >= D-
- Exact Point Pr = D, Exact Point Pr = D+, and Exact Point Pr = D-, if you specify the **POINT** option in the EXACT statement

If you request Monte Carlo estimates for the two-sample exact Kolmogorov-Smirnov test, PROC NPAR1WAY displays the following information for two-sample data:

- Estimate of Pr >= D, together with its Lower and Upper Confidence Limits
- Estimate of Pr >= D+, together with its Lower and Upper Confidence Limits
- Estimate of Pr >= D-, together with its Lower and Upper Confidence Limits
- Number of Samples used to compute the Monte Carlo estimates
- Initial Seed used to compute the Monte Carlo estimates

The Cramer-von Mises Test table includes the following information for each **CLASS** variable value, or level:

- N, the number of observations
- Summed Deviation from Mean, which is $(n_i/n) \sum_{j=1}^p t_j (F_i(x_j) - F(x_j))^2$

PROC NPAR1WAY also displays the following Cramer-von Mises statistics:

- CM, the Cramer-von Mises statistic
- CMa, the asymptotic Cramer-von Mises statistic, where $CMa = n \text{ CM}$

For two-sample data, PROC NPAR1WAY displays the Kuiper Test table, which includes the following information for each class:

- N, the number of observations
- Deviation from Mean, which is $\max_j |F_1(x_j) - F_2(x_j)|$

PROC NPAR1WAY also displays the following Kuiper two-sample test statistics:

- K, the Kuiper two-sample test statistic
- Ka, the asymptotic Kuiper two-sample test statistic, where $Ka = K \sqrt{n_1 n_2 / n}$
- Pr > Ka

ODS Table Names

PROC NPAR1WAY assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

The WILCOXON, MEDIAN, VW, SAVAGE, and EDF options are the default if you do not specify any analysis options in the PROC NPAR1WAY statement.

Table 52.6. ODS Tables Produced in PROC NPAR1WAY

ODS Table Name	Description	Statement	Option

* PROC NPAR1WAY produces this table only for two-sample data.

** PROC NPAR1WAY produces this table only for multisample data.

Examples

Example 52.1. Two-Sample Location Tests and EDF Statistics

Fifty-nine female patients with rheumatoid arthritis who participated in a clinical trial were assigned to two groups, active and placebo. The response status (excellent=5, good=4, moderate=3, fair=2, poor=1) of each patient was recorded.

The following SAS statements create the data set `Arthritis`, which contains the observed status values for all the patients. The variable `Treatment` denotes the treatment received by a patient, and the variable `Response` contains the response status of the patient. The variable `Freq` contains the frequency of the observation, which is the number of patients with the `Treatment` and `Response` combination.

```
data Arthritis;
  input Treatment $ Response Freq @@;
  datalines;
Active 5 5 Active 4 11 Active 3 5 Active 2 1 Active 1 5
Placebo 5 2 Placebo 4 4 Placebo 3 7 Placebo 2 7 Placebo 1 12
;
```

`PROC NPAR1WAY` tests the null hypothesis that there is no difference in the patient response status against an alternative hypothesis that the patient response status differs in the two treatment groups. The `WILCOXON` option requests the Wilcoxon test for difference in location, and the `MEDIAN` option requests the median test for difference in location. The `EDF` option requests empirical distribution function statistics. The variable `Treatment` is the `CLASS` variable, and the `VAR` statement specifies that the variable `Response` is the response variable.

```
proc npar1way wilcoxon median edf data=Arthritis;
  class Treatment;
  var Response;
  freq Freq;
run;
```

[Output 52.1.1](#) shows the results of the Wilcoxon analysis. The Wilcoxon two-sample test statistic equals 999.0, which is the sum of the Wilcoxon scores for the smaller sample (Active). This sum is greater than 810.0, its expected value under the null hypothesis of no difference between the two samples Active and Placebo. The one-sided p -value is 0.0016, which shows that the patient response for the Active treatment is significantly more than for the Placebo group.

Output 52.1.1. Wilcoxon Two-Sample Test

The NPAR1WAY Procedure					
Wilcoxon Scores (Rank Sums) for Variable Response Classified by Variable Treatment					
Treatment	N	Sum of Scores	Expected Under H0	Std Dev Under H0	Mean Score
Active	27	999.0	810.0	63.972744	37.000000
Placebo	32	771.0	960.0	63.972744	24.093750

Average scores were used for ties.

Wilcoxon Two-Sample Test

Statistic	999.0000
-----------	----------

Normal Approximation

Z	2.9466
One-Sided Pr > Z	0.0016
Two-Sided Pr > Z	0.0032

t Approximation

One-Sided Pr > Z	0.0023
Two-Sided Pr > Z	0.0046

Z includes a continuity correction of 0.5.

Kruskal-Wallis Test

Chi-Square	8.7284
DF	1
Pr > Chi-Square	0.0031

Output 52.1.2. Median Two-Sample Test

Median Scores (Number of Points Above Median) for Variable Response Classified by Variable Treatment					
Treatment	N	Sum of Scores	Expected Under H0	Std Dev Under H0	Mean Score
Active	27	18.916667	13.271186	1.728195	0.700617
Placebo	32	10.083333	15.728814	1.728195	0.315104

Average scores were used for ties.

Median Two-Sample Test

Statistic	18.9167
Z	3.2667
One-Sided Pr > Z	0.0005
Two-Sided Pr > Z	0.0011

Median One-Way Analysis

Chi-Square	10.6713
DF	1
Pr > Chi-Square	0.0011

Output 52.1.2 shows the results of the median two-sample test. The statistic equals 18.9167, with a one-sided p -value of 0.0005. This shows that the response for the Active treatment is significantly more than for the Placebo group.

Output 52.1.3. Empirical Distribution Function Statistics

```

Kolmogorov-Smirnov Test for Variable Response
Classified by Variable Treatment

Treatment      N      EDF at      Deviation from Mean
              N      Maximum      at Maximum
-----
Active         27      0.407407     -1.141653
Placebo        32      0.812500     1.048675
Total          59      0.627119

Maximum Deviation Occurred at Observation 3
Value of Response at Maximum = 3.0

Kolmogorov-Smirnov Two-Sample Test (Asymptotic)
KS  0.201818  D      0.405093
KSa 1.550191  Pr > KSa 0.0164

Cramer-von Mises Test for Variable Response
Classified by Variable Treatment

Treatment      N      Summed Deviation
              N      from Mean
-----
Active         27      0.526596
Placebo        32      0.444316

Cramer-von Mises Statistics (Asymptotic)
CM  0.016456  CMa 0.970912

Kuiper Test for Variable Response
Classified by Variable Treatment

Treatment      N      Deviation
              N      from Mean
-----
Active         27      0.000000
Placebo        32      0.405093

Kuiper Two-Sample Test (Asymptotic)
K  0.405093  Ka 1.550191  Pr > Ka 0.1409
    
```

Output 52.1.3 shows empirical distribution function statistics comparing these two samples. The asymptotic p -value for the Kolmogorov-Smirnov test is 0.0164. This indicates rejection of the null hypothesis that the distributions are identical for the two groups.

Example 52.2. The Exact Wilcoxon Two-Sample Test

Researchers conducted an experiment to compare the effects of two stimulants. Thirteen randomly selected subjects received the first stimulant and six randomly selected subjects received the second stimulant. The reaction times (in minutes) were measured while the subjects were under the influence of the stimulants.

The following SAS statements create the data set `React`, which contains the observed reaction times for each stimulant. The variable `Stim` represents Stimulant 1 or 2. The variable `Time` contains the reaction times observed for subjects under the stimulant.

```
data React;
  input Stim Time @@;
  datalines;
1 1.94    1 1.94    1 2.92    1 2.92    1 2.92    1 2.92    1 3.27
1 3.27    1 3.27    1 3.27    1 3.70    1 3.70    1 3.74
2 3.27    2 3.27    2 3.27    2 3.70    2 3.70    2 3.74
;
```

PROC NPAR1WAY tests the null hypothesis that there is no difference between the effects of the two stimulants against an alternative hypothesis that stimulant 1 has smaller reaction times than stimulant 2. The WILCOXON option specifies that Wilcoxon scores are to be used. The CLASS statement specifies that the variable `Stim` determines the classes. The VAR statement identifies `Time` as the response variable. The EXACT option requests the exact p -values. Since the sample size is small, the normal approximation may not be completely accurate, and it is appropriate to compute the exact test.

```
proc npar1way wilcoxon data=React;
  class Stim;
  var Time;
  exact;
run;
```

Output 52.2.1 displays the results of the Wilcoxon two-sample test. The Wilcoxon statistic equals 79.50. Since this value is greater than 60.0, the expected value under the null hypothesis, PROC NPAR1WAY displays the right-sided p -values. The one-sided exact p -value equals 0.0527, which is not significant at the 0.05 level. The normal approximation yields a one-sided p -value of 0.0421, which is significant at the 0.05 level. Thus, the normal approximation may result in rejection of the null hypothesis, while the exact test may result in acceptance.

Output 52.2.1. Wilcoxon Two-Sample Test

The NPAR1WAY Procedure					
Wilcoxon Scores (Rank Sums) for Variable Time Classified by Variable Stim					
Stim	N	Sum of Scores	Expected Under H0	Std Dev Under H0	Mean Score
1	13	110.50	130.0	11.004784	8.500
2	6	79.50	60.0	11.004784	13.250

Average scores were used for ties.

Wilcoxon Two-Sample Test

Statistic (S)	79.5000
Normal Approximation	
Z	1.7265
One-Sided Pr > Z	0.0421
Two-Sided Pr > Z	0.0843
t Approximation	
One-Sided Pr > Z	0.0507
Two-Sided Pr > Z	0.1014
Exact Test	
One-Sided Pr >= S	0.0527
Two-Sided Pr >= S - Mean	0.1054

Z includes a continuity correction of 0.5.

Kruskal-Wallis Test

Chi-Square	3.1398
DF	1
Pr > Chi-Square	0.0764

Example 52.3. The Exact Savage Multisample Test

A researcher conducting a laboratory experiment randomly assigned 15 mice to receive one of three drugs. The survival time (in days) was then recorded.

The following SAS statements create the data set `Mice`, which contains the observed survival times for all the mice. The variable `Trt` denotes the treatment received by a mouse. The variable `Days` contains the number of days the mouse survived.

```
data Mice;
  input Trt $ Days @@;
  datalines;
1 1 1 1 1 3 1 3 1 4
2 3 2 4 2 4 2 4 2 15
3 4 3 4 3 10 3 10 3 26
;
```

PROC NPAR1WAY tests the null hypothesis that there is no difference in the survival times among the three drugs against an alternative hypothesis of difference among the drugs. The SAVAGE option specifies that Savage scores are to be used. The variable Trt is the CLASS variable, and the VAR statement specifies that the variable Days is the response variable. The EXACT statement requests the exact test.

```
proc npar1way savage data=Mice;
  class Trt;
  var Days;
  exact;
run;
```

Output 52.3.1. Savage Multisample Test

The NPAR1WAY Procedure					
Savage Scores (Exponential) for Variable Days					
Classified by Variable Trt					
Trt	N	Sum of Scores	Expected Under H0	Std Dev Under H0	Mean Score
1	5	-3.367980	0.0	1.634555	-0.673596
2	5	0.095618	0.0	1.634555	0.019124
3	5	3.272362	0.0	1.634555	0.654472

Average scores were used for ties.

Savage One-Way Analysis			
Chi-Square			5.5047
DF			2
Asymptotic Pr >	Chi-Square		0.0638
Exact Pr >=	Chi-Square		0.0445

Output 52.3.1 shows the results of the Savage test. The exact p -value is 0.0445, which is significant at the 0.05 level. However, the p -value based on the chi-square approximation is 0.0638, which results in nonrejection of the null hypothesis at the 0.05 level.

Chapter 53

The ORTHOREG Procedure

Overview

The ORTHOREG procedure fits general linear models by the method of least squares. Other SAS/STAT software procedures, such as GLM or REG, fit the same types of models, but PROC ORTHOREG can produce more accurate estimates than other regression procedures when your data are ill conditioned. Instead of collecting crossproducts, PROC ORTHOREG uses Gentleman-Givens transformations to update and compute the upper triangular matrix \mathbf{R} of the QR decomposition of the data matrix, with special care for scaling (Gentleman 1972; 1973). This method has the advantage over other orthogonalization methods (for example, Householder transformations) of not requiring the data matrix to be stored in memory.

The standard SAS regression procedures (REG and GLM) are very accurate for most problems. However, if you have very ill-conditioned data, these procedures can produce estimates that yield an error sum of squares very close to the minimum but still different from the exact least-squares estimates. Normally, this coincides with estimates that have very high standard errors. In other words, the numerical error is much smaller than the statistical standard error.

Note that PROC ORTHOREG fits models by the method of linear least squares, minimizing the sum of the squared residuals for predicting the responses. It does *not* perform the modeling method known as “orthogonal regression,” which minimizes a different criterion (the distance between the X/Y points taken together and the regression line.)

Getting Started

Longley Data

The labor statistics data set of Longley (1967) is noted for being ill conditioned. Both the ORTHOREG and GLM procedures are applied for comparison (only portions of the PROC GLM results are shown). **Note:** The results from this example vary from machine to machine, depending on floating-point configuration.

The following statements read the data into the SAS data set Longley.

```

title 'PROC ORTHOREG used with Longley data';
data Longley;
  input Employment Prices GNP Jobless Military PopSize Year;
  datalines;
60323 83.0 234289 2356 1590 107608 1947
61122 88.5 259426 2325 1456 108632 1948
60171 88.2 258054 3682 1616 109773 1949

66019 101.2 397469 2904 3048 117388 1955
67857 104.6 419180 2822 2857 118734 1956
68169 108.4 442769 2936 2798 120445 1957
66513 110.8 444546 4681 2637 121950 1958
68655 112.6 482704 3813 2552 123366 1959
69564 114.2 502601 3931 2514 125368 1960
69331 115.7 518173 4806 2572 127852 1961
70551 116.9 554894 4007 2827 130081 1962
;
run;

```

The data set contains one dependent variable, **Employment** (total derived employment) and six independent variables: **Prices** (GNP implicit price deflator with year 1954 = 100), **GNP** (gross national product), **Jobless** (unemployment), **Military** (size of armed forces), **PopSize** (non-institutional population aged 14 and over), and **Year** (year).

The following statements use the ORTHOREG procedure to model the Longley data using a quadratic model in each independent variable, without interaction:

```

proc orthoreg data=Longley;
  model Employment = Prices      Prices*Prices
                   GNP          GNP*GNP
                   Jobless     Jobless*Jobless
                   Military     Military*Military
                   PopSize     PopSize*PopSize
                   Year         Year*Year;
run;

```

Figure 53.1 shows the resulting analysis.

```

```

Figure 53.1. PROC ORTHOREG Results

The estimates in [Figure 53.1](#) compare very well with the best estimates available; for additional information, refer to Longley (1967) and Beaton et al. (1976).

The following statements request the same analysis from the GLM procedure:

```

proc glm data=Longley;
  model Employment = Prices    Prices*Prices
                   GNP        GNP*GNP
                   Jobless    Jobless*Jobless
                   Military    Military*Military
                   PopSize     PopSize*PopSize
                   Year         Year*Year;

  ods select OverallANOVA
             FitStatistics
             ParameterEstimates
             Notes;

run;

```

[Figure 53.2](#) contains the over-all ANOVA table and the parameter estimates produced by PROC GLM. Notice that the ORTHOREG fit achieves a somewhat smaller root

mean square error (RMSE) and also that the GLM procedure detects spurious singularities.

```

was used to solve the normal equations. Terms whose estimates are
followed by the letter 'B' are not uniquely estimable.

```

Figure 53.2. Partial PROC GLM Results

Syntax

The following statements are available in PROC ORTHOREG.

```

PROC ORTHOREG < options > ;
  MODEL dependent=independents < / option > ;
  BY variables ;
  CLASS variables < / option > ;
  WEIGHT variable ;

```

The BY, CLASS, MODEL, and WEIGHT statements are described after the PROC ORTHOREG statement.

PROC ORTHOREG Statement

PROC ORTHOREG < options > ;

The PROC ORTHOREG statement has the following options:

DATA=SAS-data-set

specifies the input SAS data set to use. By default, the procedure uses the most recently created SAS data set. The data set specified cannot be a TYPE=CORR, TYPE=COV, or TYPE=SSCP data set.

NOPRINT

suppresses the normal display of results. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 14, “Using the Output Delivery System,” for more information.

ORDER=DATA | FORMATTED | FREQ | INTERNAL

specifies the order in which you want the levels of the classification variables (specified in the CLASS statement) to be sorted. This ordering determines which parameters in the model correspond to each level in the data. Note that the ORDER= option applies to the levels for all classification variables. The exception is the default ORDER=FORMATTED for numeric variables for which you have supplied no explicit format. In this case, the levels are ordered by their internal value. Note that this represents a change from previous releases for how class levels are ordered. In releases previous to Version 8, numeric class levels with no explicit format were ordered by their BEST12. formatted values, and in order to revert to the previous ordering you can specify this format explicitly for the affected classification variables. The change was implemented because the former default behavior for ORDER=FORMATTED often resulted in levels not being ordered numerically and usually required the user to intervene with an explicit format or ORDER=INTERNAL to get the more natural ordering.

The ORDER= option can take the following values.

Value of ORDER=	Levels Sorted By
DATA	order of appearance in the input data set
FORMATTED	external formatted value, except for numeric variables with no explicit format, which are sorted by their unformatted (internal) value
FREQ	descending frequency count; levels with the most observations come first in the order
INTERNAL	unformatted value

If you omit the ORDER= option, PROC ORTHOREG orders by the external formatted value.

OUTEST=SAS-data-set

produces an output data set containing the parameter estimates, the BY variables, and the special variables `_TYPE_` (value `PARMS`), `_NAME_` (blank), `_RMSE_` (root mean squared error), and `Intercept`.

SINGULAR=s

specifies a singularity criterion ($s \geq 0$) for the inversion of the triangular matrix **R**. By default, `SINGULAR=10E-12`.

BY Statement

BY *variables* ;

You can specify a BY statement with PROC ORTHOREG to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option `NOTSORTED` or `DESCENDING` in the BY statement for the ORTHOREG procedure. The `NOTSORTED` option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.
- Create an index on the BY variables using the DATASETS procedure (in base SAS software).

For more information on the BY statement, refer to the discussion in *SAS Language Reference: Concepts*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

CLASS Statement

CLASS *variables* < / *option* > ;

The CLASS statement names the classification variables to be used in the model. Typical class variables are `Treatment`, `Sex`, `Race`, `Group`, and `Replication`. If you use the CLASS statement, it must appear before the MODEL statement.

By default, class levels are determined from the entire formatted values of the CLASS variables. Note that this represents a slight change from previous releases in the way in which class levels are determined. In releases prior to Version 9, class levels were determined using no more than the first 16 characters of the formatted values. If you wish to revert to this previous behavior you can use the `TRUNCATE` option on the CLASS statement. In any case, you can use formats to group values into levels. Refer to the discussion of the FORMAT procedure in the *SAS Procedures Guide*.

and the discussions for the `FORMAT` statement and SAS formats in *SAS Language Reference: Dictionary*.

You can specify the following option in the `CLASS` statement after a slash(/):

TRUNCATE

specifies that class levels should be determined using only up to the first 16 characters of the formatted values of `CLASS` variables. When formatted values are longer than 16 characters, you can use this option in order to revert to the levels as determined in releases previous to Version 9.

MODEL Statement

MODEL *dependent=independents* < / option > ;

The `MODEL` statement names the dependent variable and the independent effects. Only one `MODEL` statement is allowed. The [specification of effects](#) and the parameterization of the linear model is the same as in the `GLM` procedure; see [Chapter 32](#), “The `GLM` Procedure,” for further details.

The following option can be used in the `MODEL` statement:

NOINT

omits the intercept term from the model.

WEIGHT Statement

WEIGHT *variable* ;

A `WEIGHT` statement names a variable in the input data set whose values are relative weights for a weighted least-squares regression. If the weight value is proportional to the reciprocal of the variance for each observation, the weighted estimates are the best linear unbiased estimates (BLUE). For a more complete description of the `WEIGHT` statement, see the “[WEIGHT Statement](#)” section on page 1782 in [Chapter 32](#), “The `GLM` Procedure.”

Details

Missing Values

If there is a missing value for any model variable in an observation, the entire observation is dropped from the analysis.

Output Data Set

The `OUTEST=` option produces a `TYPE=EST` output SAS data set containing the `BY` variables, parameter estimates, and four special variables. For each new value of the `BY` variables, `PROC ORTHOREG` outputs an observation to the `OUTEST=` data set. The variables in the data set are as follows:

- parameter estimates for all variables listed in the `MODEL` statement

- BY variables
- `_TYPE_`, which is a character variable with the value `PARMS` for every observation
- `_NAME_`, which is a character variable left blank for every observation
- `_RMSE_`, which is the root mean squared error (the estimate of the standard deviation of the true errors)
- `Intercept`, which is the estimated intercept. This variable does not exist in the `OUTEST=` data set if the `NOINT` option is specified.

Displayed Output

PROC ORTHOREG displays the parameter estimates and associated statistics. These include the following:

- overall model analysis of variance, including the error mean square, which is an estimate of σ^2 (the variance of the true errors), and the overall F test for a model effect
- root mean squared error, which is an estimate of the standard deviation of the true errors. It is calculated as the square root of the mean squared error.
- R-square, which is a measure between 0 and 1 that indicates the portion of the total variation that is attributed to the fit
- estimates for the parameters in the linear model

The table of parameter estimates consists of

- the terms used as regressors, including the `Intercept`, identifying the intercept parameter
- degrees of freedom (DF) for the variable. There is one degree of freedom for each parameter being estimated unless the model is not full rank.
- estimated linear coefficients
- estimates of the standard errors of the parameter estimates
- the critical t values for testing whether the parameters are zero. This is computed as the parameter estimate divided by its standard error.
- the two-sided p -value for the t -test, which is the probability that a t -statistic would obtain a greater absolute value than that observed given that the true parameter is zero

ODS Table Names

PROC ORTHOREG assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

Table 53.1. ODS Tables Produced in PROC ORTHOREG

ODS Table Name	Description	Statement
ANOVA	Analysis of variance	default
FitStatistics	Overall statistics for fit	default
Levels	Table of class levels	CLASS statement
ParameterEstimates	Parameter estimates	default

Examples

Example 53.1. Precise Analysis of Variance

The data for the following example are from Powell et al. (1982). In order to calibrate an instrument for measuring atomic weight, 24 replicate measurements of the atomic weight of silver (chemical symbol **Ag**) are made with the new instrument and with a reference instrument.

Note: The results from this example vary from machine to machine depending on floating-point configuration.

The following statements read the measurements for the two instruments into the SAS data set **AgWeight**.

```

title 'Atomic Weight of Silver by Two Different Instruments';
data AgWeight;
  input Instrument AgWeight @@;
  datalines;

2 107.8681254 2 107.8681261 2 107.8681450 2 107.8681368
;

```

Notice that the variation in the atomic weight measurements is several orders of magnitude less than their mean. This is a situation that can be difficult for standard, regression-based analysis-of-variance procedures to handle correctly.

The following statements invoke the ORTHOREG procedure to perform a simple one-way analysis of variance, testing for differences between the two instruments.

```
proc orthoreg data=AgWeight;
  class Instrument;
  model AgWeight = Instrument;
run;
```

Output 53.1.1 shows the resulting analysis.

Output 53.1.1. PROC ORTHOREG Results for Atomic Weight Example

Atomic Weight of Silver by Two Different Instruments					
The ORTHOREG Procedure					
Class Level Information					
Factor	Levels	-Values-			
Instrument	2	1	2		
Atomic Weight of Silver by Two Different Instruments					
The ORTHOREG Procedure					
Dependent Variable: AgWeight					
Source	DF	Sum of Squares	Mean Square	F Value	Pr > F
Model	1	3.6383419E-9	3.6383419E-9	15.95	0.0002
Error	46	1.0495173E-8	2.281559E-10		
Corrected Total	47	1.4133515E-8			
		Root MSE	0.0000151048		
		R-Square	0.2574265445		
Parameter	DF	Parameter Estimate	Standard Error	t Value	Pr > t
Intercept	1	107.868136354166	3.0832608E-6	3.499E7	<.0001
(Instrument='1')	1	0.00001741249999	4.3603893E-6	3.99	0.0002
(Instrument='2')	0	0	.	.	.

The mean difference between instruments is about 1.74×10^{-5} (the value of the (Instrument='1') parameter in the parameter estimates table), whereas the level of background variation in the measurements is about 1.51×10^{-5} (the value of the root mean squared error). The difference is significant, with a p -value of 0.0002.

The National Institute of Standards and Technology (1998) has provided certified ANOVA values for this data set. The following statements use ODS to examine the ANOVA values produced by both the ORTHOREG and GLM procedures more precisely for comparison with the NIST-certified values:

```

ods listing close;
ods output ANOVA          = OrthoregANOVA
           FitStatistics = OrthoregFitStat;

proc orthoreg data=AgWeight;
  class Instrument;
  model AgWeight = Instrument;
run;

ods output OverallANOVA = GLMANOVA
           FitStatistics = GLMFitStat;
proc glm data=AgWeight;
  class Instrument;
  model AgWeight = Instrument;
run;
ods listing;

data _null_; set OrthoregANOVA (in=inANOVA)
              OrthoregFitStat(in=inFitStat);
  if (inANOVA) then do;
    if (Source = 'Model') then put "Model SS: " ss e20.;
    if (Source = 'Error') then put "Error SS: " ss e20.;
  end;
  if (inFitStat) then do;
    if (Statistic = 'Root MSE') then
      put "Root MSE: " nValue1 e20.;
    if (Statistic = 'R-Square') then
      put "R-Square: " nValue1 best20.;
  end;
data _null_; set GLMANOVA (in=inANOVA)
              GLMFitStat(in=inFitStat);
  if (inANOVA) then do;
    if (Source = 'Model') then put "Model SS: " ss e20.;
    if (Source = 'Error') then put "Error SS: " ss e20.;
  end;
  if (inFitStat) then      put "Root MSE: " RootMSE e20.;
  if (inFitStat) then      put "R-Square: " RSquare best20.;
run;

```

In releases of SAS/STAT software prior to Version 8, PROC GLM gave much less accurate results than PROC ORTHOREG, as shown in the following tables, which compare the ANOVA values certified by NIST with those produced by the two procedures.

	Model SS	Error SS
NIST-certified	3.6383418750000E-09	1.0495172916667E-08
ORTHOREG	3.6383418747907E-09	1.0495172916797E-08
GLM, Version 8	3.6383418747907E-09	1.0495172916797E-08
GLM, Previous releases	0	1.0331496763990E-08

	Root MSE	R-Square
NIST-certified	1.5104831444641E-05	0.25742654453832
ORTHOREG	1.5104831444735E-05	0.25742654452494
GLM, Version 8	1.5104831444735E-05	0.25742654452494
GLM, Previous releases	1.4986585859992E-05	0

While the ORTHOREG values and the GLM values for Version 8 are quite close to the certified ones, the GLM values for prior releases are not. In fact, since the model sum of squares is so small, in prior releases the GLM procedure set it (and consequently R^2) to zero.

Example 53.2. Wampler Data

This example applies the ORTHOREG procedure to a collection of data sets noted for being ill conditioned. The OUTEST= data set is used to collect the results for comparison with values certified to be correct by the National Institute of Standards and Technology (1998).

Note: The results from this example vary from machine to machine depending on floating-point configuration.

The data are from Wampler (1970). The independent variates for all five data sets are x^i , $i = 1, \dots, 5$, for $x = 0, 1, \dots, 20$. Two of the five dependent variables are exact linear functions of the independent terms:

$$\begin{aligned}
 y_1 &= 1 + x + x^2 + x^3 + x^4 + x^5 \\
 y_2 &= 1 + 0.1x + 0.01x^2 + 0.001x^3 + 0.0001x^4 + 0.00001x^5
 \end{aligned}$$

The other three dependent variables have the same mean value as y_1 , but with nonzero errors.

$$\begin{aligned}
 y_3 &= y_1 + \mathbf{e} \\
 y_4 &= y_1 + 100\mathbf{e} \\
 y_5 &= y_1 + 10000\mathbf{e}
 \end{aligned}$$

where \mathbf{e} is a vector of values with standard deviation 2044, chosen to be orthogonal to the mean model for y_1 .

The following statements create a SAS data set Wampler containing the Wampler data, run a SAS macro program using PROC ORTHOREG to fit a fifth-order polynomial in x to each of the Wampler dependent variables, and collect the results in a data set named ParmEst.

```

data Wampler;
  do x=0 to 20;
    input e @@;
    y1 = 1 +      x      +      x**2 +      x**3
        +      x**4 +      x**5;
    y2 = 1 + .1  *x      + .01  *x**2 + .001*x**3
        + .0001*x**4 + .00001*x**5;
    y3 = y1 +      e;
    y4 = y1 + 100*e;
    y5 = y1 + 10000*e;
    output;
  end;
  datalines;
759 -2048 2048 -2048 2523 -2048 2048 -2048 1838 -2048 2048

;

%macro WTest;
  data ParmEst; if (0); run;
  %do i = 1 %to 5;
    proc orthoreg data=Wampler outest=ParmEst&i noprint;
      model y&i = x x*x x*x*x x*x*x*x x*x*x*x*x;
      data ParmEst&i; set ParmEst&i; Dep = "y&i";
      data ParmEst; set ParmEst ParmEst&i;
      label Col1='x'      Col2='x**2' Col3='x**3'
            Col4='x**4' Col5='x**5';
    run;
  %end;
%mend;
%WTest;

```

Instead of displaying the raw values of the RMSE and parameter estimates, use a further DATA step to compute the deviations from the values certified to be correct by the National Institute of Standards and Technology (1998).

```

data ParmEst; set ParmEst;
  if      (Dep = 'y1') then
    _RMSE_ = _RMSE_ - 0.000000000000000;
  else if (Dep = 'y2') then
    _RMSE_ = _RMSE_ - 0.000000000000000;
  else if (Dep = 'y3') then
    _RMSE_ = _RMSE_ - 2360.14502379268;
  else if (Dep = 'y4') then
    _RMSE_ = _RMSE_ - 236014.502379268;
  else if (Dep = 'y5') then
    _RMSE_ = _RMSE_ - 23601450.2379268;

```

```

if (Dep ^= 'y2') then do;
  Intercept = Intercept - 1.000000000000000;
  Col1      = Col1      - 1.000000000000000;
  Col2      = Col2      - 1.000000000000000;
  Col3      = Col3      - 1.000000000000000;
  Col4      = Col4      - 1.000000000000000;
  Col5      = Col5      - 1.000000000000000;
end;
else do;
  Intercept = Intercept - 1.000000000000000;
  Col1      = Col1      - 0.100000000000000;
  Col2      = Col2      - 0.100000000000000e-1;
  Col3      = Col3      - 0.100000000000000e-2;
  Col4      = Col4      - 0.100000000000000e-3;
  Col5      = Col5      - 0.100000000000000e-4;
end;
proc print data=ParmEst label noobs;
  title 'Wampler data: Deviations from Certified Values';
  format _RMSE_ Intercept Col1-Col5 e9.;
  var Dep _RMSE_ Intercept Col1-Col5;
run;

```

The results, shown in [Output 53.2.1](#), indicate that the values computed by PROC ORTHOREG are quite close to the NIST-certified values.

Chapter 54

The PHREG Procedure

Overview

The analysis of survival data requires special techniques because the data are almost always incomplete, and familiar parametric assumptions may be unjustifiable. Investigators follow subjects until they reach a prespecified endpoint (for example, death). However, subjects sometimes withdraw from a study, or the study is completed before the endpoint is reached. In these cases, the survival times (also known as failure times) are *censored*; subjects survived to a certain time beyond which their status is unknown. The uncensored survival times are sometimes referred to as *event* times. Methods for survival analysis must account for both censored and uncensored data.

There are many types of models that have been used for survival data. Two of the more popular types of models are the accelerated failure time model (Kalbfleisch and Prentice 1980) and the Cox proportional hazards model (Cox 1972). Each has its own assumptions on the underlying distribution of the survival times. Two closely related functions often used to describe the distribution of survival times are the survivor function and the hazard function (see the section “[Failure Time Distribution](#)” on page 3239 for definitions). The accelerated failure time model assumes a parametric form for the effects of the explanatory variables and usually assumes a parametric form for the underlying survivor function. Cox’s proportional hazards model also assumes a parametric form for the effects of the explanatory variables, but it allows an unspecified form for the underlying survivor function.

The PHREG procedure performs regression analysis of survival data based on the Cox proportional hazards model. Cox’s semiparametric model is widely used in the analysis of survival data to explain the effect of explanatory variables on hazard rates. The survival time of each member of a population is assumed to follow its own hazard function, $\lambda_i(t)$, expressed as

$$\lambda_i(t) = \lambda(t; \mathbf{Z}_i) = \lambda_0(t) \exp(\mathbf{Z}_i' \boldsymbol{\beta})$$

where $\lambda_0(t)$ is an arbitrary and unspecified baseline hazard function, \mathbf{Z}_i is the vector of explanatory variables for the i th individual, and $\boldsymbol{\beta}$ is the vector of unknown regression parameters associated with the explanatory variables. The vector $\boldsymbol{\beta}$ is assumed to be the same for all individuals. The survivor function can be expressed as

$$S(t; \mathbf{Z}_i) = [S_0(t)]^{\exp(\mathbf{Z}_i' \boldsymbol{\beta})}$$

where $S_0(t) = \exp(-\int_0^t \lambda_0(u) du)$ is the baseline survivor function. To estimate $\boldsymbol{\beta}$, Cox (1972; 1975) introduced the partial likelihood function, which eliminates the unknown baseline hazard $\lambda_0(t)$ and accounts for censored survival times.

The partial likelihood of Cox also allows time-dependent explanatory variables. An explanatory variable is time-dependent if its value for any given individual can change over time. Time-dependent variables have many useful applications in survival analysis. You can use a time-dependent variable to model the effect of subjects changing treatment groups. Or you can include time-dependent variables such as blood pressure or blood chemistry measures that vary with time during the course of a study. You can also use time-dependent variables to test the validity of the proportional hazards model.

An alternative way to fit models with time-dependent explanatory variables is to use the counting process style of input. The counting process formulation enables PROC PHREG to fit a superset of the Cox model, known as the multiplicative hazards model. This extension also includes recurrent events data and left truncation of failure times. The theory of these models is based on the counting process pioneered by Andersen and Gill (1982), and the model is often referred to as the Andersen-Gill Model.

Multivariate failure time data arise when each study subject can potentially experience several events (for instance, multiple infections after surgery) or when there exists some natural or artificial clustering of subjects (for instance, a litter of mice) that induces dependence among the failure times of the same cluster. Data in the former situation are referred to as multiple events data, which include recurrent events data as a special case; data in the latter situation are referred to as clustered data. You can use PROC PHREG to carry out various methods for analyzing these data.

The population under study may consist of a number of subpopulations, each of which has its own baseline hazard function. PROC PHREG performs a stratified analysis to adjust for such subpopulation differences. Under the stratified model, the hazard function for the j th individual in the i th stratum is expressed as

$$\lambda_{ij}(t) = \lambda_{i0}(t) \exp(\mathbf{Z}'_{ij}\boldsymbol{\beta})$$

where $\lambda_{i0}(t)$ is the baseline hazard function for the i th stratum, and \mathbf{Z}_{ij} is the vector of explanatory variables for the individual. The regression coefficients are assumed to be the same for all individuals across all strata.

Ties in the failure times may arise when the time scale is genuinely discrete or when survival times generated from the continuous-time model are grouped into coarser units. The PHREG procedure includes four methods of handling ties. The *discrete* logistic model is available for discrete time-scale data. The other three methods apply to continuous time-scale data. The *exact* method computes the exact conditional probability under the model that the set of observed tied event times occurs before all the censored times with the same value or before larger values. *Breslow* and *Efron* methods provide approximations to the exact method.

Variable selection is a typical exploratory exercise in multiple regression when the investigator is interested in identifying important prognostic factors from a large number of candidate variables. The PHREG procedure provides four model selection methods: forward selection, backward elimination, stepwise selection, and best subset selection. The best subset selection method is based on the likelihood score

statistic. This method identifies a specified number of best models containing one, two, three variables and so on, up to the single model containing all of the explanatory variables.

The PHREG procedure also enables you to

- include an offset variable in the model
- weight the observations in the input data
- test linear hypotheses about the regression parameters
- perform conditional logistic regression analysis for matched case-control studies
- create a SAS data set containing survivor function estimates, residuals, and regression diagnostics
- create a SAS data set containing survival distribution estimates and confidence interval for the survivor function at each event time for a given realization of the explanatory variables

PROC PHREG can also be used to fit the multinomial logit choice model to discrete choice data. See [http://support.sas.com/techsup/tnote/tnote_stat.html#market] for more information on discrete choice modeling and the multinomial logit model. Look for the latest “Discrete Choice” report.

The remaining sections of this chapter contain information on how to use PROC PHREG, information on the underlying statistical methodology, and some sample applications of the procedure. The “[Getting Started](#)” section on page 3217 introduces PROC PHREG with two examples. The “[Syntax](#)” section on page 3221 describes the syntax of the procedure. The “[Details](#)” section on page 3239 summarizes the statistical techniques employed in PROC PHREG. The “[Examples](#)” section on page 3272 includes eight additional examples of useful applications. Experienced SAS/STAT software users may decide to proceed to the “[Syntax](#)” section, while other users may choose to read both the “[Getting Started](#)” and “[Examples](#)” sections before proceeding to “[Syntax](#)” and “[Details](#).”

Experimental graphics are now available in PROC PHREG for model assessment. For more information, see the section “[ODS Graphics](#)” on page 3271.

Getting Started

PROC PHREG syntax is similar to that of the other regression procedures in the SAS System. For simple uses, only the PROC PHREG and MODEL statements are required.

Consider the following data from (Kalbfleisch and Prentice 1980). Two groups of rats received different pretreatment regimes and then were exposed to a carcinogen. Investigators recorded the survival times of the rats from exposure to mortality from vaginal cancer. Four rats died of other causes, so their survival times are censored. Interest lies in whether the survival curves differ between the two groups.

The data set `Rats` contains the variable `Days` (the survival time in days), the variable `Status` (the censoring indicator variable: 0 if censored and 1 if not censored), and the variable `Group` (the pretreatment group indicator).

```

data Rats;
  label Days = 'Days from Exposure to Death';
  input Days Status Group @@;
  datalines;
143 1 0   164 1 0   188 1 0   188 1 0
190 1 0   192 1 0   206 1 0   209 1 0
213 1 0   216 1 0   220 1 0   227 1 0
230 1 0   234 1 0   246 1 0   265 1 0
304 1 0   216 0 0   244 0 0   142 1 1
156 1 1   163 1 1   198 1 1   205 1 1
232 1 1   232 1 1   233 1 1   233 1 1
233 1 1   233 1 1   239 1 1   240 1 1
261 1 1   280 1 1   280 1 1   296 1 1
296 1 1   323 1 1   204 0 1   344 0 1
;
run;

```

In the `MODEL` statement, the response variable, `Days`, is crossed with the censoring variable, `Status`, with the value that indicates censoring enclosed in parentheses (0). The values of `Days` are considered censored if the value of `Status` is 0; otherwise, they are considered event times.

```

proc phreg data=Rats;
  model Days*Status(0)=Group;
run;

```

Results of the PROC PHREG analysis appear in [Figure 54.1](#). Since `Group` takes only two values, the null hypothesis for no difference between the two groups is identical to the null hypothesis that the regression coefficient for `Group` is 0. All three tests in the “Testing Global Null Hypothesis: BETA=0” table (see the section “Testing the Global Null Hypothesis” on page 3246) suggest that the survival curves for the two pretreatment groups may not be the same. In this model, the hazards ratio (or risk ratio) for `Group`, defined as the exponentiation of the regression coefficient for `Group`, is the ratio of the hazard functions between the two groups. The estimate is 0.551, implying that the hazard function for `Group`=1 is smaller than that for `Group`=0. In other words, rats in `Group`=1 lived longer than those in `Group`=0.

```

The PHREG Procedure

Figure 54.1. Comparison of Two Survival Curves

In this example, the comparison of two survival curves is put in the form of a proportional hazards model. This approach is essentially the same as the log-rank (Mantel-Haenszel) test. In fact, if there are no ties in the survival times, the likelihood score test in the Cox regression analysis is identical to the log-rank test. The advantage of the Cox regression approach is the ability to adjust for the other variables by including them in the model. For example, the present model could be expanded by including a variable that contains the initial body weights of the rats.

Next, consider a simple test of the validity of the proportional hazards assumption. The proportional hazards model for comparing the two pretreatment groups is given by the following:

$$\lambda(t) = \begin{cases} \lambda_0(t) & \text{if GROUP} = 0 \\ \lambda_0(t)e^{\beta_1} & \text{if GROUP} = 1 \end{cases}$$

The ratio of hazards is e^{β_1} , which does not depend on time. If the hazard ratio changes with time, the proportional hazards model assumption is invalid. Simple forms of departure from the proportional hazards model can be investigated with the following time-dependent explanatory variable $x = x(t)$:

$$x(t) = \begin{cases} 0 & \text{if GROUP} = 0 \\ \log(t) - 5.4 & \text{if GROUP} = 1 \end{cases}$$

Here, $\log(t)$ is used instead of t to avoid numerical instability in the computation. The constant, 5.4, is the average of the logs of the survival times and is included to improve interpretability. The hazard ratio in the two groups then becomes $e^{\beta_1 - 5.4\beta_2} t^{\beta_2}$, where β_2 is the regression parameter for the time-dependent variable x . The term e^{β_1} represents the hazard ratio at the geometric mean of the survival times. A nonzero value of β_2 would imply an increasing ($\beta_2 > 0$) or decreasing ($\beta_2 < 0$) trend in the hazard ratio with time.

The MODEL statement in this analysis also includes the time-dependent explanatory variable X, which is defined within the procedure by the programming statement that follows the MODEL statement. At each event time, subjects in the risk set (those alive just before the event time) have their X values changed accordingly.

```
proc phreg data=Rats;
  model Days*Status(0)=Group X;
  X=Group*(log(Days) - 5.4);
run;
```

The PHREG Procedure						
Analysis of Maximum Likelihood Estimates						
Variable	DF	Parameter Estimate	Standard Error	Chi-Square	Pr > ChiSq	Hazard Ratio
Group	1	-0.59976	0.34837	2.9639	0.0851	0.549
X	1	-0.22952	1.82489	0.0158	0.8999	0.795

Figure 54.2. A Simple Test of Trend in the Hazard Ratio

The analysis of the parameter estimates is displayed in [Figure 54.2](#). The Wald chi-square statistic for testing the null hypothesis that $\beta_2 = 0$ is 0.0158. The statistic is not statistically significant when compared to a chi-square distribution with one degree of freedom ($p = 0.8999$). Thus, you can conclude that there is no evidence of an increasing or decreasing trend over time in the hazard ratio. See the “[Examples](#)” section beginning on page 3272 for additional illustrations of PROC PHREG usage.

Syntax

The following statements are available in PROC PHREG.

```

PROC PHREG < options > ;
  ASSESS keyword < / options > ;
  MODEL response < *censor(list) > = variables < /options > ;
  < programming statements >
  STRATA variable < (list) > < ...variable < (list) >>< /option > ;
  < label: > TEST equation1 < ,... , equationk >< /option > ;
  FREQ variable ;
  WEIGHT variable < /option > ;
  ID variables ;
  OUTPUT < OUT=SAS-data-set >
    < keyword=name... keyword=name >< /options > ;
  BASELINE < OUT=SAS-data-set >
    < COVARIATES=SAS-data-set >
    < keyword=name... keyword=name >< /options > ;
  BY variables ;

```

The PROC PHREG statement invokes the procedure. All other statements except the MODEL statement are optional. Items within < > are optional, and there is no required order for the statements following the PROC PHREG statement. The MODEL statement specifies the variables that define the survival time, the censoring variable, and the explanatory variables. The STRATA statement specifies a variable or set of variables defining the strata for the analysis. The TEST statement contains equations that define linear hypotheses concerning the model parameters. The ID statement specifies the variables with values that are used to label the observations. The OUTPUT and BASELINE statements create data sets containing the survival estimates. DATA step programming statements can be included to create time-dependent explanatory variables.

PROC PHREG Statement

```

PROC PHREG < options > ;

```

You can specify the following options in the PROC PHREG statement.

COVOUT

adds the estimated covariance matrix of the parameter estimates to the OUTEST= data set. The COVOUT option has no effect unless the OUTEST= option is specified.

COVM

requests the model-based covariance matrix (which is the inverse of the observed information matrix) be presented and used in the analysis if the COVS option is also specified. The COVM option has no effect if the COVS option is not specified.

COVSANDWICH < (AGGREGATE) >**COVS < (AGGREGATE) >**

requests the robust sandwich estimate of Lin and Wei (1989) for the covariance matrix. When this option is specified, this robust sandwich estimate is used in the Wald tests for testing the global null hypothesis, null hypotheses of individual parameters, and the hypotheses in the TEST statements. In addition, a modified score test is computed in the testing of the global null hypothesis, and the parameter estimates table has an additional StdErrRatio column, which contains the ratios of the robust estimate of the standard error relative to the corresponding model-based estimate. Optionally, you can specify the keyword AGGREGATE enclosed in parentheses after the COVSANDWICH (or COVS) option, which requests a summing up of the score residuals for each distinct ID pattern in the computation of the robust sandwich covariance estimate. This AGGREGATE option has no effects if the ID statement is not specified.

DATA=SAS-data-set

names the SAS data set containing the data to be analyzed. If you omit the DATA= option, the procedure uses the most recently created SAS data set.

MULTIPASS

requests that, for each Newton-Raphson iteration, PROC PHREG recompiles the risk sets corresponding to the event times for the (start,stop) style of response and recomputes the values of the time-dependent variables defined by the programming statements for each observation in the risk sets. If the MULTIPASS option is not specified, PROC PHREG computes all risk sets and all the variable values and saves them into a utility file. The MULTIPASS option decreases required disk space at the expense of increased execution time; however, for very large data, it may actually save time since it is time consuming to write and read large utility files. This option has an effect only when the (start,stop) style of response is used or when there are time-dependent explanatory variables.

NOPRINT

suppresses all displayed output. Note that this option temporarily disables the Output Delivery System (ODS); see Chapter 14, “Using the Output Delivery System,” for more information.

NOSUMMARY

suppresses the display of the event and censored observation frequencies.

OUTEST=SAS-data-set

creates an output SAS data set that contains estimates of the regression coefficients. If you use the COVOUT option, the data set also contains the estimated covariance matrix of the parameter estimates. The data set includes

- any BY variables specified
- `_TIES_`, a character variable of length 8 with four possible values: BRESLOW, DISCRETE, EFRON, and EXACT. These are the four values of the TIES= option in the MODEL statement.

- `_TYPE_`, a character variable of length 8 with two possible values: `PARMS` for parameter estimates or `COV` for covariance estimates. If both the `COVM` and `COVS` options are specified in the `PROC LIFETEST` statement along with the `COVOUT` option, `_TYPE_=COVM` for the model-based covariance estimates and `_TYPE_=COVS` for the robust sandwich covariance estimates.
- `_STATUS_`, a character variable indicating whether the estimates have converged
- `_NAME_`, a character variable containing the name of the `TIME` variable for the row of parameter estimates and the name of each explanatory variable to label the rows of covariance estimates
- one variable for each explanatory variable in the `MODEL` statement. In a forward, backward, or stepwise regression analysis, if an explanatory variable is not included in the final model, the corresponding parameter estimate and covariances are set to missing.
- `_LNLIKE_`, a numeric variable containing the last computed value of the log likelihood

SIMPLE

displays simple descriptive statistics (mean, standard deviation, minimum, and maximum) for each explanatory variable in the `MODEL` statement.

ASSESS Statement (Experimental)

ASSESS < **VAR**=(*list*) > < **PH** > < /*options* > ;

The `ASSESS` statement performs the graphical and numerical methods of Lin, Wei, and Ying (1993) for checking the adequacy of the Cox regression model. The methods are derived from cumulative sums of martingale residuals over follow-up times or covariate values. You can assess the functional form of a covariate or you can check the proportional hazards assumption for each covariate in the Cox model. `PROC PHREG` uses the experimental ODS graphics for the graphical displays. For specific information about the experimental graphics that is available in `PROC PHREG`, see the section “[ODS Graphics](#)” on page 3271. You must specify at least one of the following to create an analysis.

VAR=(list)

specifies the list of explanatory variables for which their functional forms are assessed. For each variable on the list, the observed cumulative martingale residuals are plotted against the values of the explanatory variable along with 20 (or n if `NPATHS= n` is specified) simulated residual patterns.

PROPORTIONALHAZARDS**PH**

requests the checking of the proportional hazards assumption. For each explanatory variable in the model, the observed score process component is plotted against the follow-up time along with 20 (or n if `NPATHS= n` is specified) simulated patterns.

The following options can be specified after a slash (/).

NPATHS=*n*

specifies the number of simulated residual patterns to be displayed in a cumulative martingale residual plot or a score process plot. The default is $n=20$.

CRPANEL

requests that a plot with four panels, each containing the observed cumulative martingale residuals and two simulated residual patterns, be created.

RESAMPLE <=*n*>

requests that the Kolmogorov-type supremum test be computed on 1,000 simulated patterns or on n simulated patterns if n is specified.

SEED=*n*

specifies an integer seed for the random number generator used in creating simulated realizations for plots and for the Kolmogorov-type supremum tests. Specifying a seed enables you to reproduce identical graphs and p -values for the model assessments from the same PHREG specification. If the SEED= option is not specified, or if you specify a nonpositive seed, a random seed is derived from the time of day.

BASELINE Statement

```
BASELINE < OUT= SAS-data-set >< COVARIATES= SAS-data-set >
< keyword=name ... keyword=name >< /options > ;
```

The BASELINE statement creates a new SAS data set that contains the survivor function estimates at the event times of each stratum for every pattern of explanatory variable values (\mathbf{x}) given in the COVARIATES= data set. By default, the data set also contains the survivor function estimates corresponding to the means of the explanatory variables ($\mathbf{x} = \bar{\mathbf{z}}$) for each stratum. If you want only these estimates, you can omit the COVARIATES= option. No BASELINE data set is created if the model contains a time-dependent variable defined by means of programming statement.

The following list explains specifications in the BASELINE statement.

OUT=*SAS-data-set*

names the output BASELINE data set. If you omit the OUT= option, the data set is created and given a default name using the DATA*n* convention.

COVARIATES=*SAS-data-set*

names the SAS data set containing the set of explanatory variable values for which the survivor functions are estimated. There must be a corresponding variable in the COVARIATES= data set for each explanatory variable in the final model.

keyword=name

specifies the statistics included in the BASELINE data set and assigns names to the new variables that contain the statistics. Specify a keyword for each desired statistic (see the following list of keywords), an equal sign, and the variable to contain the statistic. The keywords and the corresponding statistics are

CMF	cumulative mean function estimate for recurrent events data. Specifying CMF=_ALL_ is equivalent to specifying CMF=CMF, STDCMF=StdErrCMF, LOWERCMF=LowerCMF,
-----	---

and UPPERCMF=UpperCMF. Nelson (2002) refers to the mean function estimate as MCF (mean cumulative function).

CUMHAZ	cumulative hazard function estimate for recurrent events data. Specifying CMFHAZ=_ALL_ is equivalent to specifying CUMHAZ=CumHaz, STDCUMHAZ=StdErrCumHaz, LOWERCUMHAZ=LowerCumHaz, and UPPERCUMHAZ=UpperCumHaz.
LOGLOGS	log of the negative log of SURVIVAL
LOGSURV	log of SURVIVAL
LOWER L	lower pointwise confidence limit for the survivor function . The confidence level is determined by the ALPHA= option.
LOWERCMF	lower pointwise confidence limit for the cumulative mean function. The confidence level is determined by the ALPHA= option.
LOWERCUMHAZ	lower pointwise confidence limit for the cumulative hazard function. The confidence level is determined by the ALPHA= option.
STDERR	standard error of the survivor function estimator
STDCMF	standard error of the cumulative mean function estimator
STDCUMHAZ	standard error of the cumulative hazard function estimator
STDXBETA	standard error of the linear predictor estimator , $\sqrt{\mathbf{x}'\widehat{\mathbf{V}}(\widehat{\boldsymbol{\beta}})\mathbf{x}}$
SURVIVAL	survivor function estimate $\widehat{S}(t) = [\widehat{S}_0(t)]^{\exp(\mathbf{x}'\widehat{\boldsymbol{\beta}})}$ Specifying SURVIVAL=_ALL_ is equivalent to specifying SURVIVAL=Survival, STDERR=StdErrSurvival, LOWER=LowerSurvival, and UPPER=UpperSurvival.
UPPER U	upper pointwise confidence limit for the survivor function . The confidence level is determined by the ALPHA= option.
UPPERCMF	upper pointwise confidence limit for the cumulative mean function. The confidence level is determined by the ALPHA= option.
UPPERCUMHAZ	upper pointwise confidence limit for the cumulative hazard function. The confidence level is determined by the ALPHA= option.
XBETA	estimate of the linear predictor, $\mathbf{x}'\widehat{\boldsymbol{\beta}}$

The following options can appear in the BASELINE statement after a slash (/).

ALPHA=value

specifies the significance level of the confidence interval for the survivor function. The value must be between 0 and 1. The default is 0.05, which results in a 95% confidence interval.

CLTYPE=method

specifies the method used to compute the confidence limits for $S(t, \mathbf{z})$, the survivor function for a subject with a fixed covariate vector \mathbf{z} at event time t . The CLTYPE= option can take the following values:

LOG	specifies that the confidence limits for $\log(S(t, \mathbf{z}))$ are to be computed using the normal theory approximation. The confidence limits for $S(t, \mathbf{z})$ are obtained by back-transforming the confidence limits for $\log(S(t, \mathbf{z}))$. The default is CLTYPE=LOG.
LOGLOG	specifies that the confidence limits for the $\log(-\log(S(t, \mathbf{z})))$ are to be computed using normal theory approximation. The confidence limits for $S(t, \mathbf{z})$ are obtained by back-transforming the confidence limits for $\log(-\log(S(t, \mathbf{z})))$.
NORMAL	specifies that the confidence limits for $S(t, \mathbf{z})$ are to be computed directly using normal theory approximation.

METHOD=method

specifies the method used to compute the survivor function estimates. The two available methods are

CH EMP NELSON	specifies that the Nelson (empirical) cumulative hazard function estimate of the survivor function is to be computed; that is, the survivor function is estimated by exponentiating the negative empirical cumulative hazard function.
PL	specifies that the product-limit estimate of the survivor function is to be computed. The default is METHOD=PL.

NOMEAN

excludes the survivor function estimates corresponding to the sample means of the explanatory variables.

The METHOD= and CLTYPE= options apply only to the survival estimates. For recurrent events data, both CMF= and CUMHAZ= statistics are the Nelson estimators, but their standard error are not the same. Confidence limits for the cumulative mean function and cumulative hazard function are based on the log transform.

BY Statement

BY variables ;

You can specify a BY statement with PROC PHREG to obtain separate analyses on observations in groups defined by the BY variables. When a BY statement appears, the procedure expects the input data set to be sorted in order of the BY variables. The *variables* are one or more variables in the input data set.

If your input data set is not sorted in ascending order, use one of the following alternatives:

- Sort the data using the SORT procedure with a similar BY statement.
- Specify the BY statement option NOTSORTED or DESCENDING in the BY statement for the PHREG procedure. The NOTSORTED option does not mean that the data are unsorted but rather that the data are arranged in groups (according to values of the BY variables) and that these groups are not necessarily in alphabetical or increasing numeric order.

- Create an index on the BY variables using the DATASETS procedure (in base SAS software).

For more information on the BY statement, refer to the discussion in *SAS Language Reference: Contents*. For more information on the DATASETS procedure, refer to the discussion in the *SAS Procedures Guide*.

FREQ Statement

FREQ *variable* < /option > ;

The *variable* in the FREQ statement identifies the variable (in the input data set) containing the frequency of occurrence of each observation. PROC PHREG treats each observation as if it appears *n* times, where *n* is the value of the FREQ variable for the observation. If not an integer, the frequency value is truncated to an integer. If the frequency value is missing, the observation is not used in the estimation of the regression parameters.

The following option can be specified in the FREQ statement after a slash (/):

NOTTRUNCATE

NOTRUNC

specifies that frequency values are not truncated to integers.

ID Statement

ID *variables* ;

The ID statement specifies additional variables for identifying observations in the input data. These variables are placed in the OUT= data set created by the OUTPUT statement. In the computation of the [robust sandwich variance estimate](#), you can aggregate over distinct values of these ID variables.

Only variables in the input data set can be included in the ID statement.

MODEL Statement

MODEL *response* < **censor* (*list*) > = *variables* < /options > ;

MODEL (*t1*, *t2*) < **censor*(*list*) > = *variables* < /options > ;

The MODEL statement identifies the variables to be used as the failure time variables, the optional censoring variable, and the explanatory variables. Two forms of MODEL syntax can be specified; the first form allows one response variable, while the second form allows two variables for the counting process style of input (see the section [“Counting Process Style of Input”](#) on page 3241 for more information).

In the first MODEL statement, preceding the equal sign, is the name of the failure time variable. This can optionally be followed by an asterisk, the name of the censoring variable, and a list of censoring values (separated by blanks or commas if there is more than one) enclosed in parentheses. If the censoring variable takes on one of these values, the corresponding failure time is considered to be censored. The

variables following the equal sign are the explanatory variables (sometimes called independent variables or covariates) for the model.

Instead of a single failure time variable, the second MODEL statement identifies a pair of failure time variables. Their names are enclosed in parentheses, and they signify the endpoints of a semi-closed interval $(t1, t2]$ during which the subject is at risk. If the censoring variable takes on one of the censoring values, the time $t2$ is considered to be censored.

The censoring variable and the explanatory variables must be numeric. The failure time variables must contain nonnegative values. Any observation with a negative failure time is excluded from the analysis, as is any observation with a missing value for any of the variables listed in the MODEL statement.

You can specify the following options in the MODEL statement.

Ties-Handling Option

TIES=method

specifies how to handle ties in the failure time. The TIES= option can take the following values:

BRESLOW uses the approximate likelihood of Breslow (1974). This is the default value.

DISCRETE replaces the proportional hazards model by the discrete logistic model

$$\frac{\lambda(t; \mathbf{z})}{1 - \lambda(t; \mathbf{z})} = \frac{\lambda_0(t)}{1 - \lambda_0(t)} \exp(\mathbf{z}'\boldsymbol{\beta})$$

where $\lambda_0(t)$ and $h(t; \mathbf{z})$ are discrete hazard functions.

EFRON uses the approximate likelihood of Efron (1977).

EXACT computes the exact conditional probability under the proportional hazards assumption that all tied event times occur before censored times of the same value or before larger values. This is equivalent to summing all terms of the marginal likelihood for $\boldsymbol{\beta}$ that are consistent with the observed data (Kalbfleisch and Prentice 1980; DeLong, Guirguis, and So 1994).

The EXACT method may take a considerable amount of computer resources. If ties are not extensive, the EFRON and BRESLOW methods provide satisfactory approximations to the EXACT method for the continuous time-scale model. In general, Efron's approximation gives results that are much closer to the EXACT method results than Breslow's approximation does. If the time scale is genuinely discrete, you should use the DISCRETE method. The DISCRETE method is also required in the analysis of case-control studies when there is more than one case in a matched set. If there are no ties, all four methods result in the same likelihood and yield identical estimates. The default, TIES=BRESLOW, is the most efficient method when there are no ties.

Model-Specification Options

ENTRYTIME=*variable*

ENTRY=*variable*

specifies the name of the variable that represents the left truncation time. This option has no effect when the counting process style of input is specified. See the section “[Left Truncation of Failure Times](#)” on page 3263 for more information.

NOFIT

performs the global score test, which tests the joint significance of all the explanatory variables in the MODEL statement. No parameters are estimated. If the NOFIT option is specified along with other MODEL statement options, NOFIT takes precedence, and all other options are ignored except the TIES= option.

OFFSET=*name*

specifies the name of an offset variable, which is an explanatory variable with a regression coefficient fixed as one. This option can be used to incorporate risk weights for the likelihood function.

SELECTION=*method*

specifies the method used to select the model. The *methods* available are

BACKWARD | B requests backward elimination.

FORWARD | F requests forward selection.

NONE | N fits the complete model specified in the MODEL statement. This is the default value.

SCORE requests best subset selection. It identifies a specified number of models with the highest score chi-square statistic for all possible model sizes ranging from one explanatory variable to the total number of explanatory variables listed in the MODEL statement.

STEPWISE | S requests stepwise selection.

For more information, see the section “[Variable Selection Methods](#)” on page 3264.

Model-Building Options

The following options enable you to provide additional specifications for the BACKWARD, FORWARD, SCORE, and STEPWISE model selection methods. They have no effect when SELECTION=NONE. Only the INCLUDE=, START=, STOP=, and BEST= options work with the SCORE method.

BEST=*n*

is used exclusively with the SCORE model selection method. The BEST=*n* option specifies that *n* models with the highest score chi-square statistics are to be displayed for each model size. If the option is omitted and there are no more than 10 explanatory variables, then all possible models are listed for each model size. If the option is omitted and there are more than 10 explanatory variables, then the number of models selected for each model size is, at most, equal to the number of explanatory variables

listed in the MODEL statement. See [Example 54.2](#) on page 3279 for an illustration of the SCORE selection method and the BEST= option.

DETAILS

produces a detailed display at each step of the model-building process. It produces an “Analysis of Variables Not in the Model” table before displaying the variable selected for entry for FORWARD or STEPWISE selection. For each model fitted, it produces the “Analysis of Maximum Likelihood Estimates” table. See [Example 54.1](#) on page 3272 for a discussion of these tables.

INCLUDE=*n*

includes the first *n* explanatory variables listed in the MODEL statement in every model. The value for *n* ranges from 1 to *s*, where *s* is the number of explanatory variables in the MODEL statement. The default value of *n* is 0.

MAXSTEP=*n*

specifies the maximum number of times the explanatory variables can move in and out of the model before the STEPWISE model-building process ends. The default value for *n* is twice the number of explanatory variables in the MODEL statement. The option has no effect for other model selection methods.

SEQUENTIAL

forces variables to be added to the model in the order specified in the MODEL statement or to be eliminated from the model in the reverse order specified in the MODEL statement.

SLENTRY=*value*

SLE=*value*

specifies the significance level (a value between 0 and 1) for entering an explanatory variable into the model in the FORWARD or STEPWISE method. For all variables not in the model, the one with the smallest *p*-value is entered if the *p*-value is less than or equal to the specified significance level. The default value is 0.05.

SLSTAY=*value*

SLS=*value*

specifies the significance level (a value between 0 and 1) for removing an explanatory variable from the model in the BACKWARD or STEPWISE method. For all variables in the model, the one with the largest *p*-value is removed if the *p*-value exceeds the specified significance level. The default value is 0.05.

START=*n*

begins the FORWARD, BACKWARD, or STEPWISE model selection process with the first *n* explanatory variables listed in the MODEL statement. The value for *n* ranges from 0 to *s*, where *s* is the total number of explanatory variables in the MODEL statement. The default value of *n* is *s* for the BACKWARD method and 0 for the FORWARD and STEPWISE methods. Note that START=*n* specifies only that the first *n* explanatory variables appear in the first model, while INCLUDE=*n* specifies that the first *n* explanatory variables be included in every model. For the SCORE method, START=*n* specifies that the smallest models contain *n* explanatory variables, where *n* ranges from 1 to *s*. The default value of *n* is 1.

STOP=*n*

specifies the maximum (FORWARD method) or minimum (BACKWARD method) number of explanatory variables to be included in the final model. The value for *n* ranges from 0 to *s*, where *s* is the number of explanatory variables in the MODEL statement. The default value of *n* is 0 for the BACKWARD method and *s* for the FORWARD method. For the SCORE method, STOP=*n* specifies that the largest models contain *n* explanatory variables, where *n* ranges from 1 to *s*. The default value of *n* is *s*. The STOP= option has no effect for the STEPWISE method.

STOPRES**SR**

specifies that the addition and deletion of variables are to be based on the result of the likelihood score test for testing the joint significance of variables not in the model. This score chi-square statistic is referred to as the residual chi-square. In the FORWARD method, the STOPRES option enters the explanatory variables into the model one at a time until the residual chi-square becomes insignificant (that is, until the *p*-value of the residual chi-square exceeds the SLENTY= value). In the BACKWARD method, the STOPRES option removes variables from the model one at a time until the residual chi-square becomes significant (that is, until the *p*-value of the residual chi-square becomes less than the SLSTAY= value). The STOPRES option has no effect for the STEPWISE method.

Optimization Options

Four convergence criteria are allowed: ABSFCNV=, FCONV=, GCONV=, and XCONV=. If you specify more than one convergence criterion, the optimization is terminated as soon as one of the criteria is satisfied. If none of the criteria is specified, the default is GCONV=1E-8.

ABSFCNV=*value*

specifies the absolute function convergence criterion. Termination requires a small change in the objective function (log partial likelihood function) in subsequent iterations,

$$|l_k - l_{k-1}| < \textit{value}$$

where l_k is the value of the objective function at iteration *k*.

CONVERGELIKE=*value*

is the same as specifying the ABSFCNV= option.

CONVERGEPARM=*value*

is the same as specifying the XCONV= option.

FCONV=*value*

specifies the relative function convergence criterion. Termination requires a small relative change in the objective function (log partial likelihood function) in subsequent iterations,

$$\frac{|l_k - l_{k-1}|}{|l_{k-1}| + 1\text{E} - 6} < value$$

where l_k is the value of the objective function at iteration k .

GCONV=value

specifies the relative gradient convergence criterion. Termination requires that the normalized prediction function reduction is small,

$$\frac{\mathbf{g}_k \mathbf{H}_k^{-1} \mathbf{g}_k}{|l_k| + 1\text{E} - 6} < value$$

where l_k is the log partial likelihood, \mathbf{g}_k is the gradient vector (first partial derivatives of the log partial likelihood), and \mathbf{H}_k is the negative Hessian matrix (second partial derivatives of the log partial likelihood), all at iteration k .

MAXITER=n

specifies the maximum number of iterations allowed. The default value for n is 25. If convergence is not attained in n iterations, the displayed output and all data sets created by PROC PHREG contain results that are based on the last maximum likelihood iteration.

RIDGING=ABSOLUTE | RELATIVE | NONE

specifies the technique to improve the log-likelihood when its value is worse than that of the previous step. For RIDGING=ABSOLUTE, the diagonal elements of the negative (expected) Hessian are inflated by adding the ridge value. For RIDGING=RELATIVE, the diagonal elements are inflated by the factor equal to 1 plus the ridge value. For RIDGING=NONE, the crude line-search method of taking half a step is used instead of ridging.

SINGULAR=value

specifies the singularity criterion for determining linear dependencies in the set of explanatory variables. The default value is 10^{-12} .

XCONV=value

specifies the relative parameter convergence criterion. Termination requires a small relative parameter change in subsequent iterations,

$$\max_i |\delta_k^{(i)}| < value$$

where

$$\delta_k^{(i)} = \begin{cases} \theta_k^{(i)} - \theta_{k-1}^{(i)} & |\theta_{k-1}^{(i)}| < .01 \\ \frac{\theta_k^{(i)} - \theta_{k-1}^{(i)}}{\theta_{k-1}^{(i)}} & \text{otherwise} \end{cases}$$

where $\theta_k^{(i)}$ is the estimate of the i th parameter at iteration k .

Display Options

ALPHA=*value*

sets the significance level used for the confidence limits for the hazards ratios. The value must be between 0 and 1. The default value is 0.05, which results in the calculation of a 95% confidence interval. This option has no effect unless the RISKLIMITS option is specified.

CORRB

displays the estimated correlation matrix of the parameter estimates.

COVB

displays the estimated covariance matrix of the parameter estimates.

ITPRINT

displays the iteration history, including the last evaluation of the gradient vector.

RISKLIMITS

RL

displays, for each explanatory variable, the $100(1 - \alpha)\%$ confidence limits for the hazards ratio (e^{β_i}). The value for α is determined by the ALPHA= option.

OUTPUT Statement

```
OUTPUT <OUT= SAS-data-set >
      < keyword=name ... keyword=name >< /options > ;
```

The OUTPUT statement creates a new SAS data set containing statistics calculated for each observation. These can include the estimated linear predictor ($\mathbf{z}'_j \hat{\boldsymbol{\beta}}$) and its standard error, survival distribution estimates, residuals, and influence statistics. In addition, this data set includes the time variable, the explanatory variables listed in the MODEL statement, the censoring variable (if specified), and the BY, STRATA, FREQ, and ID variables (if specified).

For observations with missing values in the time variable or any explanatory variables, the output statistics are set to missing. However, for observations with missing values only in the censoring variable or the FREQ variable, survival estimates are still computed. Therefore, by adding observations with missing values in the FREQ variable or the censoring variable, you can compute the survivor function estimates for new observations or for settings of explanatory variables not present in the data without affecting the model fit.

No OUTPUT data set is created if the model contains a time-dependent variable defined by means of programming statements.

The following list explains specifications in the OUTPUT statement.

OUT=SAS-data-set

names the output data set. If you omit the OUT= option, the OUTPUT data set is created and given a default name using the DATA*n* convention.

keyword=name

specifies the statistics included in the OUTPUT data set and names the new variables that contain the statistics. Specify a keyword for each desired statistic (see the following list of keywords), an equal sign, and either a variable or a list of variables to contain the statistic. The keywords that accept a list of variables are DFBETA, RESSCH, RESSCO, and WTRESSCH. For these keywords, you can specify as many names in *name* as the number of explanatory variables specified in the MODEL statement. If you specify k names and k is less than the total number of explanatory variables, only the changes for the first k parameter estimates are output. The keywords and the corresponding statistics are as follows:

DFBETA	approximate changes in the parameter estimates $(\hat{\beta} - \hat{\beta}_{(j)})$ when the j th observation is omitted. These variables are a weighted transform of the score residual variables and are useful in assessing local influence and in computing robust variance estimates.
LD	approximate likelihood displacement when the observation is left out. This diagnostic can be used to assess the impact of each observation on the overall fit of the model.
LMAX	relative influence of observations on the overall fit of the model. This diagnostic is useful in assessing the sensitivity of the fit of the model to each observation.
LOGLOGS	log of the negative log of SURVIVAL
LOGSURV	log of SURVIVAL
NUM_LEFT	number of subjects at risk at the observation time τ_j (or at the right endpoint of the at risk interval when a counting process MODEL specification is used)
RESDEV	deviance residual \hat{D}_j . This is a transform of the martingale residual to achieve a more symmetric distribution.
RESMART	martingale residual \hat{M}_j . The residual at the observation time τ_j can be interpreted as the difference over $[0, \tau_j]$ in the observed number of events minus the expected number of events given by the model.
RESSCH	Schoenfeld residuals. These residuals are useful in assessing the proportional hazards assumption.
RESSCO	score residuals. These residuals are a decomposition of the first partial derivative of the log likelihood. They can be used to assess the leverage exerted by each subject in the parameter estimation. They are also useful in constructing robust sandwich variance estimators.

STDXBETA	standard error of the estimated linear predictor , $\sqrt{\mathbf{z}'_j \widehat{\mathbf{V}}(\widehat{\boldsymbol{\beta}}) \mathbf{z}_j}$
SURVIVAL	survivor function estimate $\widehat{S}_j = [\widehat{S}_0(\tau_j)]^{\exp(\mathbf{z}'_j \widehat{\boldsymbol{\beta}})}$, where τ_j is the observation time
WTRESSCH	weighted Schoenfeld residuals. These residuals are useful in investigating the nature of nonproportionality if the proportional hazard assumption does not hold.
XBETA	estimate of the linear predictor, $\mathbf{z}'_j \widehat{\boldsymbol{\beta}}$

The following options can appear in the OUTPUT statement after a slash (/).

ORDER=*sort_order*

specifies the order of the observations in the OUTPUT data set. Available values for *sort_order* are

DATA	requests that the output observations be sorted the same as the input data set.
SORTED	requests that the output observations be sorted by strata and descending order of the time variable within each stratum.

The default is ORDER=DATA.

METHOD=*method*

specifies the method used to compute the survivor function estimates. The two available methods are

CH EMP	specifies that the empirical cumulative hazard function estimate of the survivor function is to be computed; that is, the survivor function is estimated by exponentiating the negative empirical cumulative hazard function.
PL	specifies that the product-limit estimate of the survivor function is to be computed. The default is METHOD=PL.

Programming Statements

Programming statements are used to create or modify the values of the explanatory variables in the MODEL statement. They are especially useful in fitting models with time-dependent explanatory variables. Programming statements can also be used to create explanatory variables that are not time dependent. For example, you can create indicator variables from a categorical variable and incorporate them into the model. PROC PHREG programming statements cannot be used to create or modify the values of the response variable, the censoring variable, the frequency variable, or the strata variables.

The following DATA step statements are available in PROC PHREG:

```

ABORT
ARRAY
assignment statements
CALL
DO
iterative DO
DO UNTIL
DO WHILE
END
GOTO
IF-THEN/ELSE
LINK-RETURN
PUT
SELECT
SUM statement

```

By default, the PUT statement in PROC PHREG writes to the Output window instead of the Log window. If you want the results of the PUT statements to go to the Log window, add the following statement before the PUT statements:

```
FILE LOG;
```

DATA step functions are also available. Use these programming statements the same way you use them in the DATA step. For detailed information, refer to *SAS Language Reference: Dictionary*.

Consider the following example of using programming statements in PROC PHREG. Suppose blood pressure is measured at multiple times during the course of a study investigating the effect of blood pressure on some survival time. By treating the blood pressure as a time-dependent explanatory variable, you are able to use the value of the most recent blood pressure at each specific point of time in the modeling process rather than using the initial blood pressure or the final blood pressure. The values of the following variables are recorded for each patient, if they are available. Otherwise, the variables contain missing values.

Time	survival time
Censor	censoring indicator (with 0 as the censoring value)
BP0	blood pressure on entry to the study
T1	time 1
BP1	blood pressure at T1
T2	time 2
BP2	blood pressure at T2

The following programming statements create a variable BP. At each time T, the value of BP is the blood pressure reading for that time, if available. Otherwise, it is the last blood pressure reading.

```

proc phreg;
  model Time*Censor(0)=BP;
  BP = BP0;
  if Time>=T1 and T1^=. then BP=BP1;
  if Time>=T2 and T2^=. then BP=BP2;
run;

```

For other illustrations of using programming statements, see the “Getting Started” section on page 3217 and [Example 54.4](#) on page 3285.

STRATA Statement

STRATA *variable* < (*list*) >< ... *variable* < (*list*) >>< /*option* > ;

The proportional hazards assumption may not be realistic for all data. If so, it may still be reasonable to perform a stratified analysis. The STRATA statement names the variables that determine the stratification. Strata are formed according to the nonmissing values of the STRATA variables unless the MISSING option is specified. In the STRATA statement, *variable* is a variable with values that are used to determine the strata levels, and *list* is an optional list of values for a numeric variable. Multiple variables can appear in the STRATA statement.

The values for *variable* can be formatted or unformatted. If the variable is a character variable, or if the variable is numeric and no list appears, then the strata are defined by the unique values of the variable. If the variable is numeric and is followed by a list, then the levels for that variable correspond to the intervals defined by the list. The corresponding strata are formed by the combination of levels and unique values. The list can include numeric values separated by commas or blanks, *value* to *value* by *value* range specifications, or combinations of these.

For example, the specification

```
strata age (5, 10 to 40 by 10) sex ;
```

indicates that the levels for **age** are to be less than 5, 5 to 10, 10 to 20, 20 to 30, 30 to 40, and greater than 40. (Note that observations with exactly the cutpoint value fall into the interval preceding the cutpoint.) Thus, with the **sex** variable, this STRATA statement specifies 12 strata altogether.

The following option can be specified in the STRATA statement after a slash (/).

MISSING

allows missing values (‘.’ for numeric variables and blanks for character variables) as valid STRATA variable values. Otherwise, observations with missing STRATA variable values are deleted from the analysis.

TEST Statement

`< label: > TEST equation1 < , ... , equationk > < /option > ;`

The TEST statement tests linear hypotheses about the regression coefficients. PROC PHREG performs a Wald test for the joint hypothesis specified in a single TEST statement. Each equation specifies a linear hypothesis; multiple equations (rows of the joint hypothesis) are separated by commas. The label, which must be a valid SAS name, is used to identify the resulting output, and should always be included. You can submit multiple TEST statements.

The form of an equation is as follows:

`term < ±term ... > < = < ±term < ±term ... >>>`

here *term* is a variable or a constant or a constant times a variable. The variable is any explanatory variable in the MODEL statement. When no equal sign appears, the expression is set to 0. The following code illustrates possible uses of the TEST statement:

```
proc phreg;
  model time= a1 a2 a3 a4;
  Test1: Test a1, a2;
  Test2: Test a1=0,a2=0;
  Test3: Test a1=a2=a3;
  Test4: Test a1=a2,a2=a3;
run;
```

Note that the first and second TEST statements are equivalent, as are the third and fourth TEST statements.

The following options can be specified in the TEST statement after a slash (/).

AVERAGE

enables you to assess the average effect of the variables in the given TEST statement. An overall estimate of the treatment effect is computed as a weighted average of the treatment coefficients as illustrated in the following code:

```
TREATMENT: test trt1, trt2, trt3, trt4 / average;
```

Let $\beta_1, \beta_2, \beta_3$ and β_4 be corresponding parameters for trt1, trt2, trt3, and trt4, respectively. Let $\hat{\beta} = (\hat{\beta}_1, \hat{\beta}_2, \hat{\beta}_3, \hat{\beta}_4)'$ be estimated coefficient vector and let $\hat{V}(\hat{\beta})$ be the corresponding variance estimate. Assuming $\beta_1 = \beta_2 = \beta_3 = \beta_4$. The average treatment effect is estimated by $c'\hat{\beta}$, where $c = [1_4'\hat{V}^{-1}(\hat{\beta})1_4]^{-1}\hat{V}^{-1}(\hat{\beta})1_4$ and $1_4 = (1, 1, 1, 1)'$.

E

specifies that the linear coefficients and constants be printed. When the AVERAGE option is specified along with the E option, the optimal weights of the average effect are also printed in the same tables as the coefficients.

PRINT

displays intermediate calculations. This includes $\mathbf{L}\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})\mathbf{L}'$ bordered by $(\mathbf{L}\hat{\boldsymbol{\beta}} - \mathbf{c})$, and $[\mathbf{L}\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})\mathbf{L}']^{-1}$ bordered by $[\mathbf{L}\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})\mathbf{L}']^{-1}(\mathbf{L}\hat{\boldsymbol{\beta}} - \mathbf{c})$, where \mathbf{L} is a matrix of linear coefficients and \mathbf{c} is a vector of constants. See the section “Testing Linear Hypotheses about Regression Coefficients” on page 3247.

WEIGHT Statement

WEIGHT *variable* < /option > ;

The *variable* in the WEIGHT statement identifies the variable in the input data set that contains the case weights. When the WEIGHT statement appears, each observation in the input data set is weighted by the value of the WEIGHT variable. The WEIGHT values can be nonintegral and are not truncated. Observations with negative, zero or missing values for the WEIGHT variable are not used in the model fitting. When the WEIGHT statement is not specified, each observation is assigned a weight of 1. The WEIGHT statement is available for TIES=BRESLOW and TIES=EFRON only.

The following option can be specified in the WEIGHT statement after a slash (/):

NORMALIZE**NORM**

causes the weights specified by the WEIGHT *variable* to be normalized so that they add up the actual sample size. With this option, the estimated covariance matrix of the parameter estimators is invariant to the scale of the WEIGHT variable.

Details

Failure Time Distribution

Let T be a nonnegative random variable representing the failure time of an individual from a homogeneous population. The survival distribution function (also known as the survivor function) of T is written as

$$S(t) = \Pr(T \geq t)$$

A mathematically equivalent way of specifying the distribution of T is through its hazard function. The hazard function $\lambda(t)$ specifies the instantaneous failure rate at t . If T is a continuous random variable, $\lambda(t)$ is expressed as

$$\lambda(t) = \lim_{\Delta t \rightarrow 0^+} \frac{\Pr(t \leq T < t + \Delta t \mid T \geq t)}{\Delta t} = \frac{f(t)}{S(t)}$$

where $f(t)$ is the probability density function of T . If T is discrete with masses at $x_1 < x_2 < \dots$, then $\lambda(t)$ is given by

$$\lambda(t) = \sum_j \lambda_j \delta(t - x_j)$$

where

$$\delta(u) = \begin{cases} 0 & \text{if } u < 0 \\ 1 & \text{otherwise} \end{cases}$$

$$\lambda_j = \Pr(T = x_j | T \geq x_j) = \frac{\Pr(T = x_j)}{S(x_j)}$$

for $j = 1, 2, \dots$

Partial Likelihood Function for the Cox Model

Let $\mathbf{Z}_l(t)$ denote the vector explanatory variables for the l th individual at time t . Let $t_1 < t_2 < \dots < t_k$ denote the k distinct, ordered event times. Let d_i denote the multiplicity of failures at t_i ; that is, d_i is the size of the set \mathcal{D}_i of individuals that fail at t_i . Let w_l be the weight associated with the l th individual. Using this notation, the likelihood functions used in PROC PHREG to estimate β are described in the following sections.

Continuous Time Scale

Let \mathcal{R}_i denote the risk set just before the i th ordered event time t_i . Let \mathcal{R}_i^* denote the set of individuals whose event or censored times exceed t_i or whose censored times are equal to t_i .

Exact Likelihood

$$L_1(\beta) = \prod_{i=1}^k \left\{ \int_0^{\infty} \prod_{j \in \mathcal{D}_i} \left[1 - \exp \left(- \frac{e^{\beta' \mathbf{Z}_j(t_i)}}{\sum_{l \in \mathcal{R}_i^*} e^{\beta' \mathbf{Z}_l(t_i)} t} \right) \right] \exp(-t) dt \right\}$$

Breslow Likelihood

$$L_2(\beta) = \prod_{i=1}^k \frac{e^{\beta' \sum_{j \in \mathcal{D}_i} \mathbf{Z}_j(t_i)}}{\left[\sum_{l \in \mathcal{R}_i} e^{\beta' \mathbf{Z}_l(t_i)} \right]^{d_i}}$$

Incorporating weights, the Breslow likelihood becomes

$$L_2(\beta) = \prod_{i=1}^k \frac{e^{\beta' \sum_{j \in \mathcal{D}_i} w_j \mathbf{Z}_j(t_i)}}{\left[\sum_{l \in \mathcal{R}_i} w_l e^{\beta' \mathbf{Z}_l(t_i)} \right]^{\sum_{j \in \mathcal{D}_i} w_j}}$$

Efron Likelihood

$$L_3(\beta) = \prod_{i=1}^k \frac{e^{\beta' \sum_{j \in \mathcal{D}_i} \mathbf{Z}_j(t_i)}}{\prod_{j=1}^{d_i} \left(\sum_{l \in \mathcal{R}_i} e^{\beta' \mathbf{Z}_l(t_i)} - \frac{j-1}{d_i} \sum_{l \in \mathcal{D}_i} e^{\beta' \mathbf{Z}_l(t_i)} \right)}$$

Incorporating weights, the Efron likelihood becomes

$$L_3(\beta) = \prod_{i=1}^k \frac{e^{\beta' \sum_{j \in \mathcal{D}_i} w_j \mathbf{Z}_j(t_i)}}{\left[\prod_{j=1}^{d_i} \left(\sum_{l \in \mathcal{R}_i} w_l e^{\beta' \mathbf{Z}_l(t_i)} - \frac{j-1}{d_i} \sum_{l \in \mathcal{D}_i} w_l e^{\beta' \mathbf{Z}_l(t_i)} \right) \right]^{\frac{1}{d_i} \sum_{j \in \mathcal{D}_i} w_j}}$$

Discrete Time Scale

Let \mathcal{Q}_i denote the set of all subsets of d_i individuals from the risk set \mathcal{R}_i . For each $\mathbf{q} \in \mathcal{Q}_i$, \mathbf{q} is a d_i -tuple $(q_1, q_2, \dots, q_{d_i})$ of individuals who might have failed at t_i .

Discrete Logistic Likelihood

$$L_4(\beta) = \prod_{i=1}^k \frac{e^{\beta' \sum_{j \in \mathcal{D}_i} \mathbf{Z}_j(t_i)}}{\sum_{\mathbf{q} \in \mathcal{Q}_i} e^{\beta' \sum_{l=1}^{d_i} \mathbf{Z}_{q_l}(t_i)}}$$

The computation of $L_4(\beta)$ and its derivatives is based on an adaptation of the recurrence algorithm of Gail et al. (1981) to the logarithmic scale. When there are no ties on the event times (that is, $d_i \equiv 1$), all four likelihood functions $L_1(\beta)$, $L_2(\beta)$, $L_3(\beta)$, and $L_4(\beta)$ reduce to the same expression. In a stratified analysis, the partial likelihood is the product of the partial likelihood functions for the individual strata.

Counting Process Style of Input

In the counting process formulation, data for each subject are identified by a triple $\{N, Y, \mathbf{Z}\}$ of counting, at risk, and covariate processes. Here, $N(t)$ indicates the number of events that the subject experiences over the time interval $(0, t]$; $Y(t)$ indicates whether the subject is at risk at time t (one if at risk and zero otherwise); and $\mathbf{Z}(t)$ is a vector of explanatory variables for the subject at time t . The sample path of N is a step function with jumps of size +1 at the event times, and $N(0) = 0$. Unless $\mathbf{Z}(t)$ changes continuously with time, the data for each subject can be represented by multiple observations, each identifying a semiclosed time interval $(t_1, t_2]$, the values of the explanatory variables over that interval, and the event status at t_2 . The subject remains at risk during the interval $(t_1, t_2]$, and an event may occur at t_2 . Values of the explanatory variables for the subject remain unchanged in the interval. This style of data input was originated by Terry M. Therneau (1994).

For example, a patient has a tumor recurrence at weeks 3, 10, and 15 and is followed to week 23. The explanatory variables are *Trt* (treatment), *Z1* (initial tumor number), and *Z2* (initial tumor size), and, for this patient, the values of *Trt*, *Z1*, and *Z2* are (1,1,3). The data for this patient are represented by the following four observations:

T1	T2	Event	Trt	Z1	Z2
0	3	1	1	1	3
3	10	1	1	1	3
10	15	1	1	1	3
15	23	0	1	1	3

Here (T1,T2] contains the at-risk intervals. The variable *Event* is a censoring variable indicating whether a recurrence has occurred at T2; a value of 1 indicates a tumor recurrence, and a value of 0 indicates nonrecurrence. The PHREG procedure fits the multiplicative hazards model, which is specified as follows:

```
proc phreg;
  model (T1,T2) * Event(0) = Trt Z1 Z2;
run;
```

Another useful application of the counting process formulation is delayed entry of subjects into the risk set. For example, in studying the mortality of workers exposed to a carcinogen, the survival time is chosen to be the worker's age at death by malignant neoplasm. Any worker joining the workplace at a later age than a given event failure time is not included in the corresponding risk set. The variables of a worker consist of *Entry* (age at which the worker entered the workplace), *Age* (age at death or age censored), *Status* (an indicator of whether the observation time is censored, with the value 0 identifying a censored time), and *X1* and *X2* (explanatory variables thought to be related to survival). The specification for such an application is as follows.

```
proc phreg;
  model (Entry, Age) * Status(0) = X1 X2;
run;
```

Alternatively, you can use a time-dependent variable to control the risk set, as illustrated in the following specification:

```
proc phreg;
  model Age * Status(0) = X1 X2;
  if Age < Entry then X1= .;
run;
```

Here, *X1* becomes a time-dependent variable. At a given death time t , the value of *X1* is reevaluated for each subject with $\text{Age} \geq t$; subjects with $\text{Entry} > t$ are given a missing value in *X1* and are subsequently removed from the risk set. Computationally, this approach is not as efficient as the one that uses the counting process formulation.

The Multiplicative Hazards Model

Consider a set of n subjects such that the counting process $N_i \equiv \{N_i(t), t \geq 0\}$ for the i th subject represents the number of observed events experienced over time t . The sample paths of the process N_i are step functions with jumps of size +1, with $N_i(0) = 0$. Let β denote the vector of unknown regression coefficients. The multiplicative hazards function $\Lambda(t, \mathbf{Z}_i(t))$ for N_i is given by

$$Y_i(t)d\Lambda(t, \mathbf{Z}_i(t)) = Y_i(t) \exp(\beta' \mathbf{Z}_i(t)) d\Lambda_0(t)$$

where

- $Y_i(t)$ indicates whether the i th subject is at risk at time t (specifically, $Y_i(t) = 1$ if at risk and $Y_i(t) = 0$ otherwise)
- $\mathbf{Z}_i(t)$ is the vector of explanatory variables for the i th subject at time t
- $\Lambda_0(t)$ is an unspecified baseline hazard function

Refer to Fleming and Harrington (1991) and Andersen et al. (1992). The Cox model is a special case of this multiplicative hazards model, where $Y_i(t) = 1$ until the first event or censoring, and $Y_i(t) = 0$ thereafter.

The partial likelihood for n independent triplets $(N_i, Y_i, \mathbf{Z}_i), i = 1, \dots, n$, has the form

$$\mathcal{L}(\beta) = \prod_{i=1}^n \prod_{t \geq 0} \left\{ \frac{Y_i(t) \exp(\beta' \mathbf{Z}_i(t))}{\sum_{j=1}^n Y_j(t) \exp(\beta' \mathbf{Z}_j(t))} \right\}^{\Delta N_i(t)}$$

where $\Delta N_i(t) = 1$ if $N_i(t) - N_i(t-) = 1$, and $\Delta N_i(t) = 0$ otherwise.

Proportional Rates/Means Models for Recurrent Events

Let $N(t)$ be the number of events experienced by a subject over the time interval $(0, t]$. Let $dN(t)$ be the increment of the counting process N over $[t, t + dt)$. The rate function is given by

$$d\mu_{\mathbf{Z}}(t) = E[dN(t)|Z(t)] = e^{\beta' \mathbf{Z}(t)} d\mu_0(t)$$

where $\mu_0(\cdot)$ is an unknown continuous function. If the \mathbf{Z} are time-independent, the rate model is reduced to the mean model

$$\mu_{\mathbf{Z}}(t) = e^{\beta' \mathbf{Z}} \mu_0(t)$$

The partial likelihood for n independent triplets $(N_i, Y_i, \mathbf{Z}_i), i = 1, \dots, n$, of counting, at-risk, and covariate processes is the same as that of the multiplicative hazards model. However, a robust sandwich estimate is used for the covariance matrix of the parameter estimator instead of the model-based estimate.

Let T_{ki} be the k th event time of the i th subject. Let C_i be the censoring time of the i th subject. The at-risk indicator and the failure indicator are, respectively,

$$Y_i(t) = I(C_i \geq t) \quad \text{and} \quad \Delta_{ki} = I(T_{ki} \leq C_i)$$

Denote

$$S^{(i)}(\boldsymbol{\beta}, t) = \sum_{i=1}^n Y_i(t) e^{\boldsymbol{\beta}' \mathbf{Z}_i(t)} \quad \text{and} \quad \bar{\mathbf{Z}}(\boldsymbol{\beta}, t) = \frac{\sum_{i=1}^n Y_i(t) e^{\boldsymbol{\beta}' \mathbf{Z}_i(t)} \mathbf{Z}_i(t)}{S^{(0)}(\boldsymbol{\beta}, t)}$$

Let $\hat{\boldsymbol{\beta}}$ be the maximum likelihood estimate of $\boldsymbol{\beta}$ and let $\mathcal{I}(\hat{\boldsymbol{\beta}})$ be the observed information matrix. The robust sandwich covariance matrix estimate is given by

$$\mathcal{I}^{-1}(\hat{\boldsymbol{\beta}}) \sum_{i=1}^n \left[W_i(\hat{\boldsymbol{\beta}}) W_i'(\hat{\boldsymbol{\beta}}) \right] \mathcal{I}^{-1}(\hat{\boldsymbol{\beta}})$$

where

$$W_i(\boldsymbol{\beta}) = \sum_k \Delta_{ki} \left\{ Z_i(T_{ki}) - \bar{\mathbf{Z}}(\boldsymbol{\beta}, T_{ki}) \right\} - \sum_{i=1}^n \sum_l \frac{\Delta_{lj} Y_i(T_{lj}) e^{\boldsymbol{\beta}' \mathbf{Z}_i(T_{lj})}}{S^{(0)}(\boldsymbol{\beta}, T_{lj})} \left\{ Z_i(T_{lj}) - \bar{\mathbf{Z}}(\boldsymbol{\beta}, T_{lj}) \right\}$$

For a given realization of the covariates $\boldsymbol{\xi}$, the Nelson estimator is used to predict the mean function

$$\hat{\mu}_{\boldsymbol{\xi}}(t) = e^{\hat{\boldsymbol{\beta}}' \boldsymbol{\xi}} \sum_{i=1}^n \sum_k \frac{I(T_{ki} \leq t) \Delta_{ki}}{S^{(0)}(\hat{\boldsymbol{\beta}}, T_{ki})}$$

with standard error estimate given by

$$\hat{\sigma}^2(\hat{\mu}_{\boldsymbol{\xi}}(t)) = \sum_{i=1}^n \left(\frac{1}{n} \hat{\Psi}_i(t, \boldsymbol{\xi}) \right)^2$$

where

$$\begin{aligned} \frac{1}{n} \hat{\Psi}_i(\boldsymbol{\xi}, t) &= e^{\hat{\boldsymbol{\beta}}' \boldsymbol{\xi}} \left\{ \sum_k \frac{I(T_{ki} \leq t) \Delta_{ik}}{S^{(0)}(\hat{\boldsymbol{\beta}}, T_{ki})} - \sum_{j=1}^n \sum_k \frac{Y_i(T_{kj}) e^{\hat{\boldsymbol{\beta}}' \mathbf{Z}_i(T_{kj})} I(T_{kj} \leq t) \Delta_{kj}}{[S^{(0)}(\hat{\boldsymbol{\beta}}, T_{kj})]^2} \right. \\ &\quad \left[\sum_{i=1}^n \sum_k \frac{I(T_{ki} \leq t) \Delta_{ik} [\bar{\mathbf{Z}}(\hat{\boldsymbol{\beta}}, T_{ki}) - \boldsymbol{\xi}] }{S^{(0)}(\hat{\boldsymbol{\beta}}, T_{ki})} \right] \\ &\quad \left. \times \mathcal{I}^{-1}(\hat{\boldsymbol{\beta}}) \int_0^{\tau} [\mathbf{Z}_i(u) - \bar{\mathbf{Z}}(\hat{\boldsymbol{\beta}}, u)] d\hat{M}_i(u) \right\} \end{aligned}$$

Since the cumulative mean function is always nonnegative, the log transform is used to compute confidence intervals. The $100(1 - \alpha)\%$ pointwise confidence limits for $\mu_{\xi}(t)$ are

$$\hat{\mu}_{\xi}(t)e^{\pm z_{\alpha/2} \frac{\hat{\sigma}(\hat{\mu}_{\xi}(t))}{\hat{\mu}_{\xi}(t)}}$$

where $z_{\alpha/2}$ is the upper $100\alpha/2$ percentage point of the standard normal distribution.

Newton-Raphson Method

Let $L(\beta)$ be one of the likelihood functions described in the previous subsections. Let $l(\beta) = \log L(\beta)$. Finding β such that $L(\beta)$ is maximized is equivalent to finding the solution $\hat{\beta}$ to the likelihood equations

$$\frac{\partial l(\beta)}{\partial \beta} = 0$$

With $\hat{\beta}^0 = \mathbf{0}$ as the initial solution, the iterative scheme is expressed as

$$\hat{\beta}^{j+1} = \hat{\beta}^j - \left[\frac{\partial^2 l(\hat{\beta}^j)}{\partial \beta^2} \right]^{-1} \frac{\partial l(\hat{\beta}^j)}{\partial \beta}$$

The term after the minus sign is the Newton-Raphson step. If the likelihood function evaluated at $\hat{\beta}^{j+1}$ is less than that evaluated at $\hat{\beta}^j$, then $\hat{\beta}^{j+1}$ is recomputed using half the step size. The iterative scheme continues until convergence is obtained, that is, until $\hat{\beta}_{j+1}$ is sufficiently close to $\hat{\beta}_j$. Then the maximum likelihood estimate of β is $\hat{\beta} = \hat{\beta}_{j+1}$.

The model-based variance estimate of $\hat{\beta}$ is obtained by inverting the information matrix $\mathcal{I}(\hat{\beta})$

$$\hat{\mathbf{V}}_m(\hat{\beta}) = \mathcal{I}^{-1}(\hat{\beta}) = - \left[\frac{\partial^2 l(\hat{\beta})}{\partial \beta^2} \right]^{-1}$$

Robust Sandwich Variance Estimate

For the i th subject, $i = 1, \dots, n$, let X_i , w_i , and $\mathbf{Z}_i(t)$ be the observed time, weight, and the covariate vector at time t , respectively. Let Δ_i be the event indicator and let $Y_i(t) = I(X_i \geq t)$. Let

$$S^{(r)}(\beta, t) = \sum_{j=1}^n w_j Y_j(t) e^{\beta' \mathbf{Z}_j(t)} \mathbf{Z}_j^{\otimes r}(t), \quad r = 0, 1$$

Let $\bar{\mathbf{Z}}(\boldsymbol{\beta}, t) = \frac{S^{(1)}(\boldsymbol{\beta}, t)}{S^{(0)}(\boldsymbol{\beta}, t)}$. The score residual for the i th individual is

$$\mathbf{u}_i(\boldsymbol{\beta}) = \Delta_i \left\{ \mathbf{Z}_i(X_i) - \bar{\mathbf{Z}}(\boldsymbol{\beta}, X_i) \right\} - \sum_{j=1}^n \Delta_j \frac{w_j Y_i(X_j) e^{\boldsymbol{\beta}' \mathbf{Z}_i(X_j)}}{S^{(0)}(\boldsymbol{\beta}, X_j)} \left\{ \mathbf{Z}_i(X_j) - \bar{\mathbf{Z}}(\boldsymbol{\beta}, X_j) \right\}$$

The robust sandwich variance estimate of $\hat{\boldsymbol{\beta}}$ derived by Binder (1992) who incorporated weights into the analysis is

$$\hat{\mathbf{V}}_s(\hat{\boldsymbol{\beta}}) = \mathcal{I}^{-1}(\hat{\boldsymbol{\beta}}) \left[\sum_{j=1}^n (w_j \mathbf{u}_j(\hat{\boldsymbol{\beta}})) \otimes^2 \right] \mathcal{I}^{-1}(\hat{\boldsymbol{\beta}})$$

where $\mathcal{I}(\hat{\boldsymbol{\beta}})$ is the observed information matrix, and $\mathbf{a} \otimes^2 = \mathbf{a} \mathbf{a}'$. Note that when $w_i \equiv 1$,

$$\hat{\mathbf{V}}_s(\hat{\boldsymbol{\beta}}) = \mathbf{D}' \mathbf{D}$$

where \mathbf{D} is the matrix of DFBETAS residuals. This robust variance estimate was proposed by Lin and Wei (1989) and Reid and Crèpeau (1985).

Testing the Global Null Hypothesis

The following three likelihood statistics can be used to test the global null hypothesis $H_0: \boldsymbol{\beta} = \mathbf{0}$. Under mild assumptions, each statistic has an asymptotic chi-square distribution with p degrees of freedom given the null hypothesis. The value p is the dimension of $\boldsymbol{\beta}$.

Likelihood Ratio Test

$$\chi_{LR}^2 = 2 \left[l(\hat{\boldsymbol{\beta}}) - l(\mathbf{0}) \right]$$

This formulation of the likelihood ratio test is not appropriate for the COVS option.

Wald's Test

$$\chi_W^2 = \hat{\boldsymbol{\beta}}' \left[\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}}) \right]^{-1} \hat{\boldsymbol{\beta}}$$

where $\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}}) = \hat{\mathbf{V}}_m(\hat{\boldsymbol{\beta}})$ for the model-based variance estimate and $\hat{\mathbf{V}}(\hat{\boldsymbol{\beta}}) = \hat{\mathbf{V}}_s(\hat{\boldsymbol{\beta}})$ for the robust sandwich variance estimate.

Score Test

$$\chi_S^2 = \left[\frac{\partial l(\mathbf{0})}{\partial \boldsymbol{\beta}} \right]' \mathcal{I}^{-1}(\mathbf{0}) \left[\frac{\partial l(\mathbf{0})}{\partial \boldsymbol{\beta}} \right]$$

where $\mathcal{I}(\mathbf{0}) = -\frac{\partial^2 l(\mathbf{0})}{\partial \boldsymbol{\beta}^2}$. Replacing $\mathcal{I}^{-1}(\mathbf{0})$ by the robust sandwich variance estimate $\hat{\mathbf{V}}_s(\mathbf{0})$, the modified score test is also printed when the COVS option is specified.

Hazards Ratio Estimates and Confidence Limits

Let β_i and $\hat{\beta}_i$ denote the i th component of β and $\hat{\beta}$, respectively. The hazards ratio (also known as risk ratio) for the explanatory variable with regression coefficient β_i is defined as $\exp(\beta_i)$. The hazards ratio is estimated by $\exp(\hat{\beta}_i)$. The $100(1 - \alpha)\%$ confidence limits for the hazards ratio are calculated as

$$\exp\left(\hat{\beta}_i \pm z_{\alpha/2} \sqrt{\hat{\mathbf{V}}_{ii}(\hat{\beta})}\right)$$

where $\hat{\mathbf{V}}_{ii}(\hat{\beta})$ is the i th diagonal element of the estimated covariance matrix $\hat{\mathbf{V}}(\hat{\beta})$, and $z_{\alpha/2}$ is the $100(1 - \alpha/2)$ percentile point of the standard normal distribution.

The hazards ratio is the ratio of the hazards functions that correspond to a change of one unit of the given variable and conditional on fixed values of all other variables.

Testing Linear Hypotheses about Regression Coefficients

Linear hypotheses for β are expressed in matrix form as

$$H_0: \mathbf{L}\beta = \mathbf{c}$$

where \mathbf{L} is a matrix of coefficients for the linear hypotheses, and \mathbf{c} is a vector of constants. The Wald chi-square statistic for testing H_0 is computed as

$$\chi_W^2 = (\mathbf{L}\hat{\beta} - \mathbf{c})' [\mathbf{L}\hat{\mathbf{V}}(\hat{\beta})\mathbf{L}']^{-1} (\mathbf{L}\hat{\beta} - \mathbf{c})$$

where $\hat{\mathbf{V}}(\hat{\beta})$ is the estimated covariance matrix. Under H_0 , χ_W^2 has an asymptotic chi-square distribution with r degrees of freedom, where r is the rank of \mathbf{L} .

Analysis of Multivariate Failure Time Data

Multivariate failure time data arise when each study subject can potentially experience several events (for instance, multiple infections after surgery) or when there exists some natural or artificial clustering of subjects (for instance, a litter of mice) that induces dependence among the failure times of the same cluster. Data in the former situation are referred to as multiple events data, and data in the latter situation are referred to as clustered data. The multiple events data can be further classified into ordered and unordered data. For ordered data, there is a natural ordering of the multiple failures within a subject, which includes recurrent events data as a special case. For unordered data, the multiple event times result from several concurrent failure processes.

Multiple events data can be analyzed by the Wei, Lin, and Weissfeld (1989), aka WLW, method based on the marginal Cox models. For the special case of recurrent events data, you can fit the intensity model (Andersen and Gill 1982), the proportional rates/means model (Pepe and Cai 1993; Lawless and Nadeau 1995; Lin, Wei, Yang,

and Ying 2000), or the stratified models for total time and gap time proposed by Prentice, Williams, and Peterson (1981), aka PWP. For clustered data, you can carry out the analysis of Lee, Wei, and Amato (1992) based on the marginal Cox model. To use PROC PHREG to perform these analyses correctly and effectively, you have to array your data in a specific way to produce the correct risk sets.

All examples described in this section can be found in the program *phrmult.sas* in the SAS/STAT sample library. Furthermore, the “Examples” section in this chapter contains two examples to illustrate the methods for analyzing recurrent events data and clustered data.

Marginal Cox Models for Multiple Events Data

Suppose there are n subjects and each subject can experience up to K potential events. Let $\mathbf{Z}_{ki}(\cdot)$ be the covariate process associated with the k th event for the i th subject. The marginal Cox models are given by

$$\lambda_k(t; \mathbf{Z}_{ki}) = \lambda_{k0} e^{\beta_k' \mathbf{Z}_{ki}(t)}, \quad k = 1, \dots, K; i = 1, \dots, n$$

where $\lambda_{k0}(t)$ is the (event-specific) baseline hazard function for the k th event and β_k is the (event-specific) column vector of regression coefficients for the k th event. WLW estimates β_1, \dots, β_K by the maximum partial likelihood estimates $\hat{\beta}_1, \dots, \hat{\beta}_K$, respectively, and uses a robust sandwich covariance matrix estimate for $(\hat{\beta}_1', \dots, \hat{\beta}_K')$ to account for the dependence of the multiple failure times.

By using a properly prepared input data set, you can estimate the regression parameters for all the marginal Cox models and compute the robust sandwich covariance estimates in one PROC PHREG invocation. For convenience of discussion, suppose each subject can potentially experience $K=3$ events and there are two explanatory variables **Z1** and **Z2**. The event-specific parameters to be estimated are $\beta_1 = (\beta_{11}, \beta_{21})'$ for the first marginal model, $\beta_2 = (\beta_{12}, \beta_{22})'$ for the second marginal model, and $\beta_3 = (\beta_{13}, \beta_{23})'$ for the third marginal model. Inference of these parameters is based on the robust sandwich covariance matrix estimate of the parameter estimators. It is necessary that each row of the input data set represents the data for a potential event of a subject. The input data set should contain

- an **ID** variable for identifying the subject so that all observations of the same subject have the same ID value
- an **Enum** variable to index the multiple events. For example, **Enum**=1 for the first event, **Enum**=2 for the second event, and so on.
- a **Time** variable to represent the observed time from some time origin for the event. For recurrence events data, it is the time from the study entry to each recurrence.
- a **Status** variable to indicate whether the **Time** value is a censored or uncensored time. For example, **Status**=1 indicates an uncensored time and **Status**=0 indicates a censored time.
- independent variables (**Z1** and **Z2**).

The WLW analysis can be carried out by specifying

```
proc phreg covs(aggregate);
  model Time*Status(0)=Z11 Z12 Z13 Z21 Z22 Z23;
  strata Enum;
  id ID;
  Z11= Z1 * (Enum=1);
  Z12= Z1 * (Enum=2);
  Z13= Z1 * (Enum=3);
  Z21= Z2 * (Enum=1);
  Z22= Z2 * (Enum=2);
  Z23= Z2 * (Enum=3);
run;
```

Variable Enum is specified in the STRATA statement so that there is one marginal Cox model for each distinct value of Enum. Variables Z11, Z12, Z13, Z21, Z22, and Z23 in the MODEL statement are event-specific variables derived from the independent variables Z1 and Z2 by the given programming statements. In particular, variables Z11, Z12, and Z13 are the event-specific variables for the explanatory variable Z1; variables Z21, Z22, and Z23 are event-specific variables for the explanatory variable Z2. For $j = 1, 2$, and $k = 1, 2, 3$, variable Zjk contains the same values as the explanatory variable Zj for the rows that correspond to k th marginal model and the value 0 for all other rows; as such, β_{jk} is the regression coefficient for Zjk. You can avoid using the programming statements in PROC PHREG by creating these event-specific variables in the input data set using the same programming statements in a DATA step.

The option COVS(AGGREGATE) is specified in the PROC statement to obtain the robust sandwich estimate of the covariance matrix, and the score residuals used in computing the middle part of the sandwich estimate are aggregated over identical ID values. You can also include TEST statements in the PROC PHREG code to test various linear hypotheses of the regression parameters based on the robust sandwich covariance matrix estimate.

Consider the AIDS study data in Wei, Lin, and Weissfeld (1989) from a randomized clinical trial to assess the antiretroviral capacity of ribavirin over times in AIDS patients. Blood sample were collected at weeks 4, 8, and 12 from each patients in three treatment groups (placebo, low dose of ribavirin, and high dose). For each serum sample, the failure time is the number of days before virus positivity was detected. If the sample was contaminated or it took a longer period of time than was achievable in the laboratory, the sample was censored. For example,

- Patient #1 in the placebo group has uncensored times 9, 6, and 7 days (that is, it took 9 days to detect viral positivity in the first blood sample, 6 days for the second blood sample, and 7 days for the third blood sample).
- Patient #14 in the low dose group of rabavirin has uncensored times of 16 and 17 days for the first and second sample, respectively, and a censored time of 21 days for the third blood sample.

- Patient #28 in the High dose group has an uncensored time of 21 days for the first sample, no measurement for the second blood sample, and a censored time of 25 days for the third sample.

For a full-rank parameterization, two design variables are sufficient to represent three treatment groups. Based on the reference coding with placebo as the reference, the values of the two dummy explanatory variables Z1 and Z2 representing the treatments are

Treatment Group	Z1	Z2
Placebo	0	0
Low dose ribavirin	1	0
High dose ribavirin	0	1

The bulk of the task in using PROC PHREG to perform the WLW analysis lies in the preparation of the input data set. As discussed earlier, the input data set should contain the ID, Enum, Time, and Status variables, and event-specific independent variables Z11, Z12, Z13, Z21, Z22, and Z23. Data for the three patients described earlier are arrayed as follows:

ID	Time	Status	Enum	Z1	Z2
1	9	1	1	0	0
1	6	1	2	0	0
1	7	1	3	0	0
14	16	1	1	1	0
14	17	1	2	1	0
14	21	0	3	1	0
28	21	1	1	0	1
28	25	0	3	0	1

The first three rows are data for Patient #1 with event times at 9, 6, and 7 days, one row for each event. The next three rows are data for Patient #14, who has an uncensored time of 16 days for the first serum sample, an uncensored time of 17 days for the second sample, and a censored time of 21 days for the third sample. The last two rows are data for Patient #28 of the high dose group (Z1=0 and Z2=1). Since the patient did not have a second serum sample, there are only two rows of data.

To perform the WLW analysis, you specify

```
proc phreg covs(aggregate);
  model Time*Status(0)=Z11 Z12 Z13 Z21 Z22 Z23;
  strata Enum;
  id ID;
  Z11= Z1 * (Enum=1);
  Z12= Z1 * (Enum=2);
  Z13= Z1 * (Enum=3);
  Z21= Z2 * (Enum=1);
  Z22= Z2 * (Enum=2);
  Z23= Z2 * (Enum=3);
  EqualLowDose: test Z11=Z12, Z12=Z23;
  AverageLow: test Z11,Z12,Z13 / e average;
run;
```

Two linear hypotheses are tested using the TEST statements. The specification

```
EqualLowDose: test Z11=Z12, Z12=Z13;
```

tests the null hypothesis $\beta_{11} = \beta_{12} = \beta_{13}$ of identical low-dose effects across three marginal models. The specification

```
AverageLow: test Z11,Z12,Z13 / e average;
```

tests the null hypothesis of no low-dose effects (that is, $\beta_{11} = \beta_{12} = \beta_{13} = 0$). The AVERAGE option computes the optimal weights for estimating the average low-dose effect $\beta_1^* = \beta_{11} = \beta_{12} = \beta_{13}$ and performs a 1 DF test for testing the null hypothesis that $\beta_1^* = 0$. The E option displays the coefficients for the linear hypotheses, including the optimal weights.

Marginal Cox Models for Clustered Data

Suppose there are n clusters with K_i members in the i th cluster, $i = 1, \dots, n$. Let $\mathbf{Z}_{ki}(\cdot)$ be the covariate process associated with the k th member of the i th cluster. The marginal Cox model is given by

$$\lambda(t; \mathbf{Z}_{ki}) = \lambda_0(t)e^{\beta' \mathbf{Z}_{ki}(t)} \quad k = 1, \dots, K_i; i = 1, \dots, n$$

where $\lambda_0(t)$ is an arbitrary baseline hazard function and β is the vector of regression coefficients. Lee, Wei, and Amato (1992) estimate β by the maximum partial likelihood estimate $\hat{\beta}$ under the independent working assumption, and use a robust sandwich covariance estimate to account for the intracluster dependence.

To use PROC PHREG to analyze the clustered data, each member of a cluster is represented by an observation in the input data set. The input data set to PROC PHREG should contain

- an ID variable to identify the cluster so that members of the same cluster have the same ID value

- a **Time** variable to represent the observed survival time of a member of a cluster
- a **Status** variable to indicate whether the Time value is an uncensored or censored time. For example, Status=1 indicates an uncensored time and Status=0 indicates a censored time.
- the explanatory variables thought to be related to the failure time

Consider a tumor study in which one of three female rats of the same litter was randomly subjected to a drug treatment. The failure time is the time from randomization to the detection of tumor. If a rat died before the tumor was detected, the failure time was censored. For example,

- In litter #1, the drug-treated rat has an uncensored time of 101 days, one untreated rat has a censored time of 49 days, and the other untreated rat has a failure time of 104 days.
- In litter #3, the drug-treated rat has a censored time of 104 days, one untreated rat has a censored time of 102 days, and the other untreated rat has a censored time of 104 days.

In this example, a litter is a cluster and the rats of the same litter are members of the cluster. Let Trt be a 0-1 variable representing the treatment a rat received, with value 1 for drug treatment and 0 otherwise. Data for the two litters of rats described earlier contribute six observations to the input data set:

Litter	Time	Status	Trt
1	101	0	1
1	49	1	0
1	104	0	0
3	104	0	1
3	102	0	0
3	104	0	0

The analysis of Lee, Wei, and Amato (1992) can be performed by PROC PHREG as follows:

```
proc phreg covs(aggregate);
  model Time*Status(0)=Treatment;
  id Litter;
run;
```

Intensity and Rate/Mean Models for Recurrent Events Data

Suppose each subject experiences recurrences of the same phenomenon. Let $N(t)$ be the number of events a subject experiences over the interval $[0, t]$ and let $\mathbf{Z}(\cdot)$ be the covariate process of the subject.

The intensity model (Andersen and Gill 1982) is given by

$$\lambda_{\mathbf{Z}}(t)dt = E\{dN(t)|\mathcal{F}_{t-}\} = \lambda_0(t)e^{\beta'\mathbf{Z}(t)}dt$$

where \mathcal{F}_t represents all the information of the processes N and \mathbf{Z} up to time t , $\lambda_0(t)$ is an arbitrary baseline intensity function, and β is the vector of regression coefficients. This model consists of two components: 1) all the influence of the prior events on future recurrences, if there is any, is mediated through the time-dependent covariates, and 2) the covariates have multiplicative effects on the instantaneous rate of the counting process. If the covariates are time invariant, the risk of recurrences is unaffected by the past events.

The proportional rates and means models (Pepe and Cai 1993; Lawless and Nadeau 1995; Lin, Wei, Yang, and Ying 2000) assume that the covariates have multiplicative effects on the mean and rate functions of the counting process. The rate function is given by

$$d\mu_{\mathbf{Z}}(t) = E\{dN(t)|\mathbf{Z}(t)\} = e^{\beta'\mathbf{Z}(t)}d\mu_0(t)$$

where $\mu_0(t)$ is an unknown continuous function and β is the vector of regression parameters. If \mathbf{Z} is time invariant, the mean function is given by

$$\mu_{\mathbf{Z}}(t) = E\{N(t)|\mathbf{Z}\} = e^{\beta'\mathbf{Z}}\mu_0(t)$$

For both the intensity and the proportional rates/means models, estimates of the regression coefficients are obtained by solving the the partial likelihood score function. However, the covariance matrix estimate for the intensity model is computed as the inverse of the observed information matrix, while that for the proportional rates/means model is given by a sandwich estimate. For a given pattern of fixed covariates, the Nelson estimate for the cumulative intensity function is the same for the cumulative mean function, but their standard errors are not the same.

To fit the intensity or rate/mean model using PROC PHREG, the counting process style of input is needed. A subject with K events contributes $K+1$ observations to the input data set. The k th observation of the subject identifies the time interval from the $(k-1)$ th event or time 0 (if $k=1$) to the k th event, $k=1, \dots, K$. The $(K+1)$ th observation represents the time interval from the K th event to time of censorship. The input data set should contain

- a **TStart** variable to represent the $(k-1)$ th recurrence time or the value 0 if $k=1$
- a **TStop** variable to represent the k th recurrence time or the follow-up time if $k=K+1$
- a **Status** variable indicating whether the TStop time is a recurrence time or a censored time; for example, **Status=1** for a recurrence time and **Status=0** for censored time
- explanatory variables thought to be related to the recurrence times

If the rate/mean model is used, the input data should also contain an ID variable for identifying the subjects.

Consider the Chronic Granulomatous Disease (CGD) data listed in Fleming and Harrington (1991). The disease is a rare disorder characterized by recurrent pyrogenic infections. The study is a placebo-controlled randomized clinical trial conducted by the International CGD Cooperative Study to assess the effect of gamma interferon to reduce the rate of infection. For each study patient the times of recurrent infections along with a number of prognostic factors were collected. For example,

- Patient #17404, age 38, in the gamma interferon group had a follow-up time of 293 without any infection.
- Patient #204001, age 12, in the placebo group had an infection at 219 days, a recurrent infection at 373 days, and was followed up to 414 days.

Let `Trt` be the variable representing the treatment status with value 1 for gamma interferon and value 2 for placebo. Let `Age` be a covariate representing the age of the CGD patient. Data for the two CGD patients described earlier are given in the following table.

ID	TStart	TStop	Status	Trt	Age
174054	0	293	0	1	38
204001	0	219	1	2	12
204001	219	373	1	2	12
204001	373	414	0	2	12

Since Patient #174054 had no infection through the end of the follow-up period (293 days), there is only one observation representing the period from time 0 to the end of the follow-up. Data for Patient #204001 are broken into three observations, since there are two infections. The first observation represents the period from time 0 to the first infection, the second observation represents the period from the first infection to the second infection, and the third time period represents the period from the second infection to the end of the follow-up.

The following specification fits the intensity model.

```
proc phreg;
  model (TStart,TStop)*Status(0)=Trt Age;
run;
```

You can predict the cumulative intensity function for the a given pattern of fixed covariates by specifying the `CUMHAZ=` option in the `BASELINE` statement. Suppose you are interested in two fixed patterns, one for patients of age 30 in the gamma interferon group and the other for patients of age 1 in the placebo group. You first create the SAS data set as follows:

```

data Pattern;
  Trt=1; Age=30;
  output;
  Trt=2; Age=1;
  output;
  run;

```

You then include the following BASELINE statement in the PROC PHREG specification. The CUMHAZ=_all_ option produces the cumulative hazard function estimates, the standard error estimates, and the lower and upper pointwise confidence limits.

```

baseline data=pattern out=out1 cumhaz=_all_ /nomean;

```

The following specification of PROC PHREG fits the mean model and predicts the cumulative mean function for the two patterns of covariates in the Pattern data set.

```

proc phreg covs(aggregate);
  model (Tstart,Tstop)*Status(0)=Trt Age;
  baseline data=Pattern out=out2 cmf=_all_ /nomean;
  id ID;

```

The COV(AGGREGATE) option computes the robust sandwich covariance matrix estimate. The CMF=_ALL_ option adds the cumulative mean function estimates, the standard error estimates, and the lower and upper pointwise confidence limits to the OUT=Out2 data set.

PWP Models for Recurrent Events Data

Let $N(t)$ be the number of events a subject experiences by time t . Let $\mathbf{Z}(t)$ be the covariate vectors of the subject at time t . For a subject who has K events before censorship takes place, let $t_0 = 0$, let t_k be the k th recurrence time, $k = 1, \dots, K$, and let t_{K+1} be the censored time. Prentice, Williams, and Peterson (1981) consider two time scales, a total time from the beginning of the study and a gap time from immediately preceding failure. The PWP models are stratified Cox-type models that allow the shape of the hazard function to depend on the number of preceding events and possibly on other characteristics of $\{N(t)$ and $\mathbf{Z}(t)\}$. The total time and gap time models are given, respectively, as follows:

$$\begin{aligned} \lambda(t|\mathcal{F}_{t-}) &= \lambda_{0k}(t)e^{\beta_k' \mathbf{Z}(t)}, & t_{k-1} < t \leq t_k \\ \lambda(t|\mathcal{F}_{t-}) &= \lambda_{0k}(t - t_{k-1})e^{\beta_k' \mathbf{Z}(t)}, & t_{k-1} < t \leq t_k \end{aligned}$$

where λ_{0k} is an arbitrary baseline intensity functions, and β_k is a vector of stratum-specific regression coefficients. Here, a subject moves to the k th stratum immediately after his $(k-1)$ th recurrence time and remains there until the k th recurrence occurs or until censorship takes place. For instance, a subject who experiences only one event moves from the first stratum to the second stratum after the event occurs and remains in the second stratum until the end of the follow-up.

You can use PROC PHREG to carry out the analyses of the PWP models, but you have to prepare the input data set to provide the correct risk sets. The input data set for analyzing the total time is the same as the AG model with an additional variable to represent the stratum that the subject is in. A subject with K events contributes $K+1$ observations to the input data set, one for each stratum that the subject moves to. The input data should contain

- a **TStart** variable to represent the $(k - 1)$ th recurrence time or the value 0 if $k = 1$
- a **TStop** variable to represent the k th recurrence time or the time of censorship if $k = K + 1$
- a **Status** variable with value 1 if the Time value is a recurrence time and value 0 if the Time value is a censored time
- an **Enum** variable representing the index of the stratum that the subject is in. For a subject who has only one event at t_1 and is followed to time t_c , **Enum**=1 for the first observation (where **Time**= t_1 and **Status**=1) and **Enum**=2 for the second observation (where **Time**= t_c and **Status**=0).
- explanatory variables thought to be related to the recurrence times

To analyze gap times, the input data set should also include a **GapTime** variable which is equal to (**TStop** – **TStart**).

Consider the data of two subjects in CGD data described in the previous section.

- Patients #174054, age 38, in the gamma interferon group had a follow-up time of 293 without any infection.
- Patient #204001, age 12, in the placebo group had an infection at 219 days, a recurrent infection at 373 days, and a follow-up time of 414 days.

To illustrate, suppose all subjects have at most two observed events. The data for the two subjects in the input data set are as follows:

ID	TStart	TStop	Gaptime	Status	Enum	Trt	Age
174054	0	293	293	0	1	1	38
204001	0	219	219	1	1	2	12
204001	219	373	154	1	2	2	12
204001	373	414	41	0	3	2	12

Subject #174054 contributes only one observation to the input data, since there is no observed event. Subject #204001 contributes three observations, since there are two observed events.

To fit the total time model of PWP with stratum-specific slopes, you can either create the stratum-specific explanatory variables (Trt1, Trt2, and Trt3 for Trt, and Age1, Age2, and Age3 for Age) in a DATA step, or you can specify them in PROC PHREG using programming statements as follows:

```
proc phreg;
  model (TStart,TStop)*Status(0)=Trt1 Trt2 Trt3 Age1 Age2 Age3;
  strata Enum;
  Trt1= Trt * (Enum=1);
  Trt2= Trt * (Enum=2);
  Trt3= Trt * (Enum=3);
  Age1= Age * (Enum=1);
  Age2= Age * (Enum=2);
  Age3= Age * (Enum=3);
run;
```

To fit the total time model of PWP with the common regression coefficients, you specify

```
proc phreg;
  model (TStart,TStop)*Status(0)=Trt Age;
  strata Enum;
run;
```

To fit the gap time model of PWP with stratum-specific regression coefficients, you specify

```
proc phreg;
  model Gaptime*Status(0)=Trt1 Trt2 Trt3 Age1 Age2 Age3;
  strata Enum;
  Trt1= Trt * (Enum=1);
  Trt2= Trt * (Enum=2);
  Trt3= Trt * (Enum=3);
  Age1= Age * (Enum=1);
  Age2= Age * (Enum=2);
  Age3= Age * (Enum=3);
run;
```

To fit the gap time model of PWP with common regression coefficients, you specify

```
proc phreg;
  model Gaptime*Status(0)=Trt Age;
  strata Enum;
run;
```

Residuals

The cumulative baseline hazard function Λ_0 is estimated by

$$\hat{\Lambda}_0(t) = \sum_{i=1}^n \int_0^t \frac{dN_i(s)}{\sum_{j=1}^n Y_j(s) \exp(\hat{\beta}' \mathbf{Z}_j(s))}$$

Although this formula is for the BRESLOW=TIES option, the same formula is used for other TIES= options. The discrepancies between results obtained by using an appropriate formula for a nondefault TIES= option and those obtained by the given formula are minimal.

The martingale residual at t is defined as

$$\hat{M}_i(t) = N_i(t) - \int_0^t Y_i(s) \exp(\hat{\beta}' \mathbf{Z}_i(s)) d\hat{\Lambda}_0(s)$$

Here $\hat{M}_i(t)$ estimates the difference over $(0, t]$ between the observed number of events for the i th subject and a conditional expected number of events. The quantity $\hat{M}_i \equiv \hat{M}_i(\infty)$ is referred to as the martingale residual for the i th subject. When the counting process MODEL specification is used, the RESMART= variable contains the component $(\hat{M}_i(t_2) - \hat{M}_i(t_1))$ instead of the martingale residual at t_2 . The martingale residual for a subject can be obtained by summing up these component residuals within the subject. For the Cox model with no time-dependent explanatory variables, the martingale residual for the i th subject with observation time t_i and event status δ_i , where

$$\delta_i = \begin{cases} 0 & \text{if } t_i \text{ is a censored time} \\ 1 & \text{if } t_i \text{ is an event time} \end{cases}$$

is

$$\hat{M}_i = \delta_i - \hat{\Lambda}_0(t_i) \exp(\hat{\beta}' \mathbf{z}_i)$$

The deviance residuals d_i are a transform of the martingale residuals:

$$d_i = \text{sign}(\hat{M}_i) \sqrt{2 \left[-\hat{M}_i - N_i(\infty) \log \left(\frac{N_i(\infty) - \hat{M}_i}{N_i(\infty)} \right) \right]}$$

The square root shrinks large negative martingale residuals, while the logarithmic transformation expands martingale residuals that are close to unity. As such, the deviance residuals are more symmetrically distributed about zero than the martingale residuals. For the Cox model, the deviance residual reduces to the form

$$d_i = \text{sign}(\hat{M}_i) \sqrt{2[-\hat{M}_i - \delta_i \log(\delta_i - \hat{M}_i)]}$$

When the counting process MODEL specification is used, values of the RESDEV= variable are set to missing because the deviance residuals can be calculated on a per subject basis only.

The Schoenfeld (1982) residual vector is calculated on a per event time basis as

$$\mathbf{U}_i(t) = \mathbf{Z}_i(t) - \bar{\mathbf{Z}}(t)$$

where t is an event time, and $\bar{\mathbf{Z}}(t)$ is a weighted average of the covariates over the risk set at time t and is given by

$$\bar{\mathbf{Z}}(t) = \frac{\sum_{l=1}^n Y_l(t) \mathbf{Z}_l(t) \exp(\hat{\boldsymbol{\beta}}' \mathbf{Z}_l(t))}{\sum_{l=1}^n Y_l(t) \exp(\hat{\boldsymbol{\beta}}' \mathbf{Z}_l(t))}$$

Under the proportional hazards assumption, the Schoenfeld residuals have the sample path of a random walk; therefore, they are useful in assessing time trend or lack of proportionality. Harrell (1986) proposed a z -transform of the Pearson correlation between these residuals and the rank order of the failure time as a test statistic for nonproportional hazards. Therneau, Grambsch, and Fleming (1990) considered a Kolmogorov-type test using the cumulative sum of the residuals.

The score process for the i th subject at time t is

$$\mathbf{L}_i(t) = \int_0^t [\mathbf{Z}_i(s) - \bar{\mathbf{Z}}(s)] d\hat{M}_i(s)$$

The vector $\mathbf{L}_i \equiv \mathbf{L}_i(\infty)$ is the score residual for the i th subject. When the counting process MODEL specification is used, the RESSCO= variables contain the components of $(\mathbf{L}_i(t_2) - \mathbf{L}_i(t_1))$ instead of the score process at t_2 . The score residual for a subject can be obtained by summing up these component residuals within the subject.

The score residuals are a decomposition of the first partial derivative of the log likelihood. They are useful in assessing the influence of each subject on individual parameter estimates. They also play an important role in the computation of the robust sandwich variance estimators of Lin and Wei (1989) and Wei, Lin, and Weissfeld (1989).

Diagnostics Based on Weighted Residuals

The vector of weighted Schoenfeld residuals, \mathbf{r}_i , is computed as

$$\mathbf{r}_i = n_e \hat{\mathbf{V}} \mathbf{U}_i(t_i)$$

where n_e is the total number of events, $\hat{\mathbf{V}} = \hat{\mathbf{V}}(\hat{\boldsymbol{\beta}})$ is the estimated covariance matrix of $\hat{\boldsymbol{\beta}}$, and $\mathbf{U}_i(t_i)$ is the vector of Schoenfeld residuals at the event time t_i . The components of \mathbf{r}_i are output to the WTRESSCH= variables.

The weighted Schoenfeld residuals are useful in assessing the proportional hazards assumption. The idea is that most of the common alternatives to the proportional hazards can be cast in terms of a time-varying coefficient model

$$\lambda(t, \mathbf{Z}) = \lambda_0(t) \exp(\beta_1(t) Z_1 + \beta_2(t) Z_2 + \dots)$$

where $\lambda(t, \mathbf{Z})$ and $\lambda_0(t)$ are hazards rates. Let $\hat{\beta}_j$ and r_{ij} be the j th component of $\hat{\boldsymbol{\beta}}$ and \mathbf{r}_i , respectively. Grambsch and Therneau (1994) suggest using a smoothed plot

of $(\hat{\beta}_j + r_{ij})$ versus t_i to discover the functional form of the time-varying coefficient $\beta_j(t)$. A zero slope indicates that the coefficient is not varying with time.

The weighted score residuals are used more often than their unscaled counterparts in assessing local influence. Let $\hat{\beta}_{(i)}$ be the estimate of β when the i th subject is left out, and let $\Delta_i = \hat{\beta} - \hat{\beta}_{(i)}$. The j th component of Δ_i can be used to assess any untoward effect of the i th subject on $\hat{\beta}_j$. The exact computation of Δ_i involves refitting the model each time a subject is omitted. Cain and Lange (1984) derived the following approximation of Δ_i as weighted score residuals:

$$\hat{\Delta}_i = \hat{\mathbf{V}}\mathbf{L}_i$$

Here, $\hat{\mathbf{V}} = \hat{\mathbf{V}}(\hat{\beta})$ is the estimated covariance matrix of $\hat{\beta}$, and \mathbf{L}_i is the vector of the score residuals for the i th subject. Values of $\hat{\Delta}_i$ are output to the DFBETA= variables. Again, when the counting process MODEL specification is used, the DFBETA= variables contain the component $(\hat{\mathbf{V}}\mathbf{L}_i(t_2) - \hat{\mathbf{V}}\mathbf{L}_i(t_1))$. The vector $\hat{\Delta}_i$ for a subject can be obtained by summing these components within the subject.

Note that these DFBETA statistics are a transform of the score residuals. In computing the robust sandwich variance estimators of Lin and Wei (1989) and Wei, Lin, and Weissfeld (1989), it is more convenient to use the DFBETA statistics than the score residuals (see [Example 54.8](#) on page 3304).

Influence of Observations on Overall Fit of the Model

The LD statistic approximates the likelihood displacement, which is the amount by which minus twice the log likelihood ($-2 \log \mathcal{L}(\hat{\beta})$), under a fitted model, changes when each subject in turn is left out. When the i th subject is omitted, the likelihood displacement is

$$2 \log \mathcal{L}(\hat{\beta}) - 2 \log \mathcal{L}(\hat{\beta}_{(i)})$$

where $\hat{\beta}_{(i)}$ is the vector of parameter estimates obtained by fitting the model without the i th subject. Instead of refitting the model without the i th subject, Pettitt and Bin Daud (1989) propose that the likelihood displacement for the i th subject be approximated by

$$LD_i = \mathbf{L}_i' \hat{\mathbf{V}} \mathbf{L}_i$$

This approximation is output to the LD= variable.

The LMAX statistic is another global influence statistic. This statistic is based on the symmetric matrix

$$\mathbf{B} = \mathbf{L} \hat{\mathbf{V}} \mathbf{L}'$$

where \mathbf{L} is the matrix with rows that are the score residual vectors \mathbf{L}_i . The elements of the eigenvector associated with the largest eigenvalue of the matrix \mathbf{B} , standardized to unit length, give a measure of the sensitivity of the fit of the model to each

observation in the data. The influence of the i th subject on the global fit of the model is proportional to the magnitude of ζ_i , where ζ_i is the i th element of the vector ζ that satisfies

$$\mathbf{B}\zeta = \lambda_{\max}\zeta \quad \text{and} \quad \zeta'\zeta = 1$$

with λ_{\max} being the largest eigenvalue of \mathbf{B} . The sign of ζ_i is irrelevant, and its absolute value is output to the LMAX= variable.

When the counting process MODEL specification is used, the LD= and LMAX= variables are set to missing, because these two global influence statistics can be calculated on a per subject basis only.

Survival Distribution Estimates for the Cox Model

Two estimators of the survivor function are available: one is the product-limit estimate and the other is based on the empirical cumulative hazard function.

Product-Limit Estimates

Let \mathcal{C}_i denote the set of individuals censored in the half-open interval $[t_i, t_{i+1})$, where $t_0 = 0$ and $t_{k+1} = \infty$. Let γ_l denote the censoring times in $[t_i, t_{i+1})$; l ranges over \mathcal{C}_i . The likelihood function for all individuals is given by

$$\mathcal{L} = \prod_{i=0}^k \left\{ \prod_{l \in \mathcal{D}_i} \left([S_0(t_i)]^{\exp(\mathbf{z}'_l \boldsymbol{\beta})} - [S_0(t_i + 0)]^{\exp(\mathbf{z}'_l \boldsymbol{\beta})} \right) \prod_{l \in \mathcal{C}_i} [S_0(\gamma_l + 0)]^{\exp(\mathbf{z}'_l \boldsymbol{\beta})} \right\}$$

where \mathcal{D}_0 is empty. The likelihood \mathcal{L} is maximized by taking $S_0(t) = S_0(t_i + 0)$ for $t_i < t \leq t_{i+1}$ and allowing the probability mass to fall only on the observed event times t_1, \dots, t_k . By considering a discrete model with hazard contribution $1 - \alpha_i$ at t_i , you take $S_0(t_i) = S_0(t_{i-1} + 0) = \prod_{j=0}^{i-1} \alpha_j$, where $\alpha_0 = 1$. Substitution into the likelihood function produces

$$\mathcal{L} = \prod_{i=0}^k \left\{ \prod_{j \in \mathcal{D}_i} \left(1 - \alpha_i^{\exp(\mathbf{z}'_j \boldsymbol{\beta})} \right) \prod_{l \in \mathcal{R}_i - \mathcal{D}_i} \alpha_i^{\exp(\mathbf{z}'_l \boldsymbol{\beta})} \right\}$$

If you replace $\boldsymbol{\beta}$ with $\widehat{\boldsymbol{\beta}}$ estimated from the partial likelihood function and then maximize with respect to $\alpha_1, \dots, \alpha_k$, the maximum likelihood estimate $\widehat{\alpha}_i$ of α_i becomes a solution of

$$\sum_{j \in \mathcal{D}_i} \frac{\exp(\mathbf{z}'_j \widehat{\boldsymbol{\beta}})}{1 - \widehat{\alpha}_i^{\exp(\mathbf{z}'_j \widehat{\boldsymbol{\beta}})}} = \sum_{l \in \mathcal{R}_i} \exp(\mathbf{z}'_l \widehat{\boldsymbol{\beta}})$$

When only a single failure occurs at t_i , $\widehat{\alpha}_i$ can be found explicitly. Otherwise, an iterative solution is obtained by the Newton method.

The estimated baseline cumulative hazard function is

$$\widehat{H}_0(t) = -\log(\widehat{S}_0(t))$$

where $\widehat{S}_0(t)$ is the estimated baseline survivor function given by

$$\widehat{S}_0(t) = \widehat{S}_0(t_{i-1} + 0) = \prod_{j=0}^{i-1} \widehat{\alpha}_j, \quad t_{i-1} < t \leq t_i$$

For details, refer to Kalbfleisch and Prentice (1980). For a given realization of the explanatory variables $\boldsymbol{\xi}$, the product-limit estimate of the survival function at $\mathbf{Z} = \boldsymbol{\xi}$ is

$$\widehat{S}(t, \boldsymbol{\xi}) = [\widehat{S}_0(t)]^{\exp(\boldsymbol{\beta}'\boldsymbol{\xi})}$$

Empirical Cumulative Hazards Function Estimates

Let $\boldsymbol{\xi}$ be a given realization of the explanatory variables. The empirical cumulative hazard function estimate at $\mathbf{Z} = \boldsymbol{\xi}$ is

$$\widehat{\Lambda}(t, \boldsymbol{\xi}) = \sum_{i=1}^n \int_0^t \frac{dN_i(s)}{\sum_{j=1}^n Y_j(s) \exp(\widehat{\boldsymbol{\beta}}'(\mathbf{z}_j - \boldsymbol{\xi}))}$$

The variance estimator of $\widehat{\Lambda}(t, \boldsymbol{\xi})$ is given by the following (Tsiatis 1981):

$$\begin{aligned} & \widehat{\text{var}}\{n^{\frac{1}{2}}(\widehat{\Lambda}(t, \boldsymbol{\xi}) - \Lambda(t, \boldsymbol{\xi}))\} \\ &= n \left\{ \sum_{i=1}^n \int_0^t \frac{dN_i(s)}{[\sum_{j=1}^n Y_j(s) \exp(\widehat{\boldsymbol{\beta}}'(\mathbf{z}_j - \boldsymbol{\xi}))]^2} + \mathbf{H}'(t, \boldsymbol{\xi}) \widehat{\mathbf{V}}(\widehat{\boldsymbol{\beta}}) \mathbf{H}(t, \boldsymbol{\xi}) \right\} \end{aligned}$$

where $\widehat{\mathbf{V}}(\widehat{\boldsymbol{\beta}})$ is the estimated covariance matrix of $\widehat{\boldsymbol{\beta}}$ and

$$\mathbf{H}(t, \boldsymbol{\xi}) = \sum_{i=1}^n \int_0^t \frac{\sum_{l=1}^n Y_l(s) (\mathbf{Z}_l - \boldsymbol{\xi}) \exp(\widehat{\boldsymbol{\beta}}'(\mathbf{z}_l - \boldsymbol{\xi}))}{[\sum_{j=1}^n Y_j(s) \exp(\widehat{\boldsymbol{\beta}}'(\mathbf{z}_j - \boldsymbol{\xi}))]^2} dN_i(s)$$

The empirical cumulative hazard function (CH) estimate of the survivor function for $\mathbf{Z} = \boldsymbol{\xi}$ is

$$\widetilde{S}(t, \boldsymbol{\xi}) = \exp(-\widehat{\Lambda}(t, \boldsymbol{\xi}))$$

Confidence Intervals for the Survivor Function

Let $\hat{S}(t, \xi)$ and $\tilde{S}(t, \xi)$ correspond to the product-limit (PL) and empirical cumulative hazard function (CH) estimates of the survivor function for $\mathbf{Z} = \xi$, respectively. Both the standard error of $\log(\hat{S}(t, \xi))$ and the standard error of $\log(\tilde{S}(t, \xi))$ are approximated by $\tilde{\sigma}_0(t, \xi)$, which is the square root of the variance estimate of $\hat{\Lambda}(t, \xi)$; refer to Kalbfleisch and Prentice (1980, p.116). By the delta method, the standard errors of $\hat{S}(t, \xi)$ and $\tilde{S}(t, \xi)$ are given by

$$\hat{\sigma}_1(t, \xi) \doteq \hat{S}(t, \xi)\tilde{\sigma}_0(t, \xi) \quad \text{and} \quad \tilde{\sigma}_1(t, \xi) \doteq \tilde{S}(t, \xi)\tilde{\sigma}_0(t, \xi)$$

respectively. The standard errors of $\log[-\log(\hat{S}(t, \xi))]$ and $\log[-\log(\tilde{S}(t, \xi))]$ are given by

$$\hat{\sigma}_2(t, \xi) \doteq \frac{-\tilde{\sigma}_0(t, \xi)}{\log(\hat{S}(t, \xi))} \quad \text{and} \quad \tilde{\sigma}_2(t, \xi) \doteq \frac{\tilde{\sigma}_0(t, \xi)}{\hat{\Lambda}(t, \xi)}$$

respectively.

Let $z_{\alpha/2}$ be the upper $100(1 - \frac{\alpha}{2})$ percentile point of the standard normal distribution. A $100(1 - \alpha)\%$ confidence interval for the survivor function $S(t, \xi)$ is given in the following table.

Method	CLTYPE	Confidence Limits
LOG	PL	$\exp[\log(\hat{S}(t, \xi)) \pm z_{\frac{\alpha}{2}}\tilde{\sigma}_0(t, \xi)]$
LOG	CH	$\exp[\log(\tilde{S}(t, \xi)) \pm z_{\frac{\alpha}{2}}\tilde{\sigma}_0(t, \xi)]$
LOGLOG	PL	$\exp\{-\exp[\log(-\log(\hat{S}(t, \xi))) \pm z_{\frac{\alpha}{2}}\hat{\sigma}_2(t, \xi)]\}$
LOGLOG	CH	$\exp\{-\exp[\log(-\log(\tilde{S}(t, \xi))) \pm z_{\frac{\alpha}{2}}\tilde{\sigma}_2(t, \xi)]\}$
NORMAL	PL	$\hat{S}(t, \xi) \pm z_{\frac{\alpha}{2}}\hat{\sigma}_1(t, \xi)$
NORMAL	CH	$\tilde{S}(t, \xi) \pm z_{\frac{\alpha}{2}}\tilde{\sigma}_1(t, \xi)$

Left Truncation of Failure Times

Left truncation arises when individuals only come under observation some known time after the natural time origin of the phenomenon under study. The risk set just prior to an event time does not include individuals whose left truncation times exceed the given event time. Thus, any contribution to the likelihood must be conditional on the truncation limit having been exceeded.

Although left truncation can be accommodated in PROC PHREG through the counting process style of input, such specification does not allow survival estimates to be output. Using the ENTRY= option in PROC PHREG for left truncation does not suppress computing the survival estimates.

Consider the following specifications of PROC PHREG:

```
proc phreg data=one;
  model t2*dead(0)=x1-x10/entry=t1;
  baseline out=out1 survival=s;
  title 'The ENTRY= option is Specified';
run;

proc phreg data=one;
  model (t1,t2)*dead(0)=x1-x10;
  baseline out=out2 survival=s;
  title 'Counting Process Style of Input';
run;
```

Both specifications yield the same model estimates; however, the baseline data set out2 is empty, since survivor function estimates are not computed when you use the counting process style of input.

Variable Selection Methods

Five variable selection methods are available. The simplest method (and the default) is SELECTION=NONE, for which PROC PHREG fits the complete model as specified in the MODEL statement. The other four methods are FORWARD for forward selection, BACKWARD for backward elimination, STEPWISE for stepwise selection, and SCORE for best subsets selection. These methods are specified with the SELECTION= option in the MODEL statement. Intercept parameters are forced to stay in the model unless the NOINT option is specified.

When SELECTION=FORWARD, PROC PHREG first estimates parameters for variables forced into the model. These variables are the intercepts and the first n explanatory variables in the MODEL statement, where n is the number specified by the START= or INCLUDE= option in the MODEL statement (n is zero by default). Next, the procedure computes the adjusted chi-square statistics for each variable not in the model and examines the largest of these statistics. If it is significant at the SLENTRY= level, the corresponding variable is added to the model. Once a variable is entered in the model, it is never removed from the model. The process is repeated until none of the remaining variables meet the specified level for entry or until the STOP= value is reached.

When SELECTION=BACKWARD, parameters for the complete model as specified in the MODEL statement are estimated unless the START= option is specified. In that case, only the parameters for the intercepts and the first n explanatory variables in the MODEL statement are estimated, where n is the number specified by the START= option. Results of the Wald test for individual parameters are examined. The least significant variable that does not meet the SLSSTAY= level for staying in the model is removed. Once a variable is removed from the model, it remains excluded. The process is repeated until no other variable in the model meets the specified level for removal or until the STOP= value is reached.

The SELECTION=STEPWISE option is similar to the SELECTION=FORWARD option except that variables already in the model do not necessarily remain. Variables are entered into and removed from the model in such a way that each forward selection step can be followed by one or more backward elimination steps. The stepwise selection process terminates if no further variable can be added to the model or if the variable just entered into the model is the only variable removed in the subsequent backward elimination.

For SELECTION=SCORE, PROC PHREG uses the branch and bound algorithm of Furnival and Wilson (1974) to find a specified number of models with the highest likelihood score (chi-square) statistic for all possible model sizes, from 1, 2, 3 variables, and so on, up to the single model containing all of the explanatory variables. The number of models displayed for each model size is controlled by the BEST= option. You can use the START= option to impose a minimum model size, and you can use the STOP= option to impose a maximum model size. For instance, with BEST=3, START=2, and STOP=5, the SCORE selection method displays the best three models (that is, the three models with the highest score chi-squares) containing 2, 3, 4, and 5 variables.

The SEQUENTIAL and STOPRES options can alter the default criteria for adding variables to or removing variables from the model when they are used with the FORWARD, BACKWARD, or STEPWISE selection methods.

Assessment of the Proportional Hazards Model (Experimental)

The proportional hazards model specifies that the hazard function for the failure time T associated with a $p \times 1$ column covariate vector \mathbf{Z} takes the form

$$\lambda(t; \mathbf{Z}) = \lambda_0(t)e^{\beta' \mathbf{Z}}$$

where $\lambda_0(\cdot)$ is an unspecified baseline hazard function and β is a $p \times 1$ column vector of regression parameters. Lin et al. (1993) present graphical and numerical methods for model assessment based on the cumulative sums of martingale residuals and their transforms over certain coordinates (e.g., covariate values or follow-up times). The distributions of these stochastic processes under the assumed model can be approximated by the distributions of certain zero-mean Gaussian processes whose realizations can be generated by simulation. Each observed residual pattern can then be compared, both graphically and numerically, with a number of realizations from the null distribution. Such comparisons enable you to assess objectively whether the observed residual pattern reflects anything beyond random fluctuation. These procedures are useful in determining appropriate functional forms of covariates and assessing the proportional hazards assumption. You use the ASSESS statement to carry out these model-checking procedures.

For a sample of n subjects, let $(X_i, \Delta_i, \mathbf{Z}_i)$ be the data of the i th subject; that is, X_i represents the observed failure time, Δ_i has a value of 1 if X_i is an uncensored time and 0 otherwise, and $\mathbf{Z}_i = (Z_{1i}, \dots, Z_{pi})'$ is a p -vector of covariates. Let $N_i(t) = \Delta_i I(X_i \leq t)$ and $Y_i(t) = I(X_i \geq t)$. Let

$$S^{(0)}(\boldsymbol{\beta}, t) = \sum_{i=1}^n Y_i(t) e^{\boldsymbol{\beta}' \mathbf{Z}_i} \quad \text{and} \quad \mathbf{Z}(\boldsymbol{\beta}, t) = \frac{\sum_{i=1}^n Y_i(t) e^{\boldsymbol{\beta}' \mathbf{Z}_i} \mathbf{Z}_i}{S^{(0)}(\boldsymbol{\beta}, t)}$$

Let $\hat{\boldsymbol{\beta}}$ be the maximum partial likelihood estimate of $\boldsymbol{\beta}$, and let $\mathcal{I}(\hat{\boldsymbol{\beta}})$ be the observed information matrix.

The martingale residuals are defined as

$$\hat{M}_i(t) = N_i(t) - \int_0^t Y_i(u) e^{\hat{\boldsymbol{\beta}}' \mathbf{Z}_i} d\hat{\Lambda}_0(u), \quad i = 1, \dots, n$$

where $\hat{\Lambda}_0(t) = \int_0^t \frac{\sum_{i=1}^n dN_i(u)}{S^{(0)}(\hat{\boldsymbol{\beta}}, u)}$.

The empirical score process $\mathbf{U}(\hat{\boldsymbol{\beta}}, t) = (U_1(\hat{\boldsymbol{\beta}}, t), \dots, U_p(\hat{\boldsymbol{\beta}}, t))'$ is a transform of the martingale residuals:

$$\mathbf{U}(\hat{\boldsymbol{\beta}}, t) = \sum_{i=1}^n \mathbf{Z}_i \hat{M}_i(t)$$

Checking the Functional Form of a Covariate

To check the functional form of the j th covariate, consider the partial-sum process of $\hat{M}_i = \hat{M}_i(\infty)$:

$$W_j(z) = \sum_{i=1}^n I(Z_{ji} \leq z) \hat{M}_i$$

Under that null hypothesis that the model holds, $W_j(z)$ can be approximated by the zero-mean gaussian process

$$\begin{aligned} \hat{W}_j(z) &= \sum_{l=1}^n \Delta_l \left\{ I(Z_{jl} \leq z) - \frac{\sum_{i=1}^n Y_i(t) e^{\boldsymbol{\beta}' \mathbf{Z}_i} I(Z_{ij} \leq z)}{S^{(0)}(\hat{\boldsymbol{\beta}}, X_l)} \right\} G_l - \\ &\quad \sum_{k=1}^n \int_0^\infty Y_k(s) e^{\hat{\boldsymbol{\beta}}' \mathbf{Z}_k} I(Z_{jk} \leq z) [\mathbf{Z}_k - \bar{\mathbf{Z}}(\hat{\boldsymbol{\beta}}, s)]' d\hat{\Lambda}_0(s) \\ &\quad \times \mathcal{I}^{-1}(\hat{\boldsymbol{\beta}}) \sum_{l=1}^n \Delta_l [\mathbf{Z}_k - \bar{\mathbf{Z}}(\hat{\boldsymbol{\beta}}, X_l)] G_l \end{aligned}$$

where (G_1, \dots, G_n) are independent standard normal variables that are independent of $(X_i, \Delta_i, \mathbf{Z}_i)$, $i = 1, \dots, n$.

You can assess the functional form of the j th covariate by plotting a small number of realizations (the default is 20) of $\hat{W}_j(z)$ on the same graph as the observed $W_j(z)$ and visually comparing them to see how typical the observed pattern of $W_j(z)$ is of the null distribution samples. You can supplement the graphical inspection method with a Kolmogorov-type supremum test. Let s_j be the observed value of $S_j = \sup_z |W_j(z)|$ and let $\hat{S}_j = \sup_z |\hat{W}_j(z)|$. The p -value $\Pr(S_j \geq s_j)$ is approximated by $\Pr(\hat{S}_j \geq s_j)$, which in turn is approximated by generating a large number of realizations (1000 is the default) of $\hat{W}_j(\cdot)$.

Checking the Proportional Hazards Assumption

Consider the standardized empirical score process for the j th component of \mathbf{Z}

$$U_j^*(t) = [\mathcal{I}^{-1}(\hat{\beta})_{jj}]^{\frac{1}{2}} U_j(\hat{\beta}, t),$$

Under the null hypothesis that the model holds, $U_j^*(t)$ can be approximated by

$$\begin{aligned} \hat{U}_j^*(t) = & [\mathcal{I}^{-1}(\hat{\beta})_{jj}]^{\frac{1}{2}} \left\{ \sum_{l=1}^n I(X_l \leq t) \Delta_l [Z_{jl} - \bar{Z}_j(\hat{\beta}, t)] G_l - \right. \\ & \sum_{k=1}^n \int_0^t Y_k(s) e^{\hat{\beta}' \mathbf{Z}_k} Z_{jk} [\mathbf{Z}_k - \bar{\mathbf{Z}}(\hat{\beta}, s)]' d\hat{\Lambda}_0(s) \\ & \left. \times \mathcal{I}^{-1}(\hat{\beta}) \sum_{l=1}^n \Delta_l [\mathbf{Z}_l - \bar{\mathbf{Z}}(\hat{\beta}, X_l)] G_l \right\} \end{aligned}$$

where $\bar{Z}_j(\hat{\beta}, t)$ is the j th component of $\bar{\mathbf{Z}}(\hat{\beta}, t)$, and (G_1, \dots, G_n) are independent standard normal variables that are independent of $(X_i, \Delta_i, \mathbf{Z}_i, (i = 1, \dots, n))$.

You can assess the proportional hazards assumption for the j th covariate by plotting a few realizations of $\hat{U}_j^*(t)$ on the same graph as the observed $U_j^*(t)$ and visually comparing them to see how typical the observed pattern of $U_j^*(t)$ is of the null distribution samples. Again you can supplement the graphical inspection method with a Kolmogorov-type supremum test. Let s_j^* be the observed value of $S_j^* = \sup_t |U_j^*(t)|$ and let $\hat{S}_j^* = \sup_t |\hat{U}_j^*(t)|$. The p -value $\Pr[S_j^* \geq s_j^*]$ is approximated by $\Pr[\hat{S}_j^* \geq s_j^*]$, which in turn is approximated by generating a large number of realizations (1000 is the default) of $\hat{U}_j^*(\cdot)$.

Computational Resources

Let n be the number of observations in a BY group. Let p be the number of explanatory variables. The minimum working space (in bytes) needed to process the BY group is

$$\max\{12n, 24p^2 + 160p\}$$

Extra memory is needed for certain TIES= options. Let k be the maximum multiplicity of tied times. The TIES=DISCRETE option requires extra memory (in bytes) of

$$4k(p^2 + 4p)$$

The TIES=EXACT option requires extra memory (in bytes) of

$$24(k^2 + 5k)$$

If sufficient space is available, the input data are also kept in memory. Otherwise, the input data are reread from the utility file for each evaluation of the likelihood function and its derivatives, with the resulting execution time substantially increased.

Displayed Output

If you use the NOPRINT option in the PROC PHREG statement, the procedure does not display any output. Otherwise, the displayed output of the PHREG procedure includes the following:

- the “Model Information” table, which contains:
 - the two-level name of the input data set
 - the name and label of the failure time variable
 - if you specify the censoring variable,
 - the name and label of the censoring variable
 - the values that the censoring variable assumes to indicate censored times
 - if you use the OFFSET= option in the MODEL statement, the name and label of the offset variable
 - if you specify the FREQ statement, the name and label of the frequency variable
 - if you specify the WEIGHT statement, the name and label of the weight variable
 - the method of handling ties in the failure time
- the “Summary of the Number of Event and Censored Values” table, which displays, for each stratum, the breakdown of the number of events and censored values. This table is not produced if the NOSUMMARY option is specified.
- if you specify the SIMPLE option in the PROC PHREG statement, the “Simple Statistics for Explanatory Variables” table, which displays, for each stratum, the mean, standard deviation, and minimum and maximum for each explanatory variable in the MODEL statement

- if you specify the ITPRINT option in the MODEL statement, the “Iteration History” table, which displays the iteration number, step size, log likelihood, and parameter estimates at each iteration. The last evaluation of the gradient vector is also displayed.
- the “Model Fit Statistics” table, which gives the values of -2 log likelihood for fitting a model with no explanatory variable and for fitting a model with all the explanatory variables. The AIC and SBC are also given in this table.
- the “Testing Global Null Hypothesis: BETA=0” table, which displays results of the likelihood ratio test, the score test, and the Wald test
- the “Analysis of Maximum Likelihood Estimates” table, which contains:
 - the maximum likelihood estimate of the parameter
 - the estimated standard error of the parameter estimate, computed as the square root of the corresponding diagonal element of the estimated covariance matrix
 - if you specify the COVS option in the PROC statement, the ratio of the robust standard error estimate to the model-based standard error estimate
 - the Wald Chi-Square statistic, computed as the square of the parameter estimate divided by its standard error estimate
 - the degrees of freedom of the Wald chi-square statistic. It has a value of 1 unless the corresponding parameter is redundant or infinite, in which case the value is 0.
 - the p -value of the Wald chi-square statistic with respect to a chi-square distribution with one degree of freedom
 - the hazards ratio estimate computed by exponentiating the parameter estimate
 - if you specified the RISKLIMITS option in the MODEL statement, the confidence limits for the hazards ratio
- if you specify SELECTION=SCORE in the MODEL statement, the “Regression Models Selected by Score Criterion” table, which gives the number of explanatory variables in each model, the score chi-square statistic, and the names of the variables included in the model
- if you use the FORWARD or STEPWISE selection method and you specify the DETAILS option in the MODEL statement, the “Analysis of Variables Not in the Model” table, which gives the Score chi-square statistic for testing the significance of each variable not in the model (after adjusting for the variables already in the model), and the p -value of the chi-square statistic with respect to a chi-square distribution with one degree of freedom. This table is produced before a variable is selected for entry in a forward selection step.
- if you specify the FORWARD, BACKWARD, or STEPWISE selection method, a table summarizing the model-building process, which gives the step number, the explanatory variable entered or removed at each step, the chi-square statistic, and the corresponding p -value on which the entry or removal is based

- if you use the COVB option in the MODEL statement, the estimated covariance matrix of the parameter estimates
- if you use the CORRB option in the MODEL statement, the estimated correlation matrix of the parameter estimates
- if you specify a TEST statement,
 - the “Linear Coefficients” table, which gives the coefficients and constants of the linear hypothesis (if the E option is specified)
 - the printing of the intermediate calculations of the Wald test (if the option PRINT is specified)
 - the “Test Results” table, which gives the Wald chi-square statistic, the degrees of freedom, and the p -value
 - the “Average Effect” table, which gives the weighted average of the parameter estimates for the variables in the TEST statement, the estimated standard error, the z -score, and the p -value (if the AVERAGE option is specified)

ODS Table Names

PROC PHREG assigns a name to each table it creates. You can use these names to reference the table when using the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in the following table. For more information on ODS, see Chapter 14, “Using the Output Delivery System.”

Table 54.1. ODS Tables Produced in PROC PHREG

ODS Table Name	Description	Statement	Option
BestSubsets	Best subset selection	MODEL	SELECTION=SCORE
CensoredSummary	Summary of event and censored observations	MODEL	default
ConvergenceStatus	Convergence status	MODEL	default
CorrB	Estimated correlation matrix of parameter estimators	MODEL	CORRB
CovB	Estimated covariance matrix of parameter estimators	MODEL	COVB
FitStatistics	Model fit statistics	MODEL	default
FunctionalFormSupTest (experimental)	Supremum test for functional form	ASSESS	VAR=
GlobalScore	Global chi-square test	MODEL	NOFIT
GlobalTests	Tests of the global null hypothesis	MODEL	default
IterHistory	Iteration history	MODEL	ITPRINT
LastGradient	Last evaluation of gradient	MODEL	ITPRINT
ModelBuildingSummary	Summary of model building	MODEL	SELECTION=B/F/S
ModelInfo	Model information	PROC	default
NObs	Number of observations		default
ParameterEstimates	Maximum likelihood estimates of model parameters	MODEL	default

Table 54.1. (continued)

ODS Table Name	Description	Statement	Option

SimpleStatistics	Summary statistics for explanatory variables	PROC	SIMPLE
TestAverage	Average effect for test	TEST	AVERAGE
TestCoeff	Coefficients for linear hypotheses	TEST	E
TestPrint1	$L[\text{cov}(\mathbf{b})]L'$ and $L\mathbf{b}-\mathbf{c}$	TEST	PRINT
TestPrint2	$G\text{inv}(L[\text{cov}(\mathbf{b})]L')$ and $G\text{inv}(L[\text{cov}(\mathbf{b})]L')(L\mathbf{b}-\mathbf{c})$	TEST	PRINT
TestStmts	Linear hypotheses testing results	TEST	
VariablesNotInModel	Analysis of variables not in the model	MODEL	SELECTION=F/S

ODS Graphics (Experimental)

This section describes the use of ODS for creating statistical graphs for model assessment with the PHREG procedure. These graphics are experimental in this release, meaning that both the graphical results and the syntax for specifying them are subject to change in a future release.

To request these graphs you must specify the ODS GRAPHICS statement in addition to the ASSESS statement in PROC PHREG. For more information on the ODS GRAPHICS statement, see Chapter 15, “Statistical Graphics Using ODS.”

ODS Graph Names

PROC PHREG assigns a name to each graph it creates using the ODS. You can use these names to reference the graphs when using ODS. The names are listed in Table 54.2.

Table 54.2. ODS Graphics Produced by PROC PHREG

ODS Graph Name	Description	Statement	Option
CumulativeResiduals	Cumulative martingale residual plot	ASSESS	VAR=
CumResidPanel	Panel plot of cumulative martingale residuals	ASSESS	VAR= and CRPANEL
ScoreProcess	Standardized score process plot	ASSESS	PH

Examples

Example 54.1. Stepwise Regression

Krall, Uthoff, and Harley (1975) analyzed data from a study on multiple myeloma in which researchers treated 65 patients with alkylating agents. Of those patients, 48 died during the study and 17 survived. In the data set *Myeloma*, the variable *Time* represents the survival time in months from diagnosis. The variable *VStatus* consists of two values, 0 and 1, indicating whether the patient was alive or dead, respectively, at the end of the study. If the value of *VStatus* is 0, the corresponding value of *Time* is censored. The variables thought to be related to survival are *LogBUN* (log(BUN) at diagnosis), *HGB* (hemoglobin at diagnosis), *Platelet* (platelets at diagnosis: 0=abnormal, 1=normal), *Age* (age at diagnosis in years), *LogWBC* (log(WBC) at diagnosis), *Frac* (fractures at diagnosis: 0=none, 1=present), *LogPBM* (log percentage of plasma cells in bone marrow), *Protein* (proteinuria at diagnosis), and *SCalc* (serum calcium at diagnosis). Interest lies in identifying important prognostic factors from these nine explanatory variables.

```

The stepwise selection process consists of a series of alternating step-up and step-down phases. The former adds variables to the model, while the latter removes variables from the model.

Stepwise regression analysis is requested by specifying the SELECTION=STEPWISE option in the MODEL statement. The option SLENTY=0.25 specifies that a variable has to be significant at the 0.25 level before it can be entered into the model, while the option SLSTAY=0.15 specifies that a variable in the model has to be significant at the 0.15 level for it to remain in the model. The DETAILS option requests detailed results for the variable selection process.

```

Individual score tests are used to determine which of the nine explanatory variables is first selected into the model. In this case, the score test for each variable is the global score test for the model containing that variable as the only explanatory variable. The chi-square statistic is compared to a chi-square distribution with one degree of freedom. [Output 54.1.1](#) displays the chi-square statistics and the corresponding p -values. The variable **LogBUN** has the largest chi-square value (8.5164), and it is significant ($p = 0.0035$) at the $SLENTRY=0.25$ level. The variable **LogBUN** is thus entered into the model. [Output 54.1.2](#) displays the model results. Since the Wald chi-square statistic is significant ($p = 0.0039$) at the $SLSTAY=0.15$ level, **LogBUN** stays in the model.

Output 54.1.2. First Model in the Stepwise Selection Process

```

Step 1. Variable LogBUN is entered. The model contains the following
explanatory variables:

LogBUN

Convergence Status

Convergence criterion (GCONV=1E-8) satisfied.

Testing Global Null Hypothesis: BETA=0

Test              Chi-Square      DF      Pr > ChiSq
Likelihood Ratio   11.9493         2        0.0025
Score              12.7252         2        0.0017
Wald               12.1900         2        0.0023

Analysis of Maximum Likelihood Estimates

Variable  DF      Parameter Estimate      Standard Error      Chi-Square      Pr > ChiSq      Hazard Ratio
LogBUN    1        1.67440                0.61209              7.4833           0.0062           5.336
HGB       1       -0.11899                0.05751              4.2811           0.0385           0.888

```

The next step consists of selecting another variable to add to the model. [Output 54.1.3](#) displays the chi-square statistics and p -values of individual score tests (adjusted for LogBUN) for the remaining eight variables. The score chi-square for a given variable is the value of the likelihood score test for testing the significance of the variable in the presence of LogBUN. The variable HGB is selected because it has the highest chi-square value (4.3468), and it is significant ($p = 0.0371$) at the SLENTY=0.25 level. [Output 54.1.4](#) displays the fitted model containing both LogBUN and HGB. Based on the Wald statistics, neither LogBUN nor HGB is removed from the model.

Output 54.1.5. Third Model in the Stepwise Regression

```

Step 3. Variable SCalc is entered. The model contains the following
explanatory variables:

LogBUN HGB SCalc

Convergence Status

Convergence criterion (GCONV=1E-8) satisfied.

Model Fit Statistics

Criterion          Without          With
                  Covariates       Covariates

AIC                309.716         302.078
SBC                309.716         307.692

Testing Global Null Hypothesis: BETA=0

Test              Chi-Square      DF      Pr > ChiSq
Likelihood Ratio  13.6377         3       0.0034
Score             15.3053         3       0.0016
Wald              14.4542         3       0.0023

Analysis of Maximum Likelihood Estimates

Variable  DF      Parameter Estimate  Standard Error  Chi-Square  Pr > ChiSq  Hazard Ratio
LogBUN    1       1.63593             0.62359         6.8822      0.0087      5.134
HGB       1      -0.12643            0.05868         4.6419      0.0312      0.881
SCalc     1       0.13286             0.09868         1.8127      0.1782      1.142

```

Output 54.1.5 shows Step 3 of the selection process, in which the variable **SCalc** is added, resulting in the model with **LogBUN**, **HGB**, and **SCalc** as the explanatory variables. Note that **SCalc** has the smallest Wald chi-square statistic, and it is not significant ($p = 0.1782$) at the $SLSTAY=0.15$ level. The variable **SCalc** is then removed from the model in a step-down phase in Step 4 (**Output 54.1.6**). The removal of **SCalc** brings the stepwise selection process to a stop in order to avoid repeatedly entering and removing the same variable.

Output 54.1.6. Final Model in the Stepwise Regression

```

Step 4. Variable SCalc is removed. The model contains the following
explanatory variables:

LogBUN HGB

Convergence Status

Convergence criterion (GCONV=1E-8) satisfied.

NOTE: Model building terminates because the variable to be entered is the
variable that was removed in the last step.

```

The procedure also displays a summary table of the steps in the stepwise selection process, as shown in [Output 54.1.7](#).

The stepwise selection process results in a model with two explanatory variables, LogBUN and HGB.

Output 54.1.7. Model Selection Summary

Summary of Stepwise Selection						
Step	Variable		Number In	Score Chi-Square	Wald Chi-Square	Pr > ChiSq
	Entered	Removed				
1	LogBUN		1	8.5164	.	0.0035
2	HGB		2	4.3468	.	0.0371
3	SCalc		3	1.8225	.	0.1770
4		SCalc	2	.	1.8127	0.1782

Example 54.2. Best Subset Selection

An alternative to stepwise selection of variables is best subset selection. The procedure uses the branch and bound algorithm of Furnival and Wilson (1974) to find a specified number of best models containing one, two, three variables, and so on, up to the single model containing all of the explanatory variables. The criterion used to determine “best” is based on the global score chi-square statistic. For two models A and B, each having the same number of explanatory variables, model A is considered to be better than model B if the global score chi-square statistic for A exceeds that for B.

Best subset selection analysis is requested by specifying the SELECTION=SCORE option in the MODEL statement. The BEST=3 option requests the procedure to identify only the three best models for each size. In other words, PROC PHREG will list the three models having the highest score statistics of all the models possible for a given number of covariates.

```
proc phreg data=Myeloma;
  model Time*VStatus(0)=LogBUN HGB Platelet Age LogWBC
    Frac LogPBM Protein SCalc
    / selection=score best=3;
run;
```

Output 54.2.1 displays the results of this analysis. The number of explanatory variables in the model is given in the first column, and the names of the variables are listed on the right. The models are listed in descending order of their score chi-square values within each model size. For example, among all models containing two explanatory variables, the model that contains the variables `LogBUN` and `HGB` has the largest score value (12.7252), the model that contains the variables `LogBUN` and `Platelet` has the second largest score value (11.1842), and the model that contains the variables `LogBUN` and `SCalc` has the third largest score value (9.9962).

Output 54.2.1. Best Variable Combinations

The PHREG Procedure			
Regression Models Selected by Score Criterion			
Number of Variables	Score Chi-Square	Variables Included in Model	
1	8.5164	<code>LogBUN</code>	
1	5.0664	<code>HGB</code>

8	18.1309	<code>LogBUN HGB Platelet Age LogWBC Frac Protein SCalc</code>	
9	18.4550	<code>LogBUN HGB Platelet Age LogWBC Frac LogPBM Protein SCalc</code>	

Example 54.3. Conditional Logistic Regression for $m:n$ Matching

Conditional logistic regression is used to investigate the relationship between an outcome and a set of prognostic factors in matched case-control studies. The outcome is whether the subject is a case or a control. If there is only one case and one control, the matching is 1:1. The $m:n$ matching refers to the situation in which there is a varying number of cases and controls in the matched sets. You can perform conditional

logistic regression with the PHREG procedure by using the discrete logistic model and forming a stratum for each matched set. In addition, you need to create dummy survival times so that all the cases in a matched set have the same event time value, and the corresponding controls are censored at later times.

Consider the following set of low infant birth-weight data extracted from Appendix 1 of Hosmer and Lemeshow (1989). These data represent 189 women, of whom 59 had low birth-weight babies and 130 had normal weight babies. Under investigation are the following risk factors: weight in pounds at the last menstrual period (LWT), presence of hypertension (HT), smoking status during pregnancy (Smoke), and presence of uterine irritability (UI). For HT, Smoke, and UI, a value of 1 indicates a “yes” and a value of 0 indicates a “no.” The woman’s age (Age) is used as the matching variable. The SAS data set LBW contains a subset of the data corresponding to women between the ages of 16 and 32.

```

data LBW;
  input id Age Low LWT Smoke HT UI @@;
  Time=2-Low;

;

```

The variable `LOW` is used to determine whether the subject is a case (`LOW=1`, low birth-weight baby) or a control (`LOW=0`, normal weight baby). The dummy time variable `Time` takes the value 1 for cases and 2 for controls.
