may be absent (when $r_{av} = 0$ and/or $r_{\Delta} = 0$). The most important feature of the above equations is the fact that the different variables w_i interact only through their average value. For an analogue nonlinear situation of this example, see [17].

Example 5 (permutations of identical subsystems with feature vectors). Next, consider the system $\Sigma = (\mathbb{R}, (\mathbb{R}^m)^n, \mathcal{B}) \in \mathcal{L}^{mn}$. Think of Σ as modelling n identical subsystems, each of which is described by m features. Thus $w = \text{col}(w_1, w_2, \dots, w_n)$ with each of the $w_i : \mathbb{R} \rightarrow \mathbb{R}^m, i = 1, 2, \dots, n$, where $w_i(t) \in \mathbb{R}^m$ denotes the feature vector of the i th subsystem at time t . In the case of the motion of n particles, this feature vector could be the position of the particle in the plane ($m = 2$) or in 3-space ($m = 3$), or we could consider each particle being described by a position and an external force acting on it (thus $m = 2, 4$, or 6 , depending on whether these particles are considered on the line, in the plane, or in 3-space).

Let $\rho : S_n \rightarrow GL((\mathbb{R}^m)^n)$ act as follows:

$$\rho_g \text{col}(w_1, w_2, \dots, w_n) := \text{col}(w_{g(1)}, w_{g(2)}, \dots, w_{g(n)}).$$

In this case, the decomposition of ρ into irreducible components leads to $\rho \cong m\rho_1 \oplus m\rho_2$ with ρ_1 and ρ_2 as in Example 3 or Example 4. The ρ -adapted basis may now be chosen as follows. Define, for $x = \text{col}(x_1, x_2, \dots, x_n) \in (\mathbb{R}^m)^n$, $x_{av} := (1/n)(x_1 + x_2 + \dots + x_n)$ and $\Delta x_i := x_i - x_{av}$. Represent x by the coordinate vector $\text{col}(x_{av}, \Delta x_2, \dots, \Delta x_n)$ and define V_1 by $\Delta x_2 = \dots = \Delta x_n = 0$ and V_2 by $x_{av} = 0$. Then $m\rho_1 \cong \rho|_{V_1}$ and $m\rho_2 \cong \rho|_{V_2}$. The further decomposition of $m\rho_1$ and $m\rho_2$ into their irreducible components is rather obvious but will not be given, since it will not be needed in the following.

In terms of the notation of Theorem 5, we have $m_{\mathbb{R},1} = m_{\mathbb{R},2} = m$ and $n_{\mathbb{R},1} = 1, n_{\mathbb{R},2} = n - 1$. Thus we should consider all the cases where $0 \leq m'_{\mathbb{R},2}, m''_{\mathbb{R},2} \leq m$. Proceeding exactly as in Example 4 we obtain that a system $\Sigma = (\mathbb{R}, (\mathbb{R}^m)^n, \mathcal{B}) \in \mathcal{L}^{mn}$ will be ρ -symmetric if and only if there exist $m_{av}, m_{\Delta} \in \mathbb{Z}_+$ (we could, but need not, restrict m_{av} and m_{Δ} to be $\leq m$) and polynomial matrices $R_{av} \in \mathbb{R}^{m_{av} \times m}[s]$ and $R_{\Delta} \in \mathbb{R}^{m_{\Delta} \times m}[s]$ such that Σ is described by

$$\begin{aligned} R_{av} \left(\frac{d}{dt} \right) w_{av} &= 0, \\ R_{\Delta} \left(\frac{d}{dt} \right) \Delta w_i &= 0, \quad i = 1, 2, \dots, n \end{aligned}$$

with $w_{av} := (1/n)(w_1 + w_2 + \dots + w_n)$ and $\Delta w_i := w_i - w_{av}$.

As a more specific example, consider a system of n identical particles in 3-space with external forces. Such a system will hence be described by differential equations of the form

$$\begin{aligned} P_{av} \left(\frac{d}{dt} \right) q_{av} &= Q_{av} \left(\frac{d}{dt} \right) F_{av}, \\ P_{\Delta} \left(\frac{d}{dt} \right) (q_i - q_{av}) &= Q_{\Delta} \left(\frac{d}{dt} \right) (F_i - F_{av}), \quad i = 1, 2, \dots, n \end{aligned}$$

with q_i the position of the i th particle, F_i the external force acting on it, and q_{av}, F_{av} defined in the obvious way. Thus the motion of the center of mass is governed by a law involving the mean force, while the laws governing the motion of the displacement from the center of mass involves the difference of the force acting on the particle and

the mean force and is identical for each of the particles. In particular, the particles interact only through the center of mass and the mean force.

Example 6 (permutations with two kinds of subsystems). Now consider the system

$$\Sigma = (\mathbb{R}, (\mathbb{R}^{m_1})^{n_1} \times (\mathbb{R}^{m_2})^{n_2}, \mathcal{B}) \in \mathcal{L}^{m_1 n_1 + m_2 n_2}.$$

Think of Σ as modelling n_1 identical subsystems of one kind with each m_1 features and n_2 identical subsystems of a second kind each with m_2 features.

Let $\rho : S_{n_1} \times S_{n_2} \rightarrow GL((\mathbb{R}^{m_1})^{n_1} \times (\mathbb{R}^{m_2})^{n_2})$ act as follows:

$$\rho_{g_1, g_2} \text{col}(w'_1, \dots, w'_{n_1}, w''_1, \dots, w''_{n_2}) := \text{col}(w'_{g_1(1)}, \dots, w'_{g_1(n_1)}, w''_{g_2(1)}, \dots, w''_{g_2(n_2)}).$$

The decomposition of ρ into irreducible components now becomes $\rho \cong (m_1 + m_2)\rho_1 \oplus m_1\rho'_2 \oplus m_2\rho''_2$ with ρ_1 the identity representation and $(m_1 + m_2)\rho_1 \cong \rho|_{V_1}$ with

$$V_1 = \{\text{col}(x'_1, \dots, x'_{n_1}, x''_1, \dots, x''_{n_2}) \mid x'_1 = \dots = x'_{n_1}, x''_1 = \dots = x''_{n_2}\}.$$

Furthermore, ρ'_2 and ρ''_2 are the analogues of what we denoted by ρ_2 before: ρ'_2 corresponds to the analogue of ρ_2 as an irreducible representation of S_{n_1} and ρ''_2 corresponds to the analogue of ρ_2 as an irreducible representation of S_{n_2} . Proceeding as before, Theorem 5 will show that Σ is ρ -symmetric if and only if there exist $m_{av}, m'_\Delta, m''_\Delta \in \mathbb{Z}_+$ and polynomial matrices $R_{av} \in \mathbb{R}^{m_{av} \times (m_1 + m_2)}[s]$, $R'_\Delta \in \mathbb{R}^{m'_\Delta \times m_1}[s]$, and $R''_\Delta \in \mathbb{R}^{m''_\Delta \times m_2}[s]$ such that Σ is described by

$$\begin{aligned} R_{av} \left(\frac{d}{dt} \right) \begin{bmatrix} w'_{av} \\ \dots \\ w''_{av} \end{bmatrix} &= 0, \\ R'_\Delta \left(\frac{d}{dt} \right) (w'_i - w'_{av}) &= 0, \quad i = 1, 2, \dots, n_1, \\ R''_\Delta \left(\frac{d}{dt} \right) (w''_j - w''_{av}) &= 0, \quad j = 1, 2, \dots, n_2. \end{aligned}$$

This shows that the two groups can only interact through their averages, while all the respective displacements are independent.

An interesting special case can now be obtained by taking $n_2 = 1$. We can then view the situation as modelling the dynamics of the interaction of a central control station with n identical substations. In the obvious notation, the dynamical laws then take the form

$$\begin{aligned} R_{av} \left(\frac{d}{dt} \right) \begin{bmatrix} w_{av} \\ \dots \\ w_{\text{central}} \end{bmatrix} &= 0, \\ R_\Delta \left(\frac{d}{dt} \right) (w_i - w_{av}) &= 0, \quad i = 1, 2, \dots, n. \end{aligned}$$

Thus the central controller influences only the average of the feature vectors of the substations.

Remark. The above examples all involve the action of the whole symmetric group S_n . Actually, identical results may be obtained by considering a doubly transitive subgroup G of S_n . A subgroup $G \subseteq S_n$ is said to be *transitive* if, for all $\alpha, \beta \in \{1, 2, \dots, n\}$, there exist $g \in G$ such that $g(\alpha) = \beta$; it is said to be *doubly transitive*

if, for all $\alpha', \beta', \alpha'', \beta'' \in \{1, 2, \dots, n\}$, $\alpha' \neq \alpha''$, and $\beta' \neq \beta''$, there exists $g \in G$ such that $g(\alpha') = \beta'$ and $g(\alpha'') = \beta''$. An example of a doubly transitive subgroup is the subgroup of even permutations.

It can be shown that the representations of Examples 4–6 remain valid without changes if we assume invariance of \mathcal{B} for a doubly transitive subgroup G of S_n in Example 5 and doubly transitive subgroups G_1 of S_{n_1} and G_2 of S_{n_2} in Example 6. In particular, this shows that permutation symmetry for one doubly transitive subgroup implies permutation symmetry for the whole of S_n in Example 5 and analogously for the whole of $S_{n_1} \times S_{n_2}$ in Example 6!

Example 7 (cyclic permutations). Let \mathbb{Z}_q denote the group consisting of

$$\{0, 1, \dots, q-1\}$$

with the group operation addition modulo q . It is more convenient to denote this group as $\{1, r, r^2, \dots, r^{q-1}\}$ with $r^q = 1$. Note that \mathbb{Z}_q is a subgroup of S_q . It is called the group of cyclic permutations. Let $\mathbb{Z}_q = \{1, r, \dots, r^{q-1}\}$ act on \mathbb{K}^q as in the case of permutations. Thus

$$\rho_r \text{col}(x_1, x_2, \dots, x_{q-1}, x_q) := \text{col}(x_q, x_1, x_2, \dots, x_{q-1})$$

from which $\rho_r, \dots, \rho_{r^{q-1}}$ follow.

Because the group \mathbb{Z}_q is commutative, its irreducible representations over \mathbb{C} are all one-dimensional. There are q such irreducible representations given by $\rho_1, \rho_2, \dots, \rho_q$ with $\rho_k : \mathbb{Z}_q \rightarrow GL(\mathbb{C})$ given by $\rho_{k,r} = \lambda^k$ with $\lambda := e^{i(2\pi/q)}$. A simple calculation shows that $\rho \cong \rho_1 \oplus \rho_2 \oplus \dots \oplus \rho_q$, with the invariant subspace corresponding to ρ_k given by $\text{span col}(1, \lambda^{-k}, \lambda^{-2k}, \dots, \lambda^{-(q-1)k})$. This now allows us to compute the ρ -adapted basis. We omit the detailed calculations.

Theorem 4 implies that $\Sigma = (\mathbb{R}, \mathbb{R}^q, \mathcal{B}) \in \mathcal{L}^q$ will be symmetric with respect to the cyclic permutations if and only if there exist polynomials $r_1, r_2, \dots, r_q \in \mathbb{C}[z]$, $p(\Sigma)$ of which are nonzero, such that

$$r_j \left(\frac{d}{dt} \right) \left(\sum_{k=1}^q \lambda^{-jk} w_k \right) = 0, \quad j = 1, 2, \dots, q$$

forms a minimal representation of Σ . This set of equations can be edited a bit further and leads to the following canonical form for this cyclic symmetry. Σ will be symmetric if and only if there exist polynomials $\tilde{r}_1, \tilde{r}_2, \dots, \tilde{r}_q \in \mathbb{C}[s]$ and a representation of Σ of the following form:

$$\begin{bmatrix} \tilde{r}_1 \left(\frac{d}{dt} \right) & \tilde{r}_2 \left(\frac{d}{dt} \right) & \cdots & \tilde{r}_{q-1} \left(\frac{d}{dt} \right) & \tilde{r}_q \left(\frac{d}{dt} \right) \\ \tilde{r}_q \left(\frac{d}{dt} \right) & \tilde{r}_1 \left(\frac{d}{dt} \right) & \cdots & \tilde{r}_{q-2} \left(\frac{d}{dt} \right) & \tilde{r}_{q-1} \left(\frac{d}{dt} \right) \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ \tilde{r}_2 \left(\frac{d}{dt} \right) & \tilde{r}_3 \left(\frac{d}{dt} \right) & \cdots & \tilde{r}_q \left(\frac{d}{dt} \right) & \tilde{r}_1 \left(\frac{d}{dt} \right) \end{bmatrix} \begin{bmatrix} w_1 \\ w_2 \\ \vdots \\ w_q \end{bmatrix} = 0.$$

Note that this representation (which is possibly nonminimal) puts the cyclic symmetry nicely into evidence.

In the real case where $\mathbb{K} = \mathbb{R}$, we must combine the complex conjugate irreducible representations. Similar calculations to the above ones lead to (possibly nonminimal)

behavioral equations

$$\begin{aligned}
 r_0 \left(\frac{d}{dt} \right) \left(\sum_{k=1}^q w_k \right) &= 0, \\
 r'_j \left(\frac{d}{dt} \right) \left(\sum_{k=1}^q w_k \cos \frac{2\pi j}{q} k \right) + r''_j \left(\frac{d}{dt} \right) \left(\sum_{k=1}^q w_k \sin \frac{2\pi j}{q} k \right) &= 0, \\
 r''_j \left(\frac{d}{dt} \right) \left(\sum_{k=1}^q w_k \cos \frac{2\pi j}{q} k \right) - r'_j \left(\frac{d}{dt} \right) \left(\sum_{k=1}^q w_k \sin \frac{2\pi j}{q} k \right) &= 0, \\
 &\text{for } j = 1, 2, \dots, \frac{q-1}{2}, \quad \text{if } q \text{ is odd,} \\
 &\text{for } j = 1, 2, \dots, \frac{q}{2} - 1, \quad \text{if } q \text{ is even.}
 \end{aligned}$$

In the case that q is even, there is an additional equation

$$r_{\frac{q}{2}} \left(\frac{d}{dt} \right) \left(\sum_{k=1}^q (-1)^k w_k \right) = 0,$$

where $r_0, r'_j, r''_j, r_{q/2} \in \mathbb{R}[s]$.

The above calculations are easily generalized to cyclic permutation symmetries with feature vectors. In this case, it suffices to interpret the r 's as matrices.

7.2. A quaternionic symmetry.

Example 8. Consider $(\mathbb{R}, \mathbb{R}^q, \mathcal{B}) \in \mathcal{L}^q$ with $q = 4$. Now assume that this system is symmetric in the following sense:

$$\left(\begin{bmatrix} w_1 \\ w_2 \\ w_3 \\ w_4 \end{bmatrix} \in \mathcal{B} \right) \Rightarrow \left(\begin{bmatrix} -w_2 \\ w_1 \\ -w_4 \\ w_3 \end{bmatrix}, \begin{bmatrix} -w_3 \\ w_4 \\ w_1 \\ -w_2 \end{bmatrix}, \begin{bmatrix} -w_4 \\ -w_3 \\ w_2 \\ w_1 \end{bmatrix} \in \mathcal{B} \right).$$

As we will see, this is a quaternionic symmetry. We will not give a physical example where such a symmetry can occur.

The group of quaternions consists of $\mathcal{H} = \{\pm 1, \pm i, \pm j, \pm k\}$ with multiplication table

$$i^2 = j^2 = k^2 = -1, \quad ij = -ji = k, \quad jk = -kj = i, \quad ki = -ik = -j.$$

The following defines a representation of \mathcal{H} on \mathbb{C}^2

$$\begin{aligned}
 \pm 1 &\mapsto \pm \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, & \pm i &\mapsto \pm \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}, \\
 \pm j &\mapsto \pm \begin{bmatrix} i & 0 \\ 0 & -i \end{bmatrix}, & \pm k &\mapsto \pm \begin{bmatrix} 0 & i \\ i & 0 \end{bmatrix}.
 \end{aligned}$$

This representation is irreducible. It is obviously not real and, since all the above matrices have real trace, it is a complex representation of quaternionic type. The

representation induced on \mathbb{R}^4 by combining this representation with its complex conjugate yields

$$\begin{aligned} 1 &\mapsto \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, & i &\mapsto M_1 := \begin{bmatrix} 0 & -1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 \end{bmatrix}, \\ j &\mapsto M_2 := \begin{bmatrix} 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \end{bmatrix}, & k &\mapsto M_3 := \begin{bmatrix} 0 & 0 & 0 & -1 \\ 0 & 0 & -1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{bmatrix}. \end{aligned}$$

Note that M_1, M_2, M_3 are precisely the matrices defining the static symmetry under consideration.

It follows from Theorem 5 that the Σ 's that are symmetric in this sense are precisely those that admit a representation for the form

$$\begin{aligned} a \left(\frac{d}{dt} \right) w_1 - b \left(\frac{d}{dt} \right) w_2 - c \left(\frac{d}{dt} \right) w_3 - d \left(\frac{d}{dt} \right) w_4 &= 0, \\ b \left(\frac{d}{dt} \right) w_1 + a \left(\frac{d}{dt} \right) w_2 + d \left(\frac{d}{dt} \right) w_3 - c \left(\frac{d}{dt} \right) w_4 &= 0, \\ c \left(\frac{d}{dt} \right) w_1 - d \left(\frac{d}{dt} \right) w_2 + a \left(\frac{d}{dt} \right) w_3 + b \left(\frac{d}{dt} \right) w_4 &= 0, \\ d \left(\frac{d}{dt} \right) w_1 + c \left(\frac{d}{dt} \right) w_2 - b \left(\frac{d}{dt} \right) w_3 + a \left(\frac{d}{dt} \right) w_4 &= 0 \end{aligned}$$

with $a, b, c, d \in \mathbb{R}[s]$.

7.3. Symmetries with Lie groups. A Lie group G is a topological group with the structure of a C^∞ differentiable \mathbb{K} -manifold in which the group multiplication and the inverse are C^∞ maps. A C^∞ group homomorphism $\rho : G \rightarrow GL(\mathbb{K}^n)$ is said to be a representation of the Lie group G on \mathbb{K}^n . Let $gl(\mathbb{K}^n)$ denote the set of $n \times n$ matrices over \mathbb{K} endowed with the usual commutator product $[A, B] = AB - BA$; $gl(\mathbb{K}^n)$ is the Lie algebra of $GL(\mathbb{K}^n)$. Let \mathcal{G} be the Lie algebra of G . The representation $\rho : G \rightarrow GL(\mathbb{K}^n)$ of the Lie group G on \mathbb{K}^n induces a Lie algebra homomorphism $\tilde{\rho} : \mathcal{G} \rightarrow gl(\mathbb{K}^n)$ of the Lie algebra \mathcal{G} on \mathbb{K}^n . Let $X_1, X_2, \dots, X_N \in \mathbb{K}^{n \times n}$ be a set of generators of $\tilde{\rho}(\mathcal{G})$. Then we have the following result.

THEOREM 6. *Let \mathcal{G} be a compact connected Lie group and let $\rho : G \rightarrow GL(\mathbb{K}^q)$ be a representation of the Lie group \mathcal{G} on \mathbb{K}^q . Let $X_1, X_2, \dots, X_N \in \mathbb{K}^{q \times q}$ be a set of generators of $\tilde{\rho}(\mathcal{G})$ with $\tilde{\rho}$ the induced representation of the Lie algebra \mathcal{G} on \mathbb{K}^q . Then the following are equivalent for $\Sigma = (\mathbb{R}, \mathbb{K}^q, \mathcal{B}) \in \mathcal{L}^q$:*

- (1) Σ is ρ -symmetric;
- (2) $XB \subseteq \mathcal{B}$ for all $X \in \tilde{\rho}(\mathcal{G})$;
- (3) $X_i \mathcal{B} \subseteq \mathcal{B}$ for $i = 1, 2, \dots, N$;
- (4) *There exist matrices $Y_1, Y_2, \dots, Y_n \in \mathbb{K}^{p(\Sigma) \times p(\Sigma)}$ and a $R \in \mathbb{K}^{p(\Sigma) \times q[s]}$ such that $R(d/dt)w = 0$ is a minimal representation for Σ with $Y_i R(s) = R(s)X_i$ for $i = 1, 2, \dots, N$. Moreover, the subspace generated by the Y_i 's is a Lie subalgebra of $gl(\mathbb{K}^{p(\Sigma)})$ and yields through the association $X_i \mapsto Y_i$ a subrepresentation of the Lie algebra representation $\tilde{\rho} : \mathcal{G} \rightarrow gl(\mathbb{K}^n)$.*

Proof. Assume without loss of generality that G is a subgroup of $GL(\mathbb{K}^q)$ and that ρ is the canonical injection.

We will run the circle $(4) \Rightarrow (3) \Rightarrow (2) \Rightarrow (1) \Rightarrow (4)$. The first two implications are trivial.

To show that $(2) \Rightarrow (1)$, assume that $X \in \mathcal{G}$ and consider the exponential $\exp X$. It is well known that there exist $\alpha_1, \alpha_2, \dots, \alpha_n \in \mathbb{K}$ such that $\exp X = \sum_{i=1}^n \alpha_i X^i$. This implies, by (2), that $(\exp X)\mathcal{B} \subseteq \mathcal{B}$. Since G is compact connected, $\exp : \mathcal{G} \rightarrow G$ is surjective, and hence (1) follows.

$(1) \Rightarrow (4)$: From Theorem 3, it follows that there exist $R \in \mathbb{K}^{p(\Sigma) \times q}[s]$ and a representation $\rho' : G \rightarrow GL(\mathbb{K}^{p(\Sigma)})$ such that $\rho' R(s) = R(s)\rho$. Now consider the one-parameter subgroup of G given by $G_i := \{\exp \mu X_i \mid \mu \in \mathbb{K}\}$. Then $\rho'(G_i)$ is also a one-parameter subgroup of $GL(\mathbb{K}^{p(\Sigma)})$. Hence there exists a $Y_i \in \mathfrak{gl}(\mathbb{K}^{p(\Sigma)})$ such that $\rho'(\exp \mu X_i) = \exp \mu Y_i$. Hence $(\exp \mu Y_i)R(s) = R(s)(\exp \mu X_i)$. Differentiating at $\mu = 0$ yields $Y_i R(s) = R(s)X_i$. The last part of (4) follows from the observation that $R(s)X_i X_j = Y_i R(s)X_j = Y_i Y_j R(s)$. Hence $R(s)[X_i, X_j] = [Y_i, Y_j]R(s)$. This shows that the vector space generated by these Y_i 's is a Lie subalgebra of $\mathfrak{gl}(\mathbb{K}^{p(\Sigma)})$ and that $X_i \mapsto Y_i$ generates a Lie algebra homomorphism. \square

7.4. Rotation symmetries.

Example 9 (rotations on \mathbb{R}^m with $m > 2$). Consider the group $SO(m)$ of real orthogonal $m \times m$ matrices with determinant 1. $SO(m)$ is a compact group, and it can be shown that, when $m \geq 3$, the canonical injection of $SO(m)$ into $GL(\mathbb{C}^m)$ (which will also be denoted as $SO(m)$) is irreducible over \mathbb{C} .

Now consider the system $\Sigma = (\mathbb{R}, (\mathbb{R}^m)^n, \mathcal{B})$. Assume that $SO(m)$ acts on $(\mathbb{R}^m)^n$ by $M \in SO(m)$, taking $\text{col}(w_1, w_2, \dots, w_n)$ into $\text{col}(Mw_1, Mw_2, \dots, Mw_n)$. Now consider the static symmetry induced by this action. To interpret this situation physically, think, for example, of $m = 3$ and of Σ as modelling the motion of n (not identical) particles in \mathbb{R}^3 under the influence of rotation invariant laws. Another possibility is to think of the situation $m = 3$ and $n = 2n'$ with Σ modelling the position and the force acting on n' particles.

Applying Theorem 5 and using the irreducibility of $SO(m)$ for $m > 2$ immediately shows that Σ will be symmetric if and only if there exists a polynomial matrix $R' \in \mathbb{R}^{n \times n}[s]$ such that Σ is represented as

$$\left(R' \left(\frac{d}{dt} \right) \otimes I_m \right) \begin{bmatrix} w_1 \\ w_2 \\ \vdots \\ w_n \end{bmatrix} = 0.$$

Example 10 (rotations on \mathbb{R}^2). The above example must be modified in the case where $m = 2$, since the canonical injection of $SO(2)$ into $GL(\mathbb{C}^2)$ is reducible over \mathbb{C} . $SO(2)$ can be written as $SO(2) \cong \rho \oplus \rho^*$ with

$$\rho \left(\begin{bmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{bmatrix} \right) = e^{i\theta}.$$

Applying Theorem 5 leads to the following representation of rotation symmetric systems for $m = 2$:

$$\begin{bmatrix} R_1 \left(\frac{d}{dt} \right) & -R_2 \left(\frac{d}{dt} \right) \\ R_2 \left(\frac{d}{dt} \right) & R_1 \left(\frac{d}{dt} \right) \end{bmatrix} \begin{bmatrix} w_1 \\ w_2 \end{bmatrix} = 0$$

with $R_1, R_2 \in \mathbb{R}^{(1/2)p(\Sigma) \times n}$.

This result can also be obtained from Theorem 6. Indeed, since $\begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix}$ generates $SO(2)$ through exponentiation, symmetry implies the existence of an R such that

$$\begin{bmatrix} 0_{(1/2)p(\Sigma)} & I_{(1/2)p(\Sigma)} \\ -I_{(1/2)p(\Sigma)} & 0_{(1/2)p(\Sigma)} \end{bmatrix} R(s) = R(s) \begin{bmatrix} 0_n & I_n \\ -I_n & 0_n \end{bmatrix},$$

where I_k and O_k denote the $k \times k$ identity and zero matrices, respectively. This also yields the above representation.

Finally, systems with this rotation symmetry can also be represented by introducing the complex signal $w := w_1 + iw_2$ with $w : \mathbb{R} \rightarrow \mathbb{C}$. The differential equation governing

$$\begin{bmatrix} w_1 \\ w_2 \end{bmatrix}$$

then becomes $R(d/dt)w = 0$ with $R \in \mathbb{C}^{(1/2)p(\Sigma) \times n}[s]$.

Example 11 (rotations over $2\pi/n$ degrees on \mathbb{R}^2). Let $G = \mathbb{Z}_n = \{0, 1, \dots, n-1\}$ (see Example 7 for notation) with $n \geq 3$. Now consider the representation ρ of G on \mathbb{R}^2 , defined by

$$\rho : k \mapsto \begin{bmatrix} \cos \frac{2\pi k}{n} & -\sin \frac{2\pi k}{n} \\ \sin \frac{2\pi k}{n} & \cos \frac{2\pi k}{n} \end{bmatrix}.$$

Then $(\mathbb{R}, \mathbb{R}^2, \mathcal{B}) \in \mathcal{L}^2$ being ρ -symmetric means symmetry in the sense of Example 10, by rotations of $2\pi/n$ degrees. This is a subgroup of $SO(2)$. Since the representation ρ is also irreducible, we immediately obtain from Theorem 5 the representation obtained in Example 10. This allows the interesting conclusion that $\Sigma \in \mathcal{L}^2$ being symmetric with respect to rotations of $2\pi/n$ degrees will imply that it is symmetric with respect to *all* rotations. The Lie algebra line of reasoning in Example 10 showed this already for $n = 4$, that is, for 90° rotations.

8. State space models. Many useful models encountered in applications involve auxiliary variables in addition to the variables that the model aims at describing. To distinguish between these two kinds of variables, we call the variables of primary interest *manifest* and denote them as w , and we call the auxiliary variables *latent*, and—usually—denote them as ℓ .

Proceeding with the terminology of [15], this leads to a *dynamical system with latent variables*, defined as $\Sigma_f = (\mathbb{T}, \mathbb{W}, \mathbb{L}, \mathcal{B}_f)$ with $\mathbb{T} \subseteq \mathbb{R}$ the *time axis*, \mathbb{W} the signal space of *manifest variables*, \mathbb{L} the signal space of *latent variables*, and $\mathcal{B}_f \subseteq (\mathbb{W} \times \mathbb{L})^{\mathbb{T}}$ the *full behavior*. Σ_f induces the *manifest* dynamical system $\Sigma = (\mathbb{T}, \mathbb{W}, \mathcal{B})$ with *manifest behavior* $\mathcal{B} = \{w \mid \text{there exists an } \ell \text{ such that } (w, \ell) \in \mathcal{B}_f\}$.

In the context of systems described by differential equations, this leads us to consider linear differential equations

$$(12) \quad R\left(\frac{d}{dt}\right)w = M\left(\frac{d}{dt}\right)\ell$$

linking the manifest variables $w \in C^\infty(\mathbb{R}, \mathbb{K}^q)$ to the latent variables $\ell \in C^\infty(\mathbb{R}, \mathbb{K}^d)$. Here $R \in \mathbb{K}^{\bullet \times q}[s]$ and $M \in \mathbb{K}^{\bullet \times d}[s]$ are two polynomial matrices with the same number of rows. Formally, (12) defines the latent variable dynamical system $(\mathbb{R}, \mathbb{K}^q, \mathbb{K}^d, \mathcal{B}_f)$

with $\mathcal{B}_f = \ker[R(d/dt) \vdash M(d/dt)]$. Obviously, $(\mathbb{R}, \mathbb{K}^{q+d}, \mathcal{B}_f) \in \mathcal{L}^{q+d}$. We will denote this class of latent variable dynamical systems as $\mathcal{L}^{q,d}$. This family of models is hence parametrized by pairs of polynomial matrices (R, M) .

This model with latent variables induces the manifest dynamical system $(\mathbb{R}, \mathbb{K}^q, \mathcal{B})$ with $\mathcal{B} = (R(d/dt))^{-1} \text{im } M(d/dt)$. It can be shown that $(\mathbb{R}, \mathbb{K}^q, \mathcal{B}) \in \mathcal{L}^q$, that is, that $(R(d/dt))^{-1} \text{im } M(d/dt)$ can itself be described as the solution set of a system of constant coefficient differential equations. In other words, there exists a polynomial matrix $R' \in \mathbb{R}^{\bullet \times q}[s]$ such that the manifest behavior of (12) is described by

$$(13) \quad R' \left(\frac{d}{dt} \right) w = 0.$$

The matrix R' can be obtained as follows. By premultiplying M by a suitable unimodular polynomial matrix U , UM can be brought in the form

$$UM = \begin{bmatrix} 0 \\ \dot{M}'' \end{bmatrix}$$

with $M'' \in \mathbb{K}^{\bullet \times d}_{fr}[s]$. Partitioning UR conformably as

$$UR = \begin{bmatrix} R' \\ \dot{R}'' \end{bmatrix}$$

yields the desired R' . The result that (13) then defines the manifest behavior of (12) follows easily from the observation that $M''(d/dt)$ is surjective (in other words, if $P \in \mathbb{R}^{n_1 \times n_2}_{fr}[s]$, then $P(d/dt) : C^\infty(\mathbb{R}; \mathbb{K}^{n_2}) \rightarrow C^\infty(\mathbb{R}; \mathbb{K}^{n_1})$ will be a surjective map).

A very useful class of systems with latent variables are the *state space systems*. In this case, the latent variables are denoted by x instead of by ℓ . In [15], [16], we have defined state space models abstractly in terms of concatenation of trajectories. For differential systems, the result is that state space systems are precisely those latent variable systems whose full behavior can be described by the following special type of differential equations linking the state trajectory $x \in C^\infty(\mathbb{R}; \mathbb{K}^n)$ to the manifest trajectory $w \in C^\infty(\mathbb{R}; \mathbb{K}^q)$:

$$(14) \quad \left(E \frac{d}{dt} + F \right) x + Hw = 0$$

with E, F, H matrices over \mathbb{K} of suitable dimension. The crucial feature of (14) is that this differential equation is first-order in x and zeroth-order in w .

Let us denote the state space systems with manifest signal space \mathbb{K}^q , and state space \mathbb{K}^n by $\mathcal{L}^{q,n}_s$. It follows that $\mathcal{L}^{q,n}_s$ is parametrized by $\mathbb{K}^{\bullet \times (2n+q)}$ by associating with the element $[E:F:H] \in \mathbb{K}^{\bullet \times (2n+q)}$ the behavioral equations (14). We denote the state space system described by (14) simply as (E, F, H) .

It follows immediately from the elimination of latent variables that the manifest behavior of $\Sigma_s \in \mathcal{L}^{q,n}_s$ leads to a system in \mathcal{L}^q . However, the converse also holds: for any $\Sigma \in \mathcal{L}^q$, i.e., for any polynomial matrix $R \in \mathbb{K}^{\bullet \times q}[s]$, there exist nonnegative integers $n, f \in \mathbb{N}_0$ and matrices $E, F \in \mathbb{K}^{f \times n}$, $H \in \mathbb{K}^{f \times q}$ such that the manifest behavior of (14) is represented by (1). If $\Sigma_s \in \mathcal{L}^{q,n}_s$ induces in this sense the system $\Sigma \in \mathcal{L}^q$, then we call Σ_s (or $(E, F, H) \in \mathbb{K}^{\bullet \times (2n+q)}$) a *state space representation* of $\Sigma \in \mathcal{L}^q$ (or of (1)). We denote this as $(E, F, H) \rightsquigarrow \Sigma$, or $(E, F, H) \rightsquigarrow R$.

Let $E, F \in \mathbb{K}^{f \times n}$, $H \in \mathbb{K}^{f \times q}$, and $(E, F, H) \rightsquigarrow \Sigma \in \mathcal{L}^q$. We call this state space system *minimal* if $(E', F' \in \mathbb{K}^{f' \times n}, H' \in \mathbb{K}^{f' \times q}$, and $(E', F', H') \rightsquigarrow \Sigma$) implies $(f \leq f'$ and $n \leq n')$. In [15], [16], it is shown that any system $\Sigma \in \mathcal{L}^q$ admits a minimal state space representation (in other words, both f and n can be simultaneously minimized). This implies that, in a minimal state representation, the number of state variables will depend on Σ , but not on the particular minimal state space representation of Σ . We denote this minimal number of state variables by $n(\Sigma)$. Similarly, $f(\Sigma)$ denotes the minimal number of equations in (14) representing Σ . It is easy to see [15] that $f(\Sigma) = n(\Sigma) + p(\Sigma)$. The following proposition play a crucial role in our proof of Theorem 3.

PROPOSITION 7. *Let $(E, F, H) \rightsquigarrow \Sigma \in \mathcal{L}^q$ be minimal. Then $(E', F', H') \rightsquigarrow \Sigma$ will also be minimal if and only if there exist $V \in GL(\mathbb{K}^{f(\Sigma)})$ and $T \in GL(\mathbb{K}^{n(\Sigma)})$ such that*

$$E' = VET, \quad F' = VFT, \quad \text{and} \quad H' = VH.$$

Finally, for given (E, F, H) and (E', F', H') , this V and T are unique.

Proof. For the proof, see [15]. \square

This proposition states that minimal representations of a given manifest behavior differ only in their choice of the basis in the state space and in the equation space.

THEOREM 8. *Let $\rho : G \rightarrow GL(\mathbb{K}^q)$ be a representation of the compact group G on \mathbb{K}^q . Let $\Sigma \in \mathcal{L}^q$ and let $\Sigma_s \cong (E, F, H) \in \mathcal{L}^{q,n}$ be a minimal state space representation of Σ . Then Σ is ρ -symmetric if and only if there exist representations $\rho' : G \rightarrow GL(\mathbb{K}^{n(\Sigma)})$ and $\rho'' : G \rightarrow GL(\mathbb{K}^{f(\Sigma)})$ such that*

$$(15) \quad \rho''E = E\rho', \quad \rho''F = F\rho', \quad \text{and} \quad \rho''H = H\rho.$$

Proof. The “if” part is clear. To see the “only if” part, observe that $(E, F, H\rho_g)$ is also a minimal state space representation of Σ . By Proposition 7, this implies that there exist $V_g \in GL(\mathbb{K}^{f(\Sigma)})$ and $T_g \in GL(\mathbb{K}^{n(\Sigma)})$ such that $E = V_gET_g$, $F = V_gFT_g$, and $H\rho_g = V_gH$. Define $\rho' : g \mapsto V_g$ and $\rho'' : g \mapsto (T_g)^{-1}$. We claim that ρ' and ρ'' are also representations of G . In fact, from the uniqueness condition in Proposition 7, it follows immediately that $V_{g_1g_2} = V_{g_1}V_{g_2}$ and $(T_{g_1g_2})^{-1} = (T_{g_1})^{-1}(T_{g_2})^{-1}$. \square

9. Canonical forms for state space models of symmetric systems. We now use Theorem 8 and the ideas of §6 to obtain canonical forms for state space systems. It is convenient to distinguish again between the complex case where $\mathbb{K} = \mathbb{C}$ and the real case where $\mathbb{K} = \mathbb{R}$.

9.1. Complex state space systems. Write the representations ρ, ρ' , and ρ'' of Theorem 8 in terms of irreducible representations as

$$\begin{aligned} \rho &\cong m_1\rho_1 \oplus m_2\rho_2 \oplus \cdots \oplus m_k\rho_k, \\ \rho' &\cong m'_1\rho_1 \oplus m'_2\rho_2 \oplus \cdots \oplus m'_k\rho_k, \\ \rho'' &\cong m''_1\rho_1 \oplus m''_2\rho_2 \oplus \cdots \oplus m''_k\rho_k. \end{aligned}$$

Now choose a ρ -adapted basis in the manifest signal space \mathbb{C}^q , a ρ' -adapted basis in the state space $\mathbb{C}^{n(\Sigma)}$, and a ρ'' -adapted basis in the equation space $\mathbb{C}^{f(\Sigma)}$. Now apply Schur’s lemma to (15). This yields that, in these bases E, F , and H will take the

form

$$\begin{aligned} E &= \text{diag}(E_1 \otimes I_{n_1}, E_2 \otimes I_{n_2}, \dots, E_k \otimes I_{n_k}), \\ F &= \text{diag}(F_1 \otimes I_{n_1}, F_2 \otimes I_{n_2}, \dots, F_k \otimes I_{n_k}), \\ H &= \text{diag}(H_1 \otimes I_{n_1}, H_2 \otimes I_{n_2}, \dots, H_k \otimes I_{n_k}). \end{aligned}$$

This yields the following result.

THEOREM 9. *Let G be a compact group and let $\rho : GL(\mathbb{C}^q)$ be a representation of G on \mathbb{C}^q . Assume that $\rho \cong m_1\rho_1 \oplus m_2\rho_2 \oplus \dots \oplus m_k\rho_k$ with $\rho_i : G \rightarrow GL(\mathbb{C}^{n_i})$, $i = 1, 2, \dots, k$, distinct irreducible representations. Assume that the basis in \mathbb{C}^q is ρ -adapted, as in Theorem 4. Then $\Sigma = (\mathbb{R}, \mathbb{C}^q, \mathcal{B}) \in \mathcal{L}^q$ is ρ -symmetric if and only if there exist $m'_i, m''_i \in \mathbb{Z}_+$ and matrices $E_i, F_i \in \mathbb{C}^{m'_i \times m'_i}, H_i \in \mathbb{C}^{m''_i \times m_i}$ such that Σ admits the minimal state space representation of the form*

$$(16) \quad \left(\left(E_i \frac{d}{dt} + F_i \right) \otimes I_{n_i} \right) x_i + (H_i \otimes I_{n_i}) \tilde{w}_i = 0, \quad i = 1, 2, \dots, k$$

with \tilde{w} as in Theorem 4, and where $x_i : \mathbb{R} \rightarrow (\mathbb{C}^{n_i})^{m'_i}$, $x = \text{col}(x_1, x_2, \dots, x_k)$, is the state trajectory.

9.2. Real state space systems. To obtain a canonical form for real symmetric state space systems, we proceed in complete analogy to §6.2. By considering the components of real, complex, and quaternionic type in the decomposition of ρ , the following result is obtained.

THEOREM 10. *Let G be a compact group and let $\rho : G \rightarrow GL(\mathbb{R}^q)$ be a representation of G on \mathbb{R}^q . Assume that ρ is decomposed as in (8) and that the basis in \mathbb{R}^q is ρ -adapted, as in Theorem 5. Then $\Sigma = (\mathbb{R}, \mathbb{R}^q, \mathcal{B}) \in \mathcal{L}^q$ is ρ -symmetric if and only if there exist*

$$m'_{\mathbb{R},i}, m'_{\mathbb{C},i}, m'_{\mathbb{H},i}, m''_{\mathbb{R},i}, m''_{\mathbb{C},i}, m''_{\mathbb{H},i} \in \mathbb{Z}_+$$

and matrices

$$E_{\mathbb{R},i}, F_{\mathbb{R},i} \in \mathbb{R}^{m'_{\mathbb{R},i} \times m'_{\mathbb{R},i}}, H_{\mathbb{R},i} \in \mathbb{R}^{m''_{\mathbb{R},i} \times m_{\mathbb{R},i}};$$

$$E_{\mathbb{C},i}, F_{\mathbb{C},i} \in \mathbb{C}^{m'_{\mathbb{C},i} \times m'_{\mathbb{C},i}}, H_{\mathbb{C},i} \in \mathbb{C}^{m''_{\mathbb{C},i} \times m_{\mathbb{C},i}};$$

$$E_{\mathbb{H},i}, F_{\mathbb{H},i} \in \mathbb{H}^{m'_{\mathbb{H},i} \times m'_{\mathbb{H},i}}, H_{\mathbb{H},i} \in \mathbb{C}^{m''_{\mathbb{H},i} \times m_{\mathbb{H},i}},$$

such that Σ admits a minimal state space representation of the form

$$(17) \quad \begin{aligned} &\left(\left(E_{\mathbb{R},i} \frac{d}{dt} + F_{\mathbb{R},i} \right) \otimes I_{n_{\mathbb{R},i}} \right) x_{\mathbb{R},i} + (H_{\mathbb{R},i} \otimes I_{n_{\mathbb{R},i}}) \tilde{w}_{\mathbb{R},i} = 0, \quad i = 1, 2, \dots, k_{\mathbb{R}}, \\ &\left(\left(E_{\mathbb{C},i} \frac{d}{dt} + F_{\mathbb{C},i} \right) \otimes I_{n_{\mathbb{C},i}} \right) x_{\mathbb{C},i} + (H_{\mathbb{C},i} \otimes I_{n_{\mathbb{C},i}}) \tilde{w}_{\mathbb{C},i} = 0, \quad i = 1, 2, \dots, k_{\mathbb{C}}, \\ &\left(\left(E_{\mathbb{H},i} \frac{d}{dt} + F_{\mathbb{H},i} \right) \otimes I_{n_{\mathbb{H},i}} \right) x_{\mathbb{H},i} + (H_{\mathbb{H},i} \otimes I_{n_{\mathbb{H},i}}) \tilde{w}_{\mathbb{H},i} = 0, \quad i = 1, 2, \dots, k_{\mathbb{H}} \end{aligned}$$

with \tilde{w} as in Theorem 5, and where $x = \text{col}(x_{\mathbb{R}}, x_{\mathbb{C}}, x_{\mathbb{H}})$ is the state trajectory;

$$x_{\mathbb{R}} = \text{col}(x_{\mathbb{R},1}, x_{\mathbb{R},2}, \dots, x_{\mathbb{R},k_{\mathbb{R}}}), \quad \text{with } x_{\mathbb{R},i} : \mathbb{R} \rightarrow (\mathbb{R}^{n_{\mathbb{R},i}})^{m'_{\mathbb{R},i}};$$

$$x_{\mathbb{C}} = \text{col}(x_{\mathbb{C},1}, x_{\mathbb{C},2}, \dots, x_{\mathbb{C},k_{\mathbb{C}}}), \quad \text{with } x_{\mathbb{C},i} : \mathbb{R} \rightarrow (\mathbb{C}^{n_{\mathbb{C},i}})^{m'_{\mathbb{C},i}};$$

$$x_{\mathbb{H}} = \text{col}(x_{\mathbb{H},1}, x_{\mathbb{H},2}, \dots, x_{\mathbb{H},k_{\mathbb{H}}}), \quad \text{with } x_{\mathbb{H},i} : \mathbb{R} \rightarrow (\mathbb{H}^{n_{\mathbb{H},i}})^{m'_{\mathbb{H},i}}.$$

10. Proof of Theorem 3.

10.1. The complex case. As already shown in §6, it suffices to prove that, if $\Sigma = (\mathbb{R}, \mathbb{C}^q, \mathcal{B}) \in \mathcal{L}^q$ is ρ -symmetric, then it allows a minimal representation, as given in Theorem 4. By Theorem 9, it allows a minimal state space representation as (16). Now consider in the i th equation of (16), x_i as a latent variable. Using the elimination of latent variables procedure as explained in the beginning of §8, we can conclude that the i th equation of (16) constrains \tilde{w}_i to satisfy an equation of the form $(\Lambda_i (d/dt) \otimes I_{n_i})\tilde{w}_i = 0$. This yields the i th representation of (7) and results in the desired representation of Theorem 4.

10.2. The real case. For the real case, we can use this elimination of latent variables procedure unchanged for each of the real and complex equations in (17). These will yield the corresponding real, respectively complex, term in (11) of Theorem 5. However, the quaternionic equations in (17) require separate attention, since the quaternions \mathbb{H} do not form a field. This brings us to the following algebraic excursion.

Let \mathcal{R} be a ring with an identity. Let $\mathcal{R}[s]$ denote the ring of polynomials with coefficients in \mathcal{R} , and $\mathcal{R}^{n_1 \times n_2}[s]$ the $n_1 \times n_2$ matrices with elements in $\mathcal{R}[s]$. Furthermore, let $GL(n, \mathcal{R}[s])$ denote the group of units of the ring $\mathcal{R}^{n \times n}[s]$, i.e., the set of polynomial matrices over \mathcal{R} with a polynomial inverse. We call these matrices unimodular. Now consider the problem of bringing a given element $P \in \mathcal{R}^{n_1 \times n_2}[s]$ into a convenient canonical form by premultiplying it by a suitable element $U_1 \in GL(n_1, \mathcal{R}[s])$ and postmultiplying it by a suitable element $U_2 \in GL(n_2, \mathcal{R}[s])$. We will say that P can be brought in *diagonal form* if there exist such U_1, U_2 yielding for $U_1 P U_2$ a matrix of the form

$$U_1 P U_2 = \begin{bmatrix} D & \vdots & 0 \\ \cdots & \ddots & \cdots \\ 0 & \vdots & 0 \end{bmatrix},$$

with D a diagonal polynomial matrix. It is well known that any P can be brought in diagonal form if $\mathcal{R} = \mathbb{R}$ or \mathbb{C} .

For what rings \mathcal{R} such a diagonalization is possible? We now show that it is sufficient for \mathcal{R} to be a division ring. Recall that a ring is a *division ring* (also called a *skew field*) if its nonzero elements form a group (\mathcal{R} must contain an identity distinct from the zero, and $a \neq 0$ must imply that it is a unit of \mathcal{R} (i.e., it has an inverse $a^{-1} \in \mathcal{R}$)).

LEMMA 11. *Let \mathcal{R} be a division ring. Then each $P \in \mathcal{R}^{n_1 \times n_2}[s]$ can be brought in diagonal form.*

Proof. The proof is an adaption of the case of a skew field of the proof of the Smith form for real or complex polynomial matrices as given in [3].

If $P = 0$, there is nothing to prove. Otherwise, let P_{kl} be the element of P of least degree. By permuting rows and columns we can assume that this element is in $(1, 1)$ entry. Now assume that the $(1, 2)$ entry is also nonzero. Then divide P_{12} by P_{11} with remainder, yielding $P_{12} = P_{11}d + r$ with degree $r < \text{degree } P_{11}$. Now postmultiply with the unimodular matrix

$$\begin{bmatrix} 1 & -d & 0 & \cdots & 0 \\ 0 & 1 & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \end{bmatrix}.$$

This replaces the element P_{12} by r . If $r \neq 0$, move it to the $(1, 1)$ position. Repeat this process for each element of the first row and first column (using the division with remainder $P_{21} = dP_{11} + r$ and premultiplication). Each time the division is carried out with a nonzero remainder, the degree of the $(1, 1)$ element must decrease. Hence after a finite number of steps, we will obtain a matrix of the form

$$\begin{bmatrix} * & 0 & 0 & \cdots & 0 \\ 0 & * & * & \cdots & * \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & * & * & \cdots & * \end{bmatrix},$$

and we obtain the lemma by induction. \square

Now consider the ring \mathbb{H} of quaternions over \mathbb{R} : expressions of the type $\alpha + i\beta + j\gamma + k\delta$ with $\alpha, \beta, \gamma, \delta \in \mathbb{R}$ and i, j, k elements satisfying the multiplication rules as in Example 8. With the obvious rules of addition and multiplication, \mathbb{H} is a ring. However, \mathbb{H} is not commutative, but it is easy to see that it is a division ring. Hence a polynomial matrix $P \in \mathbb{H}^{n_1 \times n_2}[s]$ can be brought in diagonal form.

Now consider a system of differential equations.

$$(18) \quad R \left(\frac{d}{dt} \right) w = M \left(\frac{d}{dt} \right) \ell,$$

where $w \in C^\infty(\mathbb{R}; \mathbb{H}^q)$, $\ell \in C^\infty(\mathbb{R}; \mathbb{H}^d)$, $R \in \mathbb{H}^{f \times q}[s]$, and $M \in \mathbb{H}^{f \times d}[s]$. Note that this is a differential equation with latent variables as (12) but in which the signals and coefficients take their values in the skew field of quaternions \mathbb{H} . We would like to eliminate the latent variables in (19), using only operations in \mathbb{H} .

Observe that the manifest behavior of (19) remains invariant if we replace R with $U_1 R$ and M with $U_1 M U_2$ with U_1 and U_2 both unimodular polynomial matrices with coefficients in \mathbb{H} . By Lemma 11, U_1 and U_2 can be chosen such that

$$U_1 M U_2 = \begin{bmatrix} 0 \\ \cdot \\ D \end{bmatrix}$$

with $D = \text{diag}(d_1, d_2, \dots, d_r)$ and $0 \neq d_i \in \mathbb{H}[s]$. Denote the conformable partition of $U_1 R$ by

$$U_1 R = \begin{bmatrix} R' \\ \cdot \\ \ddot{R}'' \end{bmatrix}.$$

Now observe that, if $0 \neq d \in \mathbb{H}[s]$, then the operator $d(d/dt) : C^\infty(\mathbb{R}; \mathbb{H}) \rightarrow C^\infty(\mathbb{R}; \mathbb{H})$ is surjective. To see this, it suffices to write this as a differential operator from $C^\infty(\mathbb{R}; \mathbb{R}^4)$ into itself and use the fact that the corresponding (4×4) polynomial matrix with real coefficients has a nonzero determinant.

This implies that the manifest behavior of (19) is governed by

$$(19) \quad R' \left(\frac{d}{dt} \right) w = 0.$$

Applying this elimination result to each of the quaternionic equations in (17) yields the corresponding quaternionic equations in (11).

This establishes that Theorem 10 yields the desired representation of Theorem 5.

11. Group representations in $GL(n, \mathbb{K}[s])$. Theorem 3 implies an interesting result about abstract group representations. A mapping $\rho : G \rightarrow GL(n, \mathbb{K}[s])$ (the unimodular $n \times n$ polynomial matrices over \mathbb{K}), which is a group homomorphism and continuous (in the sense that the map $g \in G \mapsto \rho_g(\lambda) \in GL(\mathbb{K}^n)$ is continuous for each fixed $\lambda \in \mathbb{K}$ and the map $\lambda \in \mathbb{K} \mapsto \rho_g(\lambda) \in GL(\mathbb{K}^n)$, is continuous uniformly in $g \in G$), is called a *representation of G on $GL(n, \mathbb{K}[s])$* . Two such representations ρ_1 and ρ_2 are said to be *isomorphic* if there exist a $U \in GL(n, \mathbb{K}[s])$ such that $\rho_{2,g}(s) = U(s)\rho_{1,g}(s)(U(s))^{-1}$. The representation ρ is said to be a *constant representation* if $\rho_g(s)$ is actually a constant matrix for all $g \in G$, that is, if $\rho : G \rightarrow GL(\mathbb{K}^n)$, if ρ is actually a representation of G on \mathbb{K}^n . We now show that Theorem 3 implies that *every* representation of G on $GL(n, \mathbb{K}[s])$ is isomorphic to a *constant* one. This result can be deduced from [7], where a more general theorem is proved using very different methods. Our proof, which, as we have seen, relies on the state space representation of dynamical systems in \mathcal{L}^q , provides a nice alternative “*system theoretic*” proof of this result in the theory of algebraic groups. On the other hand, we also note that Theorem 3 can be easily deduced directly from Corollary 12 (and hence from [7]). Hence Theorem 3 and Corollary 12 are fully equivalent.

COROLLARY 12. *Let $GL(n, \mathbb{K}[s])$ denote the group of unimodular $n \times n$ polynomial matrices over \mathbb{K} ($= \mathbb{R}$ or \mathbb{C}). Let G be a compact group and let $\rho : G \rightarrow GL(n, \mathbb{K}[s])$ be a representation of G on $GL(n, \mathbb{K}[s])$. Then ρ is isomorphic to a constant representation.*

Proof. 1) Consider, for each $\lambda \in \mathbb{K}$, the mapping $\rho^\lambda : G \rightarrow GL(\mathbb{K}^n)$ defined by $\rho_g^\lambda := \rho_g(\lambda)$. It is easy to see that ρ^λ is a representation of G on \mathbb{K}^n . We first prove that all the representations ρ^λ are isomorphic. It is well known that two representations of G on \mathbb{K}^n are isomorphic if and only if their characters are equal. Hence it suffices to prove that the characters $X_{\rho^\lambda} : G \rightarrow \mathbb{K}$, defined by $X_{\rho^\lambda}(g) := \text{Trace}(\rho_g(\lambda))$, are independent of $\lambda \in \mathbb{K}$. Let $\rho^\lambda \cong m_1^\lambda \rho_1 \oplus m_2^\lambda \rho_2 \oplus \cdots \oplus m_k^\lambda \rho_k \oplus \cdots$ be a decomposition of ρ^λ in terms of irreducible representations. We prove that m_k^λ is independent of λ . Now m_k^λ is given by $m_k^\lambda = \langle \chi_{\rho^\lambda}, \chi_{\rho_k} \rangle := \int_G \chi_{\rho^\lambda} \chi_{\rho_k}^* dg$, where dg is the normalized Haar measure [9] of G . This implies that m_k^λ is continuous as a function of λ for $\lambda \in \mathbb{K}$. However, since m_k^λ is integer-valued, m_k^λ must therefore be constant for $\lambda \in \mathbb{K}$. This shows that all the ρ^λ 's are isomorphic.

2) The first part of the proof yields the existence of a map $M : \mathbb{K} \rightarrow GL(\mathbb{K}^n)$ such that

$$(20) \quad \rho_g(\lambda)M(\lambda) = M(\lambda)\rho_g(0)$$

for all $\lambda \in \mathbb{K}$ and $g \in G$. We now show that this implies the existence of a polynomial matrix $R \in \mathbb{K}^{n \times n}[s]$ with $\det R \neq 0$ such that

$$(21) \quad \rho_g(s)R(s) = R(s)\rho_g(0)$$

for all $g \in G$. In other words, we show that the set of equations

$$(22) \quad \rho_g(s)X(s) = X(s)\rho_g(0), \quad g \in G$$

has a polynomial solution $X \in \mathbb{K}^{n \times n}[s]$ with $\det X \neq 0$. Note that we can rewrite (22) in vector-matrix notation as

$$(23) \quad A_g(s)x(s) = 0, \quad g \in G$$

with $x \in \mathbb{K}^{n^2}[s]$ and $A_g \in \mathbb{K}^{n^2 \times n^2}[s]$. The vector x corresponds to the elements of X in (22), while the matrix A_g corresponds to the coefficients of the linear equations in (22). Since (23) must be satisfied for each $g \in G$, there are, in principle, an infinite number of linear equations in (23). Now consider the rows of the matrices A_g and view them as vectors of rational functions, as elements of $\mathbb{K}^{1 \times n^2}(s)$. Write (23) as

$$\begin{bmatrix} A'(s) \\ \vdots \\ A''(s) \end{bmatrix} x(s) = 0$$

with A' such that its rows form a basis over $\mathbb{K}(\sim)$ for the span of the rows of all the matrices A_g , $g \in G$. Now observe that, by premultiplying x and A' by a unimodular matrix, we may as well assume that A' is in Smith form, as follows:

$$A'(s) = [D(s) \vdots 0]$$

with $D(s) = \text{diag}(d_1(s), d_2(s), \dots, d_k(s))$ and $d_i \neq 0$ for $i = 1, 2, \dots, k$. This yields that in a conformable partition A'' will be of the form $A''(s) = [\tilde{A}''(s) \vdots 0]$. Obviously, this implies that each vector polynomial

$$x(s) = \text{col}(x_1(s), \dots, x_k(s), x_{k+1}(s), \dots, x_{n^2}(s))$$

with $x_1 = x_2 = \dots = x_k = 0$ yields a solution $X(s)$ of (23).

To show that there is at least one of these solutions with $\det X \neq 0$, we will use (20). This equation yields, for each $\lambda \in \mathbb{K}$, a solution $m(\lambda)$ to (23) with, in (23), s replaced by λ . Pick a $\tilde{\lambda} \in \mathbb{K}$ such that $d_i(\tilde{\lambda}) \neq 0$ for $i = 1, 2, \dots, k$. Clearly, $m(\tilde{\lambda})$ must be of the form $\text{col}(0, \dots, 0, \tilde{m}_{k+1}, \dots, \tilde{m}_{n^2})$. Now pick a solution $x(s)$ of (23) such that $x(\tilde{\lambda}) = m(\tilde{\lambda})$. The solution $X(s)$ of (22) thus obtained will have $X(\tilde{\lambda}) = M(\tilde{\lambda})$, whence $\det X \neq 0$. This shows that (21) has a solution with $\det R \neq 0$.

3) Now consider the dynamical system $\Sigma = (\mathbb{R}, \mathbb{K}^n, \ker R(d/dt))$. Obviously, by (21), Σ is $\rho(0)$ -symmetric, and $R(d/dt)w = 0$ is a minimal representation of Σ . By Theorem 3, there exists a $U \in GL(n, \mathbb{K}[s])$ and a representation $\rho' : G \rightarrow GL(\mathbb{K}^n)$ such that

$$(24) \quad \rho'_g U(s) R(s) = U(s) R(s) \rho_g(0)$$

for all $g \in G$. Comparing (21) and (24) yields

$$\rho_g(s) = (U(s))^{-1} \rho'_g U(s),$$

which is the claim of the corollary. \square

Remark. Let $\rho : G \rightarrow GL(q, \mathbb{K}[s])$ be a representation of G on $GL(q, \mathbb{K}[s])$. Let $\Sigma = (\mathbb{R}, \mathbb{K}^q, \mathcal{B}) \in \mathcal{L}^q$ be ρ -symmetric, meaning that $\rho_g(d/dt)\mathcal{B} = \mathcal{B}$ for all $g \in G$. Note that this is a dynamic symmetry, in contrast (see §3.3) with the static symmetries studied in this paper. However, Corollary 12 shows that, by a dynamic change of variables $w \mapsto U(d/dt)w$, with U a suitable unimodular polynomial matrix, the study of this type of dynamic symmetry reduces to a static symmetry.

LANGUAGE STABILITY AND STABILIZABILITY OF DISCRETE EVENT DYNAMICAL SYSTEMS*

RATNESH KUMAR[†], VIJAY GARG[‡], AND STEVEN I. MARCUS[§]

Abstract. This paper studies the stability and stabilizability of discrete event dynamical systems (DEDSs) modeled by state machines. Stability and stabilizability are defined in terms of the behavior of the DEDSs, i.e. the language generated by the state machines (SMs). This generalizes earlier work where they were defined in terms of legal and illegal states rather than strings. The notion of reversal of languages is used to obtain algorithms for determining the stability and stabilizability of a given system. The notion of stability is then generalized to define the stability of infinite or sequential behavior of a DEDS modeled by a Büchi automaton. The relationship between the stability of finite and stability of infinite behavior is obtained and a test for stability of infinite behavior is obtained in terms of the test for stability of finite behavior. An algorithm of linear complexity for computing the regions of attraction is presented, which is used for determining the stability and stabilizability of a given system defined in terms of legal states. This algorithm is then used to obtain efficient tests for checking sufficient conditions for language stability and stabilizability.

1. Introduction. Ramadge and Wonham in their work [21] on supervisory control of discrete event dynamical systems (DEDS) have modeled a DEDS, also called a plant, by a state machine (SM), the event set of which is finite and is partitioned into sets of controllable and uncontrollable events. The language generated by such a SM is used as a model to describe the behavior of the plant at the logical level. The control task is to synthesize a controller, also called a supervisor, which disables some of the controllable events in the plant so that the closed-loop behavior equals some prespecified desired behavior, also called legal behavior. Supervisors that do not prevent any uncontrollable events from occurring are called complete. Thus there may not always exist a complete supervisor so that the closed loop system has a prespecified desired behavior. Attention is then restricted to designing a complete supervisor that is *minimally restrictive* [21], [20], [10], [1], [11] so that the closed-loop system can engage in some maximal behavior and still maintain the prescribed behavioral constraint. Thus the control objective is usually described as the synthesis of a minimally restrictive supervisor so that the controlled system has a maximally permissive legal behavior.

Sometimes such a constraint on the system behavior leads to the design of a supervisor which results in a very restrictive behavior [14], [15]. Recently there has been work [14], [15] on posing a supervisory control problem that allows the system to engage in some illegal behavior that can be tolerated. In this paper, we also allow the

possibility of the system behaving illegally. The supervisor is synthesized so that the behavior of the supervised system is “asymptotically legal.” In other words, the system is initially allowed to make illegal transitions, but after a finite number of transitions, the supervised system makes only legal transitions. With the above motivation, we define the stability and stabilizability of DEDSs in terms of their legal behavior.

In [16], [18], [2], [4], [3] the notion of stability and stabilizability of DEDS's has been presented in terms of the legal and illegal states of the system. In [2], [3] a stable system is one that starts from any arbitrary initial state and, after finitely many transitions, goes to one of the legal states and stays there; a stabilizable system is one for which there exists a supervisor so that the supervised system is stable. In [18] a system is said to be stable if after starting from any arbitrary initial state it visits the legal subset of states infinitely often; a system that can be made stable in the above context by the synthesis of an appropriate supervisor is called stabilizable. We define a system to be language-stable¹ if its eventual behavior remains confined to the legal behavior; if a supervisor exists such that the supervised system is language-stable, then the system is called language-stabilizable. We show below that the existence of an eventually reachable legal set of states implies the existence of an eventually reachable legal behavior, whereas the converse is not always true. Thus the notion of stability presented here is finer than those in [18], [2], [3] in the sense that there need not exist any fixed set of legal states. A state can eventually be reached by legal as well as illegal strings, so none of the states can be predefined to be legal. To illustrate this point consider, for example, an elevator which moves between three floors—bottom, middle, and top. Assume that a passenger requests service at the top floor. We can view the top floor to be the legal state and require that the elevator should eventually reach it. However, a “finer” constraint that the elevator should reach the top floor in no more than two moves (there are total three floors) may be desired. In this case the top floor may be reached by legal as well as illegal sequences of moves of the elevator. Thus in this example the stability based on legal states cannot capture the desired behavior of the elevator.

In [18], [2], [3], the supervisors considered for stabilizing a system are assumed to be of *static feedback* type in which the next control action is determined by the current state of the system. In general a supervisor can be of *dynamic feedback* type where the next control action is determined not necessarily by the current state but by the “path” taken to reach the current state. We refine the notion of stability and stabilizability by defining it in terms of languages rather than states and show that in some cases a static feedback-type supervisor cannot stabilize a system and a more general dynamic feedback type supervisor is needed for stabilization. In [16], the stability of systems under partial observation is studied. In this case, the supervisor is of dynamic feedback type; it can be represented as a cascade of a dynamic state observer followed by a static feedback-type controller. The supervisor considered for eventually restrictable systems in [17] is also of dynamic feedback type.

We start with the description of DEDSs and present some of the notions of stability defined in terms of states. The computational complexity of the algorithms presented in [2], [3] for determining the stability and stabilizability of DEDSs based on computing the *regions of attraction* is quadratic in the number of states of the system. We present an algorithm that is linear in the number of states of the system and is thus computationally more efficient. We then introduce the notion of

¹ We use the term language-stability to emphasize the fact that it is defined in terms of legal behavior rather than legal states, in which case it may be called state-stability.

stability in terms of languages and provide algorithms for determining the stability and stabilizability of a given system by considering an equivalent problem defined in terms of *reversal* of languages. We also discuss the computational complexity of these algorithms. Later, we provide computationally more efficient algorithms for testing the sufficiency of stability and stabilizability of systems based on our algorithm for computing the regions of attraction. In all this, we assume that perfect observation of the system behavior is possible so that the control actions are determined on the basis of observing the system evolution perfectly. We also introduce a weaker notion of language stability that is preserved under union and provide a technique for constructing the minimally restrictive stabilizing supervisor in this weaker sense of language stability.

The notion of language stability is then generalized to study the stability of sequential behaviors of DEDSs modeled by Büchi automata. The notions of ω -stability and ω -stabilizability are introduced in this context, and tests for verifying stability and stabilizability of sequential behavior are obtained by reducing the problem of testing them to the problem of testing language stability. We introduce an equivalence relation on the space of infinite strings and obtain a necessary condition of ω -stability in terms of this equivalence relation.

2. Notation and terminology. A DEDS to be controlled, called a *plant*, is modeled as a deterministic trim [8] state machine (SM) following the framework of [21]. Let the quintuple

$$P \stackrel{\text{def}}{=} (X, \Sigma, \alpha, x_0, X_m)$$

denote an SM representing a plant, where X denotes the state set; Σ denotes the finite event or alphabet set; $\alpha : \Sigma \times X \rightarrow X$ denotes the partial state transition function; $x_0 \in X$ denotes the initial state; and $X_m \subseteq X$ denotes the set of marked states. The transition function $\alpha(\cdot, \cdot)$ is extended to $\Sigma^* \times X$ in the natural way, where Σ^* denotes the set of all finite sequences of events belonging to Σ . The notation $\epsilon \in \Sigma^*$ is used to denote the empty string. The behavior of P is described by the language $L(P) \subseteq \Sigma^*$ that it *generates* and $L_m(P) \subseteq L(P)$ that it *marks* or *recognizes*. Formally,

$$L(P) = \{s \in \Sigma^* \mid \alpha(s, x_0)!\}; L_m(P) = \{s \in L(P) \mid \alpha(s, x_0) \in X_m\},$$

where the notation “!” is used to denote “is defined.” By definition, $L(P)$ is prefix-closed and also, since P is trim, $\overline{L_m(P)} = L(P)$ [8].

The event set is partitioned into $\Sigma = \Sigma_u \cup \Sigma_c$, the set of *uncontrollable* and *controllable* events. A supervisor S for controlling a plant is another DEDS, also represented as an SM,

$$S \stackrel{\text{def}}{=} (Y, \Sigma, \beta, y_0, Y_m).$$

S operates synchronously with P , thus allowing only the synchronous transitions to occur in the closed-loop system described by the SM [10], [11]

$$P \square S \stackrel{\text{def}}{=} (Z, \Sigma, \gamma, z_0, Z_m).$$

where $z_0 = (x_0, y_0)$; for $s \in \Sigma^*$, $\gamma : \Sigma^* \times Z \rightarrow Z$ is defined as $\gamma(s, z_0) = (\alpha(s, x_0), \beta(s, y_0))$ if $\alpha(s, x_0)!$ and $\beta(s, y_0)!$, undefined otherwise; $Z = \{z \in X \times Y \mid \exists s \in \Sigma^* \text{ s.t. } \gamma(s, z_0) = z\}$; and $Z_m = Z \cap (X_m \times Y_m)$. Thus $Z \subseteq X \times Y$ is the set of states that are reachable

from the initial state z_0 , and $Z_m \subseteq Z$ is the set of those reachable states that have both their “coordinates” marked.

The following remark describes the control achieved by the synchronous operation of P and S .

Remark 2.1 ([11], [10]). Let $L(P \square S)$ be the language generated and $L_m(P \square S)$ the language marked by $P \square S$; then $L(P \square S) = L(P) \cap L(S)$, and $L_m(P \square S) = L_m(P) \cap L_m(S)$, where $L(S), L_m(S)$ denote the languages generated, recognized by S , respectively.

Also, since S can disallow only the controllable events from occurring, $L(P) \cap \Sigma_u^* \subseteq L(P \square S)$, where Σ_u^* is the set of finite sequences of events belonging to Σ_u .

The supervisor as defined above represents a closed-loop control policy. This differs from open-loop control policy in which control actions are all prespecified; in closed-loop control, control actions are determined by observing all or part of the history of the system evolution.

DEFINITION 2.2. Let the map $f : L(P) \rightarrow 2^\Sigma$ denote a *control policy* as described in [21], i.e., for each string $s \in L(P)$ generated by the plant P , $f(s) \subseteq \Sigma$ is the set of events that are not disabled by a supervisor. Then the control exercised by the synchronous operation of a supervisor and the plant, as described above, defines the following control policy over the set of strings generated by the plant:

$$f(s) \stackrel{\text{def}}{=} \begin{cases} \{\sigma \in \Sigma \mid \gamma(s\sigma, z_0)!\} & \text{if } \gamma(s, z_0)! \\ \text{undefined} & \text{otherwise,} \end{cases}$$

where the string $s \in L(P)$.

Closed-loop controllers can further be classified into static and dynamic control type. Given a deterministic SM, $V \stackrel{\text{def}}{=} (Q, \Sigma, \delta, q_0, Q_m)$, there is a natural equivalence relation R_V [8], [6], [11], [10] induced by V on Σ^* , which is defined by $s \cong t(R_V) \Leftrightarrow \delta(s, q_0) = \delta(t, q_0)$ (this is meant to include the condition that $\delta(s, q_0)$ is undefined $\Leftrightarrow \delta(t, q_0)$ is undefined), where $s, t \in \Sigma^*$. Thus all those strings, which upon execution result in the same state in V , belong to the same equivalence class. We use $[s](R_V)$ to denote the equivalence class under the equivalence relation R_V containing the string s .

DEFINITION 2.3. Consider the control policy $f : L(P) \rightarrow 2^\Sigma$ defined by the synchronous composition operator as described in Definition 2.2. We say that a closed-loop control policy is *static* if $s \cong t(R_P) \Rightarrow f(s) = f(t)$ whenever both $f(s), f(t)$ are defined.

In other words, in a static feedback-type control, the same control action is applied after the execution of all strings that lead to the same state in the plant. Next we show that if a supervisor exercises a static closed-loop control, then it can be represented as an SM having structure similar to that of the plant.

DEFINITION 2.4. Let $V_1 \stackrel{\text{def}}{=} (Q_1, \Sigma, \delta_1, q_{01}, Q_{m1})$ and $V_2 \stackrel{\text{def}}{=} (Q_2, \Sigma, \delta_2, q_{02}, Q_{m2})$ be two SMs. V_1 is said to be a *subautomaton* [5] of V_2 if there exists a one-to-one map $h : Q_1 \rightarrow Q_2$ such that $h(\delta_1(s, q_{01})) = \delta_2(s, q_{02})$ for each $s \in L(V_1)$.

Thus if V_1 is a subautomaton of V_2 , then $L(V_1) \subseteq L(V_2)$. Note that if the map h in Definition 2.3 is also onto, then V_1 and V_2 are structurally identical.

PROPOSITION 2.5 ([9]). *The following are true:*

1. *If S is a subautomaton of P , then the control policy $f : L(P) \rightarrow 2^\Sigma$ defined by S is static.*
2. *If $f : L(P) \rightarrow 2^\Sigma$ is a static control policy, then there exists S that defines the same control policy as f and is a subautomaton of P .*

DEFINITION 2.6. A closed-loop control policy is said to be *dynamic* if it is not static.

Example 2.7. Consider, for example, a plant P , with language $L(P) = (a + b)^*$ defined over the event set $\Sigma = \{a, b\}$. Assume that $\Sigma_c = \Sigma$ (see Fig. 1; “○” denotes the states, an entering arrow “ \rightarrow ” to “○” represents the initial state, and “○” denotes the marked states). Then the language generated by the coupled system under

FIG. 1. Diagram illustrating Example 2.7

a static feedback control policy could be one of the following: $L(P \square S) = (a + b)^*$ or a^* or b^* or ϵ , depending on whether the events disabled in the only state of the system are \emptyset , $\{b\}$, $\{a\}$, or $\{a, b\}$.

On the other hand, the language marked by the coupled system can be made to be any sublanguage $K \subseteq (a + b)^*$ by using a dynamic feedback control policy. This can be done because all the events are controllable [10], [11] (pick the supervisor S , so that $L(S) = K$). An example for the case $K = (ab)^*$ is shown in Fig. 1.

3. Stability: region of attraction. With the above introduction on our supervisory control model, we next consider the stability issues for DEDSs. First, we discuss the definitions and results of some of the earlier works, in which the stability is defined in terms of a set of legal states of the system. Later, we present our own notions of stability defined in terms of legal behavior of the system.

Consider a plant $P \stackrel{\text{def}}{=} (X, \Sigma, \alpha, x_0, X_m)$. Let $\hat{X} \subseteq X$ be the prescribed subset of states or the legal states. The notions of *strong* and *weak attraction* [2], [3] are defined as follows: A state $x \in X$ is said to be *strongly attractable* to \hat{X} if, after starting from the state x , the system always reaches a state in the set \hat{X} after a finite number of transitions. The set of all the strongly attractable states is called the *region of strong attraction* of \hat{X} and is denoted by $\Omega(\hat{X})$. Formally, let for $s \in \Sigma^*$, $|s|$ denote the length of s , and for $X' \subseteq X$, let $|X'|$ denote the number of states in the set X' .

DEFINITION 3.1. $x \in X$ is strongly attractable to \hat{X} if for all s such that $\alpha(s, x)!$ and $|s| \geq |X - \hat{X}|$ there exists a prefix $u_s \in \Sigma^*$ of s with $|u_s| \leq |X - \hat{X}|$ so that $\alpha(u_s, x) \in \hat{X}$ [2,3].

DEFINITION 3.2. A state $x \in X$ is said to be *weakly attractable* to \hat{X} if there exists a static feedback supervisor S such that x is strongly attractable to \hat{X} in the coupled system $P \square S$. The set of all the weakly attractable states is called the *region of weak attraction* and is denoted by $\Lambda(\hat{X})$.

Clearly, $\Omega(\hat{X}) \subseteq \Lambda(\hat{X})$. If $\Omega(\hat{X}) = X$, then P is said to be *stable* with respect to \hat{X} and if $\Lambda(\hat{X}) = X$, then P is said to be *stabilizable* with respect to \hat{X} . Thus, to test whether a given system is stable (stabilizable) with respect to a given set of legal states, we must compute the region of strong (weak) attraction. The definitions of strongly and weakly attractable states are the same as those of *prestable* and *prestabilizable* states, respectively [18].

Remark 3.3. Algorithms for constructing the regions of strong and weak attraction are presented in [18], [2], [3]. The complexity of these algorithms is quadratic in number of states of the system. An algorithm of linear time complexity in the number of states of the system for constructing the regions of strong and weak attraction is presented in Appendix A of this paper. This algorithm is used later for arriving at a computationally more efficient test for determining a sufficient condition of stability and stabilizability introduced below.

4. Language-Stability. So far we have discussed stability of DEDSs defined in terms of their legal states and provided an efficient algorithm for testing it by computing the regions of attraction (refer to Appendix A for the algorithm). Next, we provide motivation for a more general notion of stability, which we call language-stability, and discuss some of the issues related to stability in this framework.

In some cases, it might be desirable that the eventual behavior (rather than the whole behavior) of the system be legal, so the whole behavior of the system need not be confined to a legal language as in [21], [20]. Thus in these cases the control task can be formulated as the synthesis of a supervisor such that the behavior of the supervised system is eventually legal. This leads to the design of supervisors that are less restrictive and as a result, the behavior of the supervised system is a larger language. Hence, we will formalize the notion of eventual behavior of the systems and define stability and stabilizability of systems in terms of their behavior. As discussed in the previous sections, the notions of stability defined in terms of languages can also be viewed as a generalization to the ones defined in terms of states [18], [16], [2], [4], and [3].

Example 4.1. Consider the machine P shown in Fig. 2. P can either be in “idle,” “working,” “broken,” or “display” state. Assume that initially it is in the idle state and goes to the working state when the action “start” is executed. While in the working state, P can either “stop” and go back to the idle state or can “fail” and go to the broken state. In the broken state it can execute either the action “repair” and go to the display state or the action “replace” and go back to the initial idle state. While in the display state, the action “reject” or “approve” can be executed, so the resulting state of P can either be broken (if reject is executed) or idle (if approve is executed).

FIG. 2. Machine P of Example 4.1.

Consider the above example for the stability analysis in the framework of [18], [16], [2], [4], and [3]. The states idle and working are the “good” or legal states of P . The actions start, repair, and replace are the controllable actions, whereas the actions stop, fail, reject, and approve are the uncontrollable actions. Clearly, P is not *stable* with respect to its legal states (once P executes fail, it is not guaranteed to get back to the legal states). To show that P is *stabilizable*: once it executes fail and goes to the broken state, it must execute the controllable action replace to go back to the legal state either permanently (as in [4], [2], [3]) or temporarily (as in [18]). Suppose instead that it executes the controllable action repair and goes to the display state; there it might not execute the uncontrollable action approve in which case it would remain in the illegal state. Hence the only way P can be stabilized is by executing the action replace after it executes fail. This however, may not be desired, for replacing (and not repairing) P whenever it fails might be cost ineffective. Thus in this example, the framework of [18], [16], [3] may be too restrictive for *stabilizing* the machine P .

We would like the desired behavior of P to be such that it allows P to execute the repair-reject sequence for a finite number of times. In other words, the desired behavior of P is that if it executes fail, it should execute replace or approve after a finite number of executions of the repair-reject sequence; otherwise it should execute the start-stop sequence. The way P is designed, after executing fail, it might never execute replace or approve and continue executing the repair-reject sequence, in which case the desired behavior is not achieved. We note that the desired behavior of P as described above cannot be achieved by use of a static feedback controller.

Moreover, in the above example, P is allowed to execute “illegal” actions (the repair-reject sequence) after it executes fail, provided it eventually executes one of the “legal” actions (replace or approve). Thus the whole behavior of the system need not always be confined to a legal language as in [21], [20].

With this motivation, we formally define stability of systems in terms of their legal behavior. For $n \in \mathcal{N}$, let Σ^n denote the set of strings, each of length n , of events belonging to Σ . We use $\Sigma^{\leq N}$ to denote $\bigcup_{n \leq N} \Sigma^n$ for each $N \in \mathcal{N}$.

DEFINITION 4.2. Let $L, K \subseteq \Sigma^*$ be two languages. L is said to be *language stable* (ℓ -stable) with respect to K if there exists $N \in \mathcal{N}$ such that $L \subseteq \Sigma^{\leq N} K$.

Since $\Sigma^{\leq N} \subseteq \Sigma^{\leq N'}$ whenever $N \leq N'$ ($N, N' \in \mathcal{N}$), it follows that if L is ℓ -stable with respect to K , then there exists a smallest integer $N_0 \in \mathcal{N}$ such that $L \subseteq \Sigma^{\leq N_0} K$. Given a string $s \in \Sigma^*$, let $u_n \in \Sigma^*$ be the prefix of length n of s ($n < |s|$), and let $v_n \in \Sigma^*$ be such that $s = u_n v_n$. We define a map $\Pi_n : \Sigma^* \rightarrow \Sigma^*$ in the following manner:

$$\Pi_n(s) = \begin{cases} v_n, & \text{for } n < |s| \\ \epsilon, & \text{otherwise} \end{cases}$$

Thus the effect of the map $\Pi_n(\cdot)$ on a string s is to remove the initial n symbols of s .

It follows from Definition 4.2 that $L \subseteq \Sigma^*$ is ℓ -stable with respect to $K \subseteq \Sigma^*$ if and only if there exists $N \in \mathcal{N}$ such that for every string $s \in L$ there exists a prefix $u_s \in \Sigma^*$ of s with $|u_s| \leq N$ such that $\Pi_{|u_s|}(s) \in K$. Thus L is ℓ -stable with respect to K , if after removing a prefix of length at most N from a string in L , it matches some string in K . The language L can be thought to be representing the plant behavior and the language K can be thought to be representing the eventual legal behavior of plant. If L is not ℓ -stable with respect to K , then it is said to be *ℓ -stabilizable* with respect to K if there exists a supervisor S such that the closed loop behavior is ℓ -stable with respect to K . Formally,

DEFINITION 4.3. Consider $L, K \subseteq \Sigma^*$. L is said to be ℓ -stabilizable with respect to K if there exists a nonempty controllable [21] sublanguage $H \subseteq L$ such that H is ℓ -stable with respect to K .

Assume that L is recognized by a plant P , i.e. $L_m(P) = L$. Let S be a supervisor such that the language recognized by the closed loop system $L_m(P \square S)$ is ℓ -stable and controllable with respect to K ; then clearly L is ℓ -stabilizable with respect to K with $H = L_m(P \square S)$. It is known that the closed-loop behavior $L_m(P \square S)$ is controllable if and only if S is a *complete*² supervisor [21], [11], [10]. Thus Definition 4.3 can equivalently be stated as: L is said to be ℓ -stabilizable with respect to K if there exists a complete supervisor S such that $L_m(P \square S)$ is ℓ -stable with respect to K .

PROPOSITION 4.4. If $P \stackrel{\text{def}}{=} (X, \Sigma, \alpha, x_0, X_m)$ is stable (stabilizable) with respect to $\hat{X} \subseteq X$, then $L_m(P)$ is ℓ -stable (ℓ -stabilizable) with respect to $\bigcup_{x \in \hat{X}} L_m(P, x)$, where $L_m(P, x)$ is the language marked by P assuming the initial state to be x .

Proof. Assume that the SM, $P \stackrel{\text{def}}{=} (X, \Sigma, \alpha, x_0, X_m)$ is stable with respect to the legal set $\hat{X} \subseteq X$. Let $L = L_m(P)$, and $K = \bigcup_{x \in \hat{X}} L_m(P, x)$. Define $N \stackrel{\text{def}}{=} |X - \hat{X}|$. We will show that $L \subseteq \Sigma^{\leq N} K$. Consider $s \in L$. If $|s| \leq N$, then $s \in \Sigma^{\leq N}$; hence $s \in \Sigma^{\leq N} K$. If $|s| > N$, then there exists a prefix $u_s < s$, $|u_s| \leq N$, such that $\alpha(u_s, x_0) \in \hat{X}$ (follows from the fact that x_0 is strongly attractable to \hat{X}). Thus $\Pi_{|u_s|}(s) \in K$ (by definition of K). Hence $s \in \Sigma^{\leq N} K$; which shows that L is ℓ -stable with respect to K .

Similarly, it can be shown that if P is stabilizable with respect to \hat{X} , then L is ℓ -stabilizable with respect to K . \square

Proposition 4.4 shows that stability (stabilizability) in terms of states in some sense implies ℓ -stability (ℓ -stabilizability). We show in the next example that the converse does not necessarily hold, thus showing that the notion of ℓ -stability (ℓ -stabilizability) is finer than that of stability (stabilizability).

Example 4.5. Let $\Sigma = \Sigma_u = \{a, b, c, d\}$. Consider the languages $L, K_i (i \geq 1) \subseteq \Sigma^*$ given by: $L = (ab)^* cd^*$ and $K_i = d^* + b(ab)^i (ab)^* cd^*$. Generators for L and $K_1 = d^* + bab(ab)^* cd^*$ are shown in Fig. 3. Letting $N \stackrel{\text{def}}{=} 2i + 1$, it can be easily verified that $L \subseteq \Sigma^{\leq N} K_i$ for each $i \geq 1$, and also that N is the smallest integer for which the last inclusion holds. Fix, for example, $i = 1$. We show that $L \subseteq \Sigma^{\leq 3} K_1$. L consists of strings cd^* (no ab followed by cd^*), $abcd^*$ (one ab followed by cd^*), and $(ab)^{\geq 2} cd^*$ (two or more ab followed by cd^*). First, consider the strings in $cd^* \subseteq L$. Then $\Pi_1(cd^*) = d^* \subseteq K_1$. Next, consider the strings in $abcd^* \subseteq L$. Then $\Pi_3(abcd^*) = d^* \subseteq K_1$. Finally, consider $(ab)^{\geq 2} cd^* \subseteq L$. Then $\Pi_1((ab)^{\geq 2} cd^*) = b(ab)^{\geq 1} cd^* = bab(ab)^* cd^* \subseteq K_1$. Thus it follows that $L \subseteq \Sigma^{\leq 3} K_1$.

Since L is ℓ -stable with respect to each K_i it follows that L is also ℓ -stabilizable with respect to each K_i .

Let P, V_i be the minimal SMs generating L, K_i , respectively. Then P, V_i must have $3, 2i + 4$ states, respectively (refer to Fig. 3 for $i = 1$). It can be easily seen that P is not stable with respect to any of its subset of states. Since $\Sigma_u = \Sigma$, P is not stabilizable with respect to any of its subset of states either.

Example 4.6. Consider the languages $L = (ac + b)a(a + b)^*$ and $K = (ab)^*$ defined over $\Sigma = \Sigma_c = \{a, b, c\}$. We will show that L is not ℓ -stable with respect to K , i.e., there exists no $N \in \mathcal{N}$ such that $L \subseteq \Sigma^{\leq N} K$. To prove this, we assume for contradiction that there exists $N_0 \in \mathcal{N}$ is such that $L \subseteq \Sigma^{\leq N_0} K$. Consider the

² A supervisor S is said to be *complete* if for all $s \in \Sigma^*, \sigma_u \in \Sigma_u : s \in L(P \square S), s\sigma_u \in L(P) \Rightarrow s\sigma_u \in L(P \square S)$.

FIG. 3. Diagram illustrating Example 4.5 with $i = 1$.

string $baa^{N_0} \in L$. Any substring of it obtained by removing an initial finite segment of length less than N_0 does not match any string in K (a string in K contains the symbol b at the end, whereas the string baa^{N_0} ends with the symbol a).

FIG. 4. Diagram illustrating Example 4.6.

Consider a sublanguage $H = (ac + b)a(ab)^* \subseteq L$ as shown in Fig. 4. Since $\Sigma_c = \Sigma$, H is controllable with respect to L . It can be easily seen that $H = (ac + b)a(ab)^*$ is ℓ -stable with respect to $K = (ab)^*$ (consider any string from H and remove the initial segment, either aca or ba , whichever is appropriate; the resulting string belongs to K). Thus L is ℓ -stabilizable to K .

In this example, it is clear that a dynamic feedback-type supervisor has been used to ℓ -stabilize the given language. Also, a static feedback-type control cannot be used to stabilize $L = (ac + b)a(a + b)^*$ with respect to $K = (ab)^*$. This follows since any string in K contains an equal number of a 's and b 's, and L cannot be restricted to a language $H \subseteq L$ with all its strings having an equal number of a 's and b 's at its end by using a static supervisor (refer to Example 2.7). In [18], [2], [3], where stability is defined in terms of the legal states, the supervisors considered for stabilizing DEDSs are all assumed to be of static feedback type. Thus a more general type of control is needed to ℓ -stabilize the behavior of a given system, which also shows that the notion of ℓ -stability (ℓ -stabilizability) is a finer notion.

Example 4.7. Consider a system consisting of a single buffer of unbounded capacity. Only two types of events arrival, denoted a , and departure, denoted b , occur in this system, i.e., $\Sigma = \{a, b\}$. The behavior of this system can be described by the language

$$L = \{s \in \Sigma^* \mid \#(a, s) \geq \#(b, s)\},$$

where the symbol $\#(x, y)$ is used to denote the number of times the symbol x occurs in the string y . We may be interested in determining whether there exists some number $N \in \mathcal{N}$ such that after execution of all strings of length larger than N , the buffer content is bounded above by a fixed number $N_0 \in \mathcal{N}$. The above problem can be posed as a ℓ -stability problem with the “eventually reachable” language $K \subseteq \Sigma^*$ defined as

$$K = \{s \in \Sigma^* \mid \#(a, s) - \#(b, s) \leq N_0\}.$$

K corresponds to the content of the buffer being bounded above by N_0 .

It is easy to see that L is not ℓ -stable with respect to K , i.e., there does not exist any N such that after execution of all strings of length larger than N , the buffer content is bounded above by N_0 . Note that in this example, $K \subseteq L$ and if the arrival event a is controllable, then L can be restricted to the language K by disabling a whenever the buffer content becomes equal to N_0 . This proves that L is ℓ -stabilizable with respect to K . Next we present algorithms for testing ℓ -stability and ℓ -stabilizability of a language L with respect to another language K .

4.1. Algorithms for testing ℓ -stability and ℓ -stabilizability. To test whether a language L is ℓ -stable (ℓ -stabilizable) with respect to another language K , we must test whether there exists an integer $N \in \mathcal{N}$ such that $L \subseteq \Sigma^{\leq N} K$ ($H \subseteq \Sigma^{\leq N} K$, where $H \subseteq L$). This problem can equivalently be posed in terms of the *reversal* [1] of languages that we define next.

DEFINITION 4.8. Given a string $s \in \Sigma^*$, its *reversal* $s^R \in \Sigma^*$, is the string obtained by reversing s . Given a language $L \subseteq \Sigma^*$, its reversal $L^R \subseteq \Sigma^*$ is defined to be: $L^R \stackrel{\text{def}}{=} \{s^R \in \Sigma^* \mid s \in L\}$.

Next we discuss some of the properties of the reversal operator. We use L, L_1, L_2 to denote languages defined on Σ .

LEMMA 4.9.

1. *Reversal preserves regularity, i.e., if L is regular, then so is L^R .*
2. $(L^R)^R = L$.
3. *Reversal is monotone, i.e., if $L_1 \subseteq L_2$, then $L_1^R \subseteq L_2^R$.*
4. $(L_1 L_2)^R = L_2^R L_1^R$.

Proof. 1. The proof is based on constructing an FSM that recognizes L^R using an FSM realization for L , and can be found in [8].

2. The proof follows from the definition of the reversal of languages and the fact that for any string $s \in \Sigma^*$, $(s^R)^R = s$.

3. Pick $s \in L_1^R$; then $s^R \in L_1$. Since $L_1 \subseteq L_2$, it follows that $s^R \in L_2$, i.e., $(s^R)^R = s \in L_2^R$.

4. We first show that $(L_1 L_2)^R \subseteq L_2^R L_1^R$. Pick $s \in (L_1 L_2)^R$; then $s^R \in L_1 L_2$, i.e., there exist $u_s \in L_1$ and $v_s \in L_2$ such that $u_s v_s = s^R$. Hence $s = (s^R)^R = (u_s v_s)^R = v_s^R u_s^R \in L_2^R L_1^R$.

Next we show that $L_2^R L_1^R \subseteq (L_1 L_2)^R$. Pick $s \in L_2^R L_1^R$; then there exist $v_s \in L_2$ and $u_s \in L_1$ such that $v_s^R u_s^R = s$. Hence $s = (s^R)^R = ((v_s^R u_s^R)^R)^R = (u_s v_s)^R \in (L_1 L_2)^R$. \square

COROLLARY 4.10. $L \subseteq \Sigma^{\leq N} K$ if and only if $L^R \subseteq K^R \Sigma^{\leq N}$, where $L, K \subseteq \Sigma^*$ and $N \in \mathcal{N}$.

Proof. Assume that $L \subseteq \Sigma^{\leq N} K$; then it follows from part 3 of Lemma 4.9 that $L^R \subseteq (\Sigma^{\leq N} K)^R$. Since $(\Sigma^{\leq N})^R = \Sigma^{\leq N}$, it follows from part 4 of Lemma 4.9 that $L^R \subseteq K^R \Sigma^{\leq N}$.

Assume next that $L^R \subseteq K^R \Sigma^{\leq N}$; then from part 3 of Lemma 4.9 it follows that $(L^R)^R \subseteq (K^R \Sigma^{\leq N})^R$. Thus from part 4 of Lemma 4.9 we obtain $(L^R)^R \subseteq \Sigma^{\leq N} (K^R)^R$. It then follows from part 2 of Lemma 4.9 that $L \subseteq \Sigma^{\leq N} K$. \square

Thus the problem of testing ℓ -stability of a language L with respect to another language K can be equivalently posed as that of determining an integer $N \in \mathcal{N}$, if it exists, such that $L^R \subseteq K^R \Sigma^{\leq N}$. Hence, given two languages $L, K \subseteq \Sigma^*$, we next analyze the problem of determining an integer $N \in \mathcal{N}$, if it exists, such that $L^R \subseteq K^R \Sigma^{\leq N}$.

Let $P \stackrel{\text{def}}{=} (X, \Sigma, \alpha, x_0, X_m)$ and $V \stackrel{\text{def}}{=} (Q, \Sigma, \delta, q_0, Q_m)$ be two SMs such that $L_m(P) = L^R$ and $L_m(V) = K^R$. Assume further that P is trim [8] so that $L(P) = \overline{L_m(P)} = \overline{L^R}$, and V is such that $L(V) = \Sigma^*$, i.e. V is an SM that recognizes K^R and has an additional dump state in order to generate Σ^* . Consider a slightly different synchronous composition of P and V , denoted $P \square' V$, given by the 5-tuple:

$$P \square' V \stackrel{\text{def}}{=} (R, \Sigma, \rho, r_0, R_m),$$

where the state set R , the transition function $\rho(\cdot, \cdot)$, and the initial state r_0 are defined as in the definition of synchronous composition in §2, and

$$R_m = \{r \in X_m \times Q \mid \exists s \in \Sigma^* \text{ s.t. } \rho(s, r_0) = r\}.$$

This is a slight variation to the earlier definition of marked states in synchronous composition of two state machines. Note that R_m consists of those states in $X_m \times Q$ that are reachable from the initial state r_0 ; hence $R_m \subseteq X_m \times Q$. Also, note that all transitions are defined in all states of V , i.e., given any event $\sigma \in \Sigma$ and any state $q \in Q$, $\delta(\sigma, q)!$. Hence for any event $\sigma \in \Sigma$ and state $r = (x, q) \in R$, $\rho(\sigma, (x, q))$ is defined if and only if $\alpha(\sigma, x)$ is defined.

LEMMA 4.11. *Let P and V be the two SMs as defined above. Then $L_m(P \square' V) = L_m(P)$, and $L(P \square' V) = L(P)$.*

Proof. First we show that $L_m(P \square' V) \subseteq L_m(P)$. Pick $s \in L_m(P \square' V)$; then $\rho(s, r_0) \in R_m$. Since $\rho(s, r_0)$ is defined if and only if $\alpha(s, x_0)$ is defined, and $R_m \subseteq X_m \times Q$, it follows that $\alpha(s, x_0) \in X_m$. Thus $s \in L_m(P)$. Next we show that $L_m(P) \subseteq L_m(P \square' V)$. Pick $s \in L_m(P)$; then $\alpha(s, x_0) \in X_m$. Again, since $\alpha(s, r_0)$ is defined if and only if $\rho(s, r_0)$ is defined, $\rho(s, r_0) \in X_m \times Q$. The state $\rho(s, r_0)$ is clearly a reachable state from r_0 , hence $\rho(s, r_0) \in R_m$, which shows that $s \in L_m(P \square' V)$.

Since $L(P \square' V) = L(P) \cap L(V) = L(P) \cap \Sigma^* = L(P)$, the other result follows. \square

Given two languages $L, K \subseteq \Sigma^*$, next we present a necessary and sufficient condition to determine whether there exists an integer $N \in \mathcal{N}$ such that $L^R \subseteq K^R \Sigma^{\leq N}$ in terms of the graphical structure of SMs recognizing the languages L^R, K^R .

Consider R , the state set of $P \square' V$. Let R^* denote the set of all finite sequences of states belonging to R . Consider $p \in R^*$ such that $p = (r_1 r_2 \dots r_i \dots r_n) \in R^*$, where $r_i \in R$ for each $1 \leq i \leq n$ and $n \in \mathcal{N}$. Then p is said to be a *path* starting at r_1 and ending at r_n in $P \square' V$, if there exist a string $s_p \in \Sigma^*$, $s_p = \sigma_1 \sigma_2 \dots \sigma_i \dots \sigma_{n-1}$, where $\sigma_i \in \Sigma$ for each $1 \leq i \leq n-1$, such that $\rho((\sigma_1 \dots \sigma_{i-1}), r_1) = r_i$ for each $1 < i \leq n$. $s_p \in \Sigma^*$ as described above is called the string corresponding to path p . Thus, given

a path p in $P \square' V$, there exists at least one string $s_p \in \Sigma^*$ corresponding to p . A state $r \in R$ is said to be a *path-state* of the path p if $r = r_i$ for some $1 \leq i \leq n$. p is said to be a *loop-path* if there exist i, j with $1 \leq i < j \leq n$ such that $r_i = r_j$, in which case the portion $r_i \dots r_j$ of p is called the *loop-portion* of p . p is said to be a *loopfree-path* if p is not a loop-path.

THEOREM 4.12. *Let $L^R, K^R \subseteq \Sigma^*$ be the languages recognized by the SMs P, V , respectively, as described above. Then there exists an integer $N \in \mathcal{N}$ such that $L^R \subseteq K^R \Sigma^{\leq N}$ if and only if the following hold in the SM $P \square' V$:*

(C1) *For each $r_m \in R_m$ and for every path p in $P \square' V$ that starts at r_0 and ends at r_m , there exists a path-state $r = (x, q) \in X \times Q$ of p such that $q \in Q_m$.*

(C2) *For each $r = (x, q) \in X \times Q_m$ and each $r_m \in R_m$, if a path p in $P \square' V$ that starts at r and ends at r_m has none of its path-states in $X \times Q_m$ (other than the one at which it starts), then p is a loopfree-path.*

Proof. Assume that there exists an integer $N \in \mathcal{N}$ such that $L^R \subseteq K^R \Sigma^{\leq N}$; then we first show that (C1) holds.

Fix a path p in $P \square' V$ such that p starts at r_0 and ends at $r_m \in R_m$. Then there exists a string $s_p \in L_m(P \square' V)$ such that $\rho(s_p, r_0) = r_m$. Since $L_m(P \square' V) = L_m(P) = L^R$ (Lemma 4.9 and definition of P), $s_p \in L^R$. Thus it follows from the assumption that $s_p \in K^R \Sigma^{\leq N}$, i.e., there exist $u_{s_p} \in K^R$ and $v_{s_p} \in \Sigma^{\leq N}$ such that $s_p = u_{s_p} v_{s_p}$. Consider the path-state $r = (x, q) = \rho(u_{s_p}, r_0)$ of p . Since $u_{s_p} \in K^R$, the state q reached by accepting u_{s_p} in V belongs to Q_m , i.e., $r = (x, q) \in X \times Q_m$.

Next we show that (C2) holds. Fix a path p in $P \square' V$ such that p starts at $r = (x, q) \in X \times Q_m$ and ends at $r_m \in R_m$ and none of the path-states of p other than the first one are in $X \times Q_m$. Assume for contradiction that (C2) is false, i.e., p is a loop-path. Consider the string $s \in L(P \square' V)$ such that $\rho(s, r_0) = r = (x, q)$. Since $q \in Q_m$, $s \in L_m(V) = K^R$. Let $t_p = u_p v_p w_p \in \Sigma^*$ be a string corresponding to the path p , where v_p represents the string corresponding to the loop-portion of p . Then $st_p = su_p v_p w_p \in L_m(P \square' V) = L^R$ (since $\rho(st_p, r_0) = r_m \in R_m$). Hence the string $tu_p(v_p)^{N+1}w_p \in L^R$. Then there exists no prefix $s' \in K^R$ of the string $su_p(v_p)^{N+1}w_p$ such that $\Pi_{|s'|}(su_p(v_p)^{N+1}w_p) \in \Sigma^{\leq N}$, which contradicts the fact that $L^R \subseteq K^R \Sigma^{\leq N}$. This completes the proof of the fact that (C1) and (C2) are necessary conditions for an integer $N \in \mathcal{N}$ to exist such that $L^R \subseteq K^R \Sigma^{\leq N}$. It remains to show that (C1) and (C2) are sufficient conditions also.

Assume then that (C1) and (C2) hold for SM $P \square' V$. Since (C2) holds, any path p in $P \square' V$ that starts at $r = (x, q) \in X \times Q_m$ and ends at $r_m \in R_m$ with none of its path-states (other than the first one) in $X \times Q_m$, is a loopfree-path. Let \mathcal{P} denote the collection of all such paths (paths that satisfy condition (C2)). Define $N \stackrel{\text{def}}{=} \max_{p \in \mathcal{P}} |p|$, where $|p|$ denotes the length of path p . Then we will show that $L^R \subseteq K^R \Sigma^{\leq N}$. Note that since (C2) holds, all the paths $p \in \mathcal{P}$ are loopfree-paths, hence the maximum in the definition of N exists. To show that $L^R \subseteq K^R \Sigma^{\leq N}$, pick $s \in L^R$. Then $s \in L_m(P \square' V)$. Let $\rho(s, r_0) = r_m \in R_m$. Consider the path p_s in $P \square' V$ corresponding to string s . Since $P \square' V$ is deterministic, p_s is unique. Also, p_s starts at r_0 and ends at $r_m \in R_m$. Hence by (C1), there exists a path-state $r = (x, q)$ of p_s such that $r = (x, q) \in X \times Q_m$. Let r' be the last such path-state of p_s , i.e., $r' \in X \times Q_m$ and all the path-states of p_s that follow r' do not belong to $X \times Q_m$. Let the portion of p_s that starts at r' and ends at r_m be denoted by p' ; then from (C2) p' is a loopfree-path, also $p' \in \mathcal{P}$. It follows from the definition of N that $|p'| \leq N$. Let $u' \in \Sigma^*$ be the prefix of s such that $\rho(u', r_0) = r'$, then $u' \in K^R$ (since $r' \in X \times Q_m$), and $\Pi_{|u'|}(s) \in \Sigma^{\leq N}$. Thus $s \in K^R \Sigma^{\leq N}$. This completes the proof of Theorem

4.12. \square

Remark 4.13. Conditions (C1) and (C2) can be tested in $P \square' V$ in the following manner:

1. Consider the state set R of $P \square' V$ and remove all the states $r = (x, q) \in R$ (and the transitions entering or leaving these states) for which $q \in Q_m$. Then for (C1) to hold, there must not exist any path connecting r_0 to any $r_m \in R_m$ in the machine obtained by removing the above states. Thus (C1) can be verified by performing a *single* reachability test on the reduced machine as described above.

2. Next fix a state $r = (x, q) \in R$ with $q \in Q_m$ and remove from $P \square' V$ all the other states $r' = (x', q') \in R$ (and the transitions entering or leaving these states) having $q' \in Q_m$. Then for (C2) to hold for this state r , any path connecting r to any $r_m \in R_m$ in the machine obtained by removing the above states must be acyclic. Repeat the above for every state $r'' = (x'', q'') \in R$ with $q'' \in Q_m$ and test for acyclicity. Since for each such state acyclicity can be tested by computing its reachability set, testing (C2) requires at most $|P \square' V|$ reachability tests to be performed, where $|P \square' V|$ denotes the number of states in $P \square' V$.

Thus it follows from above that testing (C1) and (C2) requires at most $|P \square' V| + 1$ reachability tests to be performed. Since the reachability set can be computed in $O(|P \square' V|)$ time, the complexity of testing (C1) and (C2) is of order $O(|P \square' V|^2)$. Let $m, n \in \mathcal{N}$ be the number of states in the minimal SMs recognizing L, K , respectively, then the number of states in SMs P, V recognizing L^R, K^R , respectively, is $2^m, 2^n$, respectively (reversal operation requires nondeterministic to deterministic conversion of SMs). Hence the computational complexity of testing ℓ -stability of L with respect to K is $O(2^{2(m+n)})$.

Example 4.14. Consider the languages $L, K_1 \subseteq \{a, b, c, d\}^*$ as in Example 4.5: $L = (ab)^*cd^*$ and $K_1 = d^* + bab(ab)^*cd^*$. Recognizers for L and K_1 are shown in Fig. 3. Then $L^R = d^*c(ba)^*$ and $K_1^R = d^* + d^*c(ba)^*bab = d^* + d^*cbab(ab)^*$. Let P, V be state machines such that $L_m(P) = L^R, L_m(V) = K_1^R$, and $L(P) = L_m(P), L(V) = \Sigma^*$, respectively, as in Theorem 4.12. Construct $P \square' V$ as described above. Recognizers for $P, V, P \square' V$ are shown in Fig. 5. A state (x, q) in the state set R of $P \square' V$ is marked

FIG. 5. Diagram illustrating Example 4.14.

if and only if the state $x \in X_m$. Since state $2 \in X$ is the only state marked in P , the states $(2, 2), (2, 4)$ and $(2, 6)$ are the marked states in $P \square' V$. We now check whether conditions (C1) and (C2) of Theorem 4.12 hold. Consider any path in $P \square' V$ starting

from the initial state $(1, 1)$ and ending at one of the marked states $(2, 2)$, $(2, 4)$, or $(2, 6)$. Then this path obviously visits the state $(1, 1)$. Since $(1, 1) \in X \times Q_m$ (state 1 is marked in V), condition (C1) holds. To show that (C2) holds, consider any path in $P \square V$ starting at the initial state $(1, 1)$ and ending at one of the marked states $(2, 2)$, $(2, 4)$, or $(2, 6)$. If the path ends at $(2, 2)$, then the last state (x, q) such that $q \in Q_m$ visited along this path is $(1, 1)$. Consider the path segment between $(1, 1)$ and $(2, 2)$; it is loopfree. If the path ends at $(2, 4)$, then the last state (x, q) with $q \in Q_m$ visited along this path is again $(1, 1)$, and again the path segment between $(1, 1)$ and $(2, 4)$ is loopfree. Finally, if the path ends at $(2, 6)$, then the last state (x, q) with $q \in Q_m$ visited is $(3, 5)$, and the path segment between $(3, 5)$ and $(2, 6)$ is again loopfree. Thus condition (C2) also holds. It then follows from Theorem 4.12 that L is ℓ -stable with respect to K_1 as expected (refer to the discussion in Example 4.5).

COROLLARY 4.15. *Consider two regular languages $L, K \subseteq \Sigma^*$. Let $m, n \in \mathcal{N}$ be the number of states in the minimal SMs recognizing L, K , respectively. L is ℓ -stable with respect to K , if and only if $L \subseteq \Sigma^{\leq 2^{m+n}} K$.*

Proof. To prove the “if” part, we must show that $L \subseteq \Sigma^{\leq 2^{m+n}} K$ implies L is ℓ -stable with respect to K . This is trivially true: set $N = 2^{m+n}$ in the definition of ℓ -stability. To prove the “only if” part, we need to show that if L is ℓ -stable with respect to K , then $L \subseteq \Sigma^{\leq 2^{m+n}} K$. Since L is ℓ -stable with respect to K , it follows from Corollary 4.10 that there exists $N \in \mathcal{N}$ such that $L^R \subseteq K^R \Sigma^{\leq N}$. Let P, V be machines recognizing L^R, K^R , respectively, as in Theorem 4.12. It then follows from Theorem 4.12 that $N \leq |P \square V|$ (refer to the second part of the proof of Theorem 4.12, where N is defined to be $N \stackrel{\text{def}}{=} \max_{p \in \mathcal{P}} |p|$; since each $p \in \mathcal{P}$ is loopfree, $|p| \leq |P \square V|$, hence $N \leq |P \square V|$). Since the number of states in SMs recognizing L, K is m, n , respectively, the number of states in P, V is $2^m, 2^n$, respectively (reversal operation requires nondeterministic to deterministic conversion of SMs [1]). Thus it follows that $N \leq |P \square V| = (2^m)(2^n) = 2^{m+n}$. \square

Remark 4.16. Thus ℓ -stability of a given language L with respect to another language K can also be determined by testing whether $L \subseteq \Sigma^{\leq 2^{m+n}} K$, where $m, n \in \mathcal{N}$ are the numbers of states present in SMs recognizing L, K , respectively.

Next we consider the problem of testing ℓ -stabilizability of a given language $L \subseteq \Sigma^*$ with respect to another language $K \subseteq \Sigma^*$. Let P be the trim SM recognizing language L , then $L(P) = \bar{L}$. The supervisor that disables all the controllable transitions of P (treated as a plant) is called the *maximally restrictive supervisor*. The behavior of P under the maximally restrictive control equals $L(P) \cap \Sigma_u^*$, which is the *infimal controllable sublanguage* of $L(P)$. The existence result and formula for the infimal controllable sublanguage of a prefix-closed language is given in [14]. Hence, if L is prefix closed, then $L(P) = \bar{L} = L$, and we obtain that the infimal controllable sublanguage of L equals $L \cap \Sigma_u^*$.

THEOREM 4.17. *If $L \subseteq \Sigma^*$ is prefix closed, then L is ℓ -stabilizable with respect to $K \subseteq \Sigma^*$ if and only if $L \cap \Sigma_u^*$ is ℓ -stable with respect to K .*

Proof. Assume that L is ℓ -stabilizable with respect to K . Then there exists $N \in \mathcal{N}$ and a nonempty controllable sublanguage $H \subseteq L$ such that $H \subseteq \Sigma^{\leq N} K$. Note that $L \cap \Sigma_u^* \subseteq H$ (by infimality of $L \cap \Sigma_u^*$). Hence $L \cap \Sigma_u^* \subseteq \Sigma^{\leq N} K$. Thus $L \cap \Sigma_u^*$ is ℓ -stable with respect to K .

Next assume that $L \cap \Sigma_u^*$ is nonempty and ℓ -stable with respect to K . Since $L \cap \Sigma_u^*$ is controllable and $L \cap \Sigma_u^* \subseteq L$, it follows that L is ℓ -stabilizable with respect to K . \square

Remark 4.18. Thus ℓ -stabilizability of a given closed language L with respect to

another language K can be determined by testing whether $L \cap \Sigma_u^*$ is nonempty and ℓ -stable with respect to K . Let m denote the number of states in the SM P that generates the language L , then $L \cap \Sigma_u^*$ can be computed in time $O(m)$ by deleting all the controllable transitions from P .

As stated in Remark 4.13, the algorithm for testing ℓ -stability of L with respect to K is of computational complexity that is exponential in the number of states present in SMs recognizing L and K . Hence so is the complexity of the algorithm that tests the ℓ -stabilizability. Next we present a sufficient condition for ℓ -stability of L with respect to K that can be tested in polynomial time. Let $P \stackrel{\text{def}}{=} (X, \Sigma, \alpha, x_0, X_m)$ and $V \stackrel{\text{def}}{=} (Q, \Sigma, \delta, q_0, Q_m)$ be two SMs recognizing L and K , respectively. Define the following subset of states $X_S \subseteq X$:

$$X_S = \{x \in X \mid L_m(P, x) \subseteq K\},$$

where $L_m(P, x)$ is the language recognized by P assuming its initial state to be $x \in X$.

PROPOSITION 4.19. *Consider SMs P, V as defined above. If $x_0 \in \Omega(X_S)$, then L is ℓ -stable with respect to K .*

Proof. Define $N \stackrel{\text{def}}{=} |X - X_S|$; then to prove ℓ -stability of L with respect to K , we need to show that $L \subseteq \Sigma^{\leq N} K$. Consider $s \in L$. If $|s| \leq N$, then clearly $s \in \Sigma^{\leq N} K$. So let $s \in L$ be such that $|s| > N$. Then it follows from the definition of the region of strong attraction that there exists a prefix $u_s \in \Sigma^*, |u_s| \leq N$, of s such that $\alpha(u_s, x_0) \in X_S$. Also, by the definition of X_S , $\Pi_{|u_s|}(s) \in K$, which shows that $s \in \Sigma^{\leq N} K$. \square

Thus if x_0 is strongly attractable to a state in X_S , then P , after starting from x_0 , reaches a state in X_S in at most $|X - X_S|$ transitions, and then onwards follows a string in K . The following algorithm checks the sufficient condition of ℓ -stability of Proposition 4.19.

ALGORITHM 4.20.

1. Determine the subset of states $X_S \subseteq X$ defined above.
2. Compute $\Omega(X_S)$ using Algorithm A.1.
3. If $x_0 \in \Omega(X_S)$, then L is ℓ -stable with respect to K .

Let P, V be the minimal SMs recognizing L, K , respectively, and let $m, n \in \mathcal{N}$ be the number of states in P, V , respectively. Then step 1 of Algorithm 4.20 can be determined in $O(m^2n)$ time, and steps 2 and 3 can both be determined in $O(m)$ time (refer to Theorem A.2). Hence the computational complexity of Algorithm 4.20 is $O(m^2n)$, which is polynomial in m, n . Note that Algorithm 4.20 tests only for the sufficiency condition of ℓ -stability. Hence if the condition in step 3 of Algorithm 4.20 is not satisfied, ℓ -stability of L with respect to K is determined by testing conditions (C1) and (C2) of Theorem 4.12 as described in Remark 4.13. Next we present a sufficient condition for ℓ -stabilizability of L with respect to K , which can also be tested in polynomial time.

PROPOSITION 4.21. *Consider the SMs P, V . Let $X'_S \stackrel{\text{def}}{=} \{x \in X \mid L_m(P, x) \subseteq K\}$. If $x_0 \in \Lambda(X'_S)$, then L is ℓ -stabilizable with respect to K .*

Proof. The proof is similar to the proof of Proposition 4.19. \square

The following algorithm can be used for testing the sufficient condition of ℓ -stabilizability of Proposition 4.21.

ALGORITHM 4.22.

1. Compute $X'_S \subseteq X$.

2. Compute $\Lambda(X'_S)$ using the modification to Algorithm A.1 described in Remark A.3.
3. If $x_0 \in \Lambda(X'_S)$, then L is ℓ -stabilizable with respect to K .

The computational complexity of Algorithm 4.22 is also $O(m^2n)$, where m, n is the number of states in P, V , respectively.

5. Weakly stabilizing supervisors. In the previous section we showed that given a plant P with physical behavior $L \subseteq \Sigma^*$ and desired eventual behavior $K \subseteq \Sigma^*$, it can be verified whether or not L is ℓ -stable or ℓ -stabilizable with respect to K . In the case where L is ℓ -stable with respect to K , the eventual behavior of P is contained in K ; hence no supervisor is needed. If L is not ℓ -stable but is ℓ -stabilizable with respect to K , then a supervisor must be constructed to insure that the eventual closed-loop behavior of the system is a sublanguage of K . The ℓ -stabilizability of L guarantees the existence of a stabilizing supervisor, but a minimally restrictive stabilizing supervisor need not in general exist. This is evident from the following proposition.

PROPOSITION 5.1. *ℓ -stability is not preserved under union.*

Proof. We show by the following example that ℓ -stabilizability is not preserved under union. Let $\Sigma = \Sigma_c = \{a, b\}$, $L = a^*b^*$ denote the plant behavior and $K = b^*$ denote the desired eventual behavior. Then there does not exist any integer $N \in \mathcal{N}$ such that $L \subseteq \Sigma^{\leq N}K$, i.e., L is not ℓ -stable with respect to K .

Next consider the following family of sublanguages $\{L_i\}_{i \in \mathcal{N}}$ of L with $L_i = a^ib^*$ for each $i \in \mathcal{N}$. Then it is clear that for each $i \in \mathcal{N}$, L_i is controllable (since $\Sigma_c = \Sigma$) and also ℓ -stable (since $L_i \subseteq \Sigma^{\leq i}K$) sublanguage of L . But $\bigcup_{i \in \mathcal{N}} L_i = L$ is not ℓ -stable with respect to K ; thus showing that ℓ -stability is not preserved under union. \square

The implication of Proposition 5.1 is that if the plant behavior L is not ℓ -stable with respect to the desired eventual behavior K , then the minimally restrictive stabilizing supervisor, which will restrict the plant behavior to the supremal ℓ -stable sublanguage of L , cannot in general be constructed. Next we define a weaker notion of language stability that we call *weak ℓ -stability*, which is preserved under union so that the minimally restrictive stabilizing supervisor can be constructed.

DEFINITION 5.2. A language $L \subseteq \Sigma^*$ is said to be *weakly ℓ -stable* with respect to another language $K \subseteq \Sigma^*$ if $L \subseteq \Sigma^*K$. If there exists a nonempty controllable sublanguage $H \subseteq L$ such that H is weakly ℓ -stable with respect to K , then L is said to be *weakly ℓ -stabilizable* with respect to K .

Thus if L is weakly ℓ -stable with respect to K , then every string in L after removing a prefix from it matches some string in K . Note that here no uniform bound on the size of the prefix to be removed from a string in L is assumed.

Remark 5.3. Since $\Sigma^{\leq N} \subseteq \Sigma^*$ for any $N \in \mathcal{N}$, it follows that ℓ -stability implies weak ℓ -stability. However, the converse does not hold in general. Consider, for example, the languages $L = a^*b^*$ and $K = b^*$ defined over the event set $\Sigma = \{a, b\}$. Then as stated in the proof of Proposition 5.1, L is not ℓ -stable with respect to K . But clearly L is weakly ℓ -stable with respect to K , for $a^*b^* \subseteq \Sigma^*b^*$.

The following result, analogous to that stated in Theorem 4.17, holds also for weak ℓ -stabilizability.

THEOREM 5.4. *If L is prefix closed, then L is weakly ℓ -stabilizable with respect to K if and only if $L \cap \Sigma_u^*$ is nonempty and weakly ℓ -stable with respect to K .*

Proof. The proof is similar to the proof of Theorem 4.17. \square

Next we discuss how to verify weak ℓ -stability and weak ℓ -stabilizability of a given

plant behavior with respect to its desired eventual behavior. Let

$$P \stackrel{\text{def}}{=} (X, \Sigma, \alpha, x_0, X_m), \quad V \stackrel{\text{def}}{=} (Q, \Sigma, \delta, q_0, Q_m)$$

be the minimal SMs recognizing the languages L, K , respectively. Assuming that the languages L, K , are regular, let m, n be the number of states in P, V , respectively. An SM that recognizes Σ^*K is constructed by first adding the self-loop corresponding to Σ^* at the initial state of V and then converting it to a deterministic SM. Let this SM be denoted by V' ; then the number of states in V' is 2^n .

Remark 5.5. The weak ℓ -stability of L with respect to K can be verified by determining whether $L_m(P) \subseteq L_m(V')$. Since the number of states in P, V' is $m, 2^n$, respectively, the computational complexity of verifying weak ℓ -stability of L with respect to K is $O(m2^n)$. It also follows, in view of Theorem 5.4, that the computational complexity of testing weak ℓ -stabilizability of prefix-closed L with respect to K is again $O(m2^n)$.

Since ℓ -stability (ℓ -stabilizability) implies weak ℓ -stability (weak ℓ -stabilizability), the condition in Proposition 4.19 (Proposition 4.21) is sufficient for weak ℓ -stability (weak ℓ -stabilizability). Thus Algorithm 4.20 (Algorithm 4.22) can be employed to test this sufficient condition for weak ℓ -stability (weak ℓ -stabilizability), the computational complexity of which is polynomial in m, n .

Next we prove that weak ℓ -stability is preserved under union, i.e., the supremal weakly ℓ -stable sublanguage of a given language exists.

PROPOSITION 5.6. *The supremal weakly ℓ -stable sublanguage of a given language exists and is unique.*

Proof. Let L, K denote the plant and desired eventual behavior, respectively. Let Λ be an indexing set such that the family of weakly ℓ -stable sublanguages of L is given by $\{L_\lambda\}_{\lambda \in \Lambda}$, i.e., L_λ is weakly ℓ -stable sublanguage of L for each $\lambda \in \Lambda$. Such a family is nonempty because \emptyset is weakly ℓ -stable sublanguage of L . Consider the language $H \stackrel{\text{def}}{=} \bigcup_{\lambda \in \Lambda} L_\lambda$; then clearly $H \subseteq L$ and H is weakly ℓ -stable. The last assertion follows from the fact that $L_\lambda \subseteq \Sigma^*K$ for each $\lambda \in \Lambda$ which implies that $\bigcup_{\lambda \in \Lambda} L_\lambda = H \subseteq \Sigma^*K$. This completes the proof of Proposition 5.6. \square

COROLLARY 5.7. *The supremal controllable and weakly ℓ -stable sublanguage of a given language exists and is unique.*

Proof. The proof follows from Proposition 5.6 and the fact that controllability is preserved under union [21], [20]. \square

We have proved the existence and uniqueness of the supremal controllable and weakly ℓ -stable sublanguage of a given language. Next we present a closed-form expression for it. We use the notation H^\dagger to denote the supremal controllable sublanguage of a given language $H \subseteq \Sigma^*$ [20,1,10].

THEOREM 5.8. *Let $L, K \subseteq \Sigma^*$ denote the plant and desired eventual behavior, respectively. Then the supremal controllable and weakly ℓ -stable sublanguage of L is given by $(L \cap \Sigma^*K)^\dagger$.*

Proof. Let $H \subseteq \Sigma^*$ denote the supremal controllable and weakly ℓ -stable sublanguage of L with respect to K . Then we must show that $H = (L \cap \Sigma^*K)^\dagger$.

First we show that $(L \cap \Sigma^*K)^\dagger \subseteq H$. Since H is the supremal controllable and weakly ℓ -stable sublanguage of L , it suffices to show that $(L \cap \Sigma^*K)^\dagger$ is a controllable and weakly ℓ -stable sublanguage of L . By its definition, $(L \cap \Sigma^*K)^\dagger$ is a controllable sublanguage of L . Also, since $(L \cap \Sigma^*K)^\dagger \subseteq L \cap \Sigma^*K \subseteq \Sigma^*K$, it follows that $(L \cap \Sigma^*K)^\dagger$ is weakly ℓ -stable with respect to K . Thus $(L \cap \Sigma^*K)^\dagger$ is a controllable and weakly ℓ -stable sublanguage of L .

Next we prove that $H \subseteq (L \cap \Sigma^* K)^\dagger$. Since H is weakly ℓ -stable, it follows that $H \subseteq \Sigma^* K$; also, $H \subseteq L$, hence $H \subseteq L \cap \Sigma^* K$. Note that H is controllable also. Thus H is controllable and is contained in $L \cap \Sigma^* K$. Since $(L \cap \Sigma^* K)^\dagger$ is the supremal controllable sublanguage contained in $L \cap \Sigma^* K$, it follows that $H \subseteq (L \cap \Sigma^* K)^\dagger$. \square

Thus if L is not ℓ -stable with respect to K , but is weakly ℓ -stabilizable with respect to K , then a minimally restrictive stabilizing supervisor can be constructed so that the behavior of the closed-loop system is given by $(L \cap \Sigma^* K)^\dagger$. Note that the result of Theorem 5.8 is not surprising, as we are interested in finding the supremal sublanguage $H \subseteq L$ such that H is weakly stable, i.e., $H \subseteq \Sigma^* K$ and H is controllable. Since $H \subseteq L$ and $H \subseteq \Sigma^* K$, it follows that $H \subseteq L \cap \Sigma^* K$. Thus we are interested in finding the supremal controllable sublanguage $H \subseteq L \cap \Sigma^* K$, which obviously equals $(L \cap \Sigma^* K)^\dagger$. This, however, offers an alternative interpretation of minimally restrictive weakly stabilizing supervisors: the problem of finding the minimally restrictive weakly stabilizing supervisor for a plant with behavior L and *desired eventual behavior* K is equivalent to the problem of finding the minimally restrictive supervisor for the same plant with *desired behavior* $L \cap \Sigma^* K$. Hence techniques developed in [21], [20], [1], [11], etc., can be used to solve the problem.

6. Stability of sequential behavior. Thus far we have discussed the stability of the *finite* behavior of a DEDS. We will show how the notions of ℓ -stability and ℓ -stabilizability defined above can be easily generalized to describe the stability of *infinite* or *sequential* behaviors of DEDSs. In this section, we introduce the notion of ω -stability for formally describing the the notion of eventual sequential behavior.

In [19], [22], [13], [12], [23] the supervisory control problem for controlling the sequential behavior of a DEDS is studied, and conditions under which a supervisor can be constructed so that the sequential behavior of the controlled system is equal to some desired sequential behavior are obtained. As discussed above, such a control problem formulation may lead to synthesis of a very restrictive supervisor. In some cases, it might suffice to design a supervisor that would ensure that the sequential behavior of the controlled system is eventually contained in the desired sequential behavior. So we introduce the notion of the desired eventual sequential behavior and obtain conditions under which the plant's sequential behavior is eventually contained in this sequential behavior. We follow the framework of [19] for addressing the supervisory control problem of sequential behavior.

Let Σ^ω denote the set of all infinite strings of events belonging to Σ . An *infinite* or ω -*language* is a sublanguage of Σ^ω . Let $e^n \in \Sigma^*$ denote the prefix of size n of the infinite string $e \in \Sigma^\omega$. A suitable metric can be defined on the space Σ^ω [7]. Given two infinite strings $e_1, e_2 \in \Sigma^\omega$, the distance $d(e_1, e_2)$ between the two infinite strings is defined to be

$$d(e_1, e_2) \stackrel{\text{def}}{=} \begin{cases} 1/(n+1), & \text{if } e_1^n = e_2^n \text{ and } e_1^{n+1} \neq e_2^{n+1} \ (n \in \mathcal{N}) \\ 0, & \text{if } e_1 = e_2. \end{cases}$$

Given a language $L \subseteq \Sigma^*$, its *limit*, denoted as L^∞ , is the ω -language defined as

$$L^\infty \stackrel{\text{def}}{=} \{e \in \Sigma^\omega \mid e^n \in L \text{ for infinitely many } n \in \mathcal{N}\}.$$

We will use $t \leq s$ to denote that $t \in \Sigma^*$ is a prefix of $s \in \Sigma^* \cup \Sigma^\omega$. If t is a proper prefix of s , then it is written as $t < s$. Given an infinite sequence of strings $s_1 < s_2 < \dots < s_n < \dots$ with $s_n \in \Sigma^*$ for each n , there exists a unique infinite string $e \in \Sigma^\omega$ such that $s_n < e$ for each n . In this case, the infinite string e is also written

as $e = \lim_{n \rightarrow \infty} s_n$. Given an ω -language $\mathcal{L} \subseteq \Sigma^\omega$, its *prefix*, denoted by $pr\mathcal{L}$, is the following language:

$$pr\mathcal{L} \stackrel{\text{def}}{=} \{s \in \Sigma^* \mid \exists e \in \mathcal{L} \text{ s.t. } s < e\}.$$

Note that $pr\mathcal{L} = pr\bar{\mathcal{L}}$, where $\bar{\mathcal{L}}$ denotes the topological closure³ of \mathcal{L} in the metric space (Σ^ω, d) [7]. It can be proved [7] that for a ω -language $\mathcal{L} \subseteq \Sigma^\omega$,

$$(pr\mathcal{L})^\infty = \bar{\mathcal{L}}.$$

With the above preliminary notions we can address the issue of stability of the infinite behavior of a given DEDS. Let $P \equiv (X, \Sigma, \alpha, x_0, X_m)$ denote the plant. Then as defined above, $L_m(P), L(P) \subseteq \Sigma^*$ denote its (finite) marked, generated languages respectively. The ω -language generated by P , denoted by $\mathcal{L}(P)$, is defined to be

$$\mathcal{L}(P) \stackrel{\text{def}}{=} \{e \in (L(P))^\infty \mid \exists \text{ infinitely many } n \in \mathcal{N} \text{ s.t. } \alpha(e^n, x_0) \in X_m\} = (L_m(P))^\infty.$$

Note that the ω -language $\mathcal{L}(P)$ generated by P as defined above is also the ω -language generated by P viewed as a Büchi automaton [7]. P is said to be *nonblocking* if $pr\mathcal{L}(P) = L(P)$. Let $S \equiv (Y, \Sigma, \beta, y_0, Y_m)$ denote the supervisor that controls P by synchronization as defined above. Then the ω -language generated by the closed-loop system $P \square S$ is defined to be

$$\mathcal{L}(P \square S) \stackrel{\text{def}}{=} (L(P \square S))^\infty \cap \mathcal{L}(P).$$

Let $\mathcal{K} \subseteq \mathcal{L}(P)$ be the desired ω -language. It is shown in [19] that a complete, nonblocking supervisor exists for achieving the desired sequential behavior if and only if \mathcal{K} is ω -controllable with respect to P .

DEFINITION 6.1. An ω -language $\mathcal{K} \subseteq \Sigma^\omega$ is said to be ω -controllable with respect to the plant P if $pr\mathcal{K}$ is controllable with respect to P , and \mathcal{K} is topologically closed with respect to $\mathcal{L}(P)$; i.e.,

1. $pr(\mathcal{K})\Sigma_u \cap L(P) \subseteq pr\mathcal{K}$, and
2. $\bar{\mathcal{K}} \cap \mathcal{L}(P) = \mathcal{K}$.

It is further shown in [19] that if \mathcal{K} is not ω -controllable, but is topologically closed with respect to $\mathcal{L}(P)$, then the *supremal ω -controllable* sublanguage, denoted by \mathcal{K}^\uparrow , of \mathcal{K} exists.⁴ Thus the construction of the *minimally restrictive supervisor* is possible. A closed-form expression for the supremal ω -controllable sublanguage, as well as an efficient algorithm for computing it, is presented in [13], [12].

Next, let $\mathcal{K} \subseteq \Sigma^\omega$ represent the desired eventual sequential behavior of the plant $P \equiv (X, \Sigma, \alpha, x_0, X_m)$. The notion of ω -stability is defined as follows.

DEFINITION 6.2. The plant sequential behavior $\mathcal{L}(P)$ is said to be ω -stable with respect to the desired eventual sequential behavior \mathcal{K} if there exists an integer $N \in \mathcal{N}$ such that $\mathcal{L}(P) \subseteq \Sigma^{\leq N}\mathcal{K}$. $\mathcal{L}(P)$ is said to be ω -stabilizable with respect to \mathcal{K} if there exists a nonempty ω -controllable sublanguage $\mathcal{H} \subseteq \mathcal{L}(P)$ such that \mathcal{H} is ω -stable with respect to \mathcal{K} .

³ The notation $\bar{\mathcal{L}}$ is used to denote topological closure whenever $\mathcal{L} \subseteq \Sigma^\omega$, and the notation \bar{L} is used to denote the prefix closure whenever $L \subseteq \Sigma^*$.

⁴ The notation \mathcal{K}^\uparrow is used to denote the supremal ω -controllable sublanguage of $\mathcal{K} \subseteq \Sigma^\omega$, and the notation K^\uparrow is used to denote the supremal controllable sublanguage of $K \subseteq \Sigma^*$.

Let $e \in \Sigma^\omega$ be an infinite string and for each $n \in \mathcal{N}$, let $f_n \in \Sigma^\omega$ be such that $e = e^n f_n$. Then the *projection* operator $\Pi_n : \Sigma^\omega \rightarrow \Sigma^\omega$ ($n \in \mathcal{N}$) is defined in the following manner:

$$\Pi_n(e) = f_n.$$

In other words, given an infinite string $e \in \Sigma^\omega$, its projection $\Pi_n(e)$ is obtained by deleting its prefix of size n from it. Thus if $\mathcal{L}(P)$ is ω -stable with respect to \mathcal{K} , then for each $e \in \mathcal{L}(P)$ there exists an integer $n_e \leq N$ such that $\Pi_{n_e}(e) \in \mathcal{K}$. In other words, each infinite string in $\mathcal{L}(P)$ after removing a prefix of size at most N matches an infinite string in \mathcal{K} . The ω -language \mathcal{K} thus can be thought of to be representing the desired eventual sequential behavior. If $\mathcal{L}(P)$ is not ω -stable but ω -stabilizable with respect to \mathcal{K} , then there exists a nonempty ω -controllable sublanguage $\mathcal{H} \subseteq \mathcal{L}(P)$ that is ω -stable with respect to \mathcal{K} also. Thus a nonblocking and complete [19] supervisor, which can restrict the sequential behavior of the plant to \mathcal{H} that “stabilizes” to the desired eventual sequential behavior \mathcal{K} , can be constructed.

6.1. Tests for ω -stability and ω -stabilizability. In this subsection we show that under certain assumptions ω -stability can be tested by performing the test for ℓ -stability. First, we define the notion of *complete* languages, which is useful in the context of studying the stability of infinite behaviors.

DEFINITION 6.3. Consider a language $L \subseteq \Sigma^*$. A string $s \in L$ is said to have an *extension* in L if there exists a $t \in L$ such that $s < t$. L is said to be *complete*⁵ if for every string $s \in L$, there exists an extension in L .

Note that a language is complete if and only if a trim SM recognizing it is *live* (has at least one transition defined at each of its states) [13]. First, we show that ℓ -stability of a given language with respect to another implies ω -stability of the limit of the given language with respect to the limit of the other.

THEOREM 6.4. Consider $L, K \subseteq \Sigma^*$. If L is ℓ -stable with respect to K , then L^∞ is ω -stable with respect to K^∞ .

We prove the following lemma before proving the result of Theorem 6.4.

LEMMA 6.5. Consider $L \subseteq \Sigma^*$. Then for any $N \in \mathcal{N}$, $(\Sigma^{\leq N} L)^\infty = \Sigma^{\leq N} L^\infty$.

Proof. First, we show that $\Sigma^{\leq N} L^\infty \subseteq (\Sigma^{\leq N} L)^\infty$. Pick $e \in \Sigma^{\leq N} L^\infty$. Then e can be written as $e = e^n f$, where $n \leq N$ and $f \in L^\infty$. Thus there exist infinitely many $m \in \mathcal{N}$ such that $f^m \in L$. Then the strings $e^n f^m \in \Sigma^{\leq N} L$ for each $m \in \mathcal{N}$. Hence $\lim_{m \rightarrow \infty} e^n f^m \in (\Sigma^{\leq N} L)^\infty$. Also, since $e^n f^1 < e^n f^2 < \dots < e^n f^m < \dots < e$, it follows that $\lim_{m \rightarrow \infty} e^n f^m = e$, which shows that $e \in (\Sigma^{\leq N} L)^\infty$.

Next, we show that $(\Sigma^{\leq N} L)^\infty \subseteq \Sigma^{\leq N} L^\infty$. Pick $e \in (\Sigma^{\leq N} L)^\infty$. Then there exist infinitely many $n \in \mathcal{N}$ such that $e^n \in \Sigma^{\leq N} L$. Thus each e^n can be written as $e^n = u_n v_n$, where $u_n \in \Sigma^{\leq N}$ and $v_n \in L$. Since the set $\Sigma^{\leq N}$ is finite, it follows that there exists at least one integer $n_0 \in \mathcal{N}$ such that $u_{n_0} = u_n$ for infinitely many n . Let $\{n_k\}_{k \in \mathcal{N}}$ be a subsequence such that $u_{n_1} = u_{n_2} = \dots = u_{n_k} = \dots = u_{n_0}$. Then $e^{n_k} = u_{n_0} v_{n_k}$ for each $k \in \mathcal{N}$. Hence $e = \lim_{k \rightarrow \infty} e^{n_k} = u_{n_0} \lim_{k \rightarrow \infty} v_{n_k}$. Since $u_{n_0} \in \Sigma^{\leq N}$ and $v_{n_k} \in L$ for each $k \in \mathcal{N}$, it follows that $e \in \Sigma^{\leq N} L^\infty$. \square

Proof of Theorem 6.4. Since L is ℓ -stable with respect to K , there exists an integer $N \in \mathcal{N}$ such that $L \subseteq \Sigma^{\leq N} K$. Hence, by taking limits on both sides of the last inclusion, we obtain $L^\infty \subseteq (\Sigma^{\leq N} K)^\infty$. It then follows from Lemma 6.5 that $L^\infty \subseteq \Sigma^{\leq N} K^\infty$, which shows that L^∞ is ω -stable with respect to K^∞ . \square

⁵ Completeness is also defined to be a property of supervisors; here we define it to be a property of languages. The two definitions are unrelated and not to be confused with.

Example 6.6. Consider languages L, K_1 of Example 4.5. Then $L^\infty = ((ab)^*cd^*)^\omega = (ab)^*cd^\omega$ and $(K_1)^\infty = (d^* + bab(ab)^*cd^*)^\infty = d^\omega + bab(ab)^*cd^\omega$. Using arguments similar to those in Example 4.5, it can be easily verified that $L^\infty \subseteq \Sigma^{\leq 3}(K_1)^\infty$. This shows, as expected from the result of Theorem 6.4, that L^∞ is ω -stable with respect to $(K_1)^\infty$. However, the converse of Theorem 6.4 does not hold in general. Consider, for example, languages $L, K \subseteq \{a, b\}^*$: $L = (ab)^*$ and $K = (ba)^*$. Then $L^\infty = (ab)^\omega$ and $K^\infty = (ba)^\omega$. Since $(ab)^\omega = a(ba)^\omega$, it is obvious that L^∞ is ω -stable with respect to K^∞ ($L^\infty = aK^\infty$). It can also be easily checked that L is not ℓ -stable with respect to K : a string in L ends with the symbol b , whereas a string in K ends with the symbol a . Thus, given any string in L , no suffix of it matches any string in K .

Next we prove that under certain assumptions the converse of Theorem 6.4 holds.

THEOREM 6.7. *Consider $L, K \subseteq \Sigma^*$. Assume that L is complete and K is prefix closed. Then ω -stability of L^∞ with respect to K^∞ implies ℓ -stability of L with respect to K .*

Before proving the result of Theorem 6.7, we prove the following lemma.

LEMMA 6.8. *Consider two languages $L_1, L_2 \subseteq \Sigma^*$. Assume that L_1 is complete and L_2 is closed. Then $(L_1)^\infty \subseteq (L_2)^\infty$ if and only if $L_1 \subseteq L_2$.*

Proof. It is clear that $L_1 \subseteq L_2$ implies $L_1^\infty \subseteq L_2^\infty$. Hence it suffices to show that if $(L_1)^\infty \subseteq (L_2)^\infty$, then $L_1 \subseteq L_2$. Pick $s \in L_1$. Since L_1 is complete, there exists a sequence of strings $s_1 < s_2 < \dots < s_n < \dots$ such that $s_n \in L_1$ for each $n \in \mathcal{N}$ and $s < s_1$. Let $e = \lim_{n \rightarrow \infty} s_n$; then $e \in (L_1)^\infty$. It then follows from the assumption that $e \in (L_2)^\infty$. Hence there exist infinitely many $n \in \mathcal{N}$ such that $e^n \in L_2$. Pick $m \in \mathcal{N}$ such that $s < e^m$. Since $e^m \in L_2$ and L_2 is closed, it follows that $s \in L_2$. \square

Proof of Theorem 6.7. Assume that L^∞ is ω -stable with respect to K^∞ . Then there exists an integer $N \in \mathcal{N}$ such that $L^\infty \subseteq \Sigma^{\leq N}K^\infty$. Thus it follows from Lemma 6.5 that $L^\infty \subseteq (\Sigma^{\leq N}K)^\infty$. Note that since $\Sigma^{\leq N}$ is closed, and prefix closure is preserved under concatenation of languages, $\Sigma^{\leq N}K$ is a closed language (by assumption K is closed). Since L is complete (by assumption) and $\Sigma^{\leq N}K$ is closed, we obtain from Lemma 6.8 that $L^\infty \subseteq (\Sigma^{\leq N}K)^\infty$ if and only if $L \subseteq \Sigma^{\leq N}K$. \square

Example 6.9. Consider the languages $L = (ab)^*$ and $K = (ba)^*$ of Example 6.6. It was noted in Example 6.6 that L^∞ is ω -stable with respect to K^∞ ; however, L is not ℓ -stable with respect to K . The reason is that although L is a complete language, K is not prefix closed. Let us replace K by its prefix closure, i.e., consider $K' = \overline{K} = (ba)^* = (ba)^* + b(ab)^*$. Then clearly L is ℓ -stable with respect to K' ($L = (ab)^* = ab + ab(ab)^* \subseteq \Sigma^{\leq 2}K'$).

The results of Theorem 6.4 and Theorem 6.7 can be combined to arrive at a test for ω -stability based on the test for ℓ -stability (Theorem 4.12).

THEOREM 6.10. *Let $\mathcal{L}(P) = (L_m(P))^\infty \subseteq \Sigma^\omega$ denote the plant ω -behavior and $\mathcal{K} \subseteq \Sigma^\omega$ denote the desired eventual behavior. If P is live and \mathcal{K} is topologically closed, then $\mathcal{L}(P)$ is ω -stable with respect to \mathcal{K} if and only if $L_m(P)$ is ℓ -stable with respect to $pr\mathcal{K}$.*

Proof. Since P is live, $L_m(P)$ is complete. Also, since \mathcal{K} is topologically closed, $\mathcal{K} = \overline{\mathcal{K}} = (pr\mathcal{K})^\infty$. Thus $\mathcal{L}(P)$ is the limit of the complete language $L_m(P)$ and \mathcal{K} is the limit of the prefix-closed language $pr\mathcal{K}$. Hence it follows from Theorem 6.4 and Theorem 6.7 that $\mathcal{L}(P)$ is ω -stable with respect to \mathcal{K} if and only if $L_m(P)$ is ℓ -stable with respect to $pr\mathcal{K}$. \square

Next we relate the notion of ω -stabilizability to that of ω -stability through the following theorem.

THEOREM 6.11. $\mathcal{L}(P)$ is ω -stabilizable with respect to \mathcal{K} if and only if $\mathcal{L}(P) \cap \Sigma_u^\omega$ is nonempty and ω -stable with respect to \mathcal{K} , where $\Sigma_u^\omega = (\Sigma_u^*)^\omega$.

Proof. We first show that $\mathcal{L}(P) \cap \Sigma_u^\omega$ is the infimal ω -controllable sublanguage of $\mathcal{L}(P)$, i.e., it is the sequential behavior of P under the control of maximally restrictive complete and nonblocking supervisor [19]. Consider the supervisor that disables all the controllable events in P . Then the behavior of the closed-loop system under this control law is given by $L(P) \cap \Sigma_u^*$. Hence the sequential behavior of the closed-loop system is given by $(L(P) \cap \Sigma_u^*)^\omega \cap \mathcal{L}(P) = (L(P))^\omega \cap (\Sigma_u^*)^\omega \cap \mathcal{L}(P) = \mathcal{L}(P) \cap \Sigma_u^\omega$, where the first equality follows from the fact that $L(P), \Sigma_u^*$ are both closed languages and the second equality follows from the fact that $\mathcal{L}(P) \subseteq (L(P))^\omega$ and $(\Sigma_u^*)^\omega = \Sigma_u^\omega$. Note that the supervisor that disables all the controllable transitions in P is complete (it never disables any uncontrollable transition) and nonblocking (since $pr(\mathcal{L}(P) \cap \Sigma_u^\omega) = L(P) \cap \Sigma_u^*$). Hence $\mathcal{L}(P) \cap \Sigma_u^\omega$ is ω -controllable [19]. Since it is the sequential behavior under the maximally restrictive complete and nonblocking control law, if $\mathcal{H} \subseteq \mathcal{L}(P)$ is any ω -controllable sublanguage of $\mathcal{L}(P)$, then $\mathcal{L}(P) \cap \Sigma_u^\omega \subseteq \mathcal{H}$.

Assume then that $\mathcal{L}(P)$ is ω -stabilizable with respect to \mathcal{K} . Then by the definition of ω -stabilizability, there exists a nonempty ω -controllable sublanguage $\mathcal{H} \subseteq \mathcal{L}(P)$ and an integer $N \in \mathcal{N}$ such that $\mathcal{H} \subseteq \Sigma^{\leq N} \mathcal{K}$. Since $\mathcal{L}(P) \cap \Sigma_u^\omega \subseteq \mathcal{H}$, it follows that $\mathcal{L}(P) \cap \Sigma_u^\omega \subseteq \Sigma^{\leq N} \mathcal{K}$; which shows that $\mathcal{L}(P) \cap \Sigma_u^\omega$ is ω -stable with respect to \mathcal{K} .

Assume next that $\mathcal{L}(P) \cap \Sigma_u^\omega$ is nonempty and ω -stable with respect to \mathcal{K} . Since $\mathcal{L}(P) \cap \Sigma_u^\omega \subseteq \mathcal{L}(P)$ and is ω -controllable (proved above), it follows that $\mathcal{L}(P)$ is ω -stabilizable with respect to \mathcal{K} . \square

Remark 6.12. A necessary condition for ω -stability is obtained using an equivalence relation on the space Σ^ω introduced in Appendix B. It is also shown in Appendix B that if a weaker definition of ω -stability is used the necessary condition obtained in terms of the equivalence relation is also a sufficient condition.

7. Conclusion. In this paper, we have introduced the notions of stability and stabilizability of DEDSs in terms of their behavior. In many situations, since the behavior rather than the states of the system is observed directly, it is more natural to study the stability of systems in terms of their behavior. Also, in some cases, it might be desired that the eventual (rather than the whole) behavior of the system be legal, so it is necessary to define formally the notion of language stability. Earlier works concerning stability of DEDSs [18], [2], [3] are all based in terms of the states of the systems and can be viewed as a special case of the work presented here (refer to Proposition 4.4). The earlier works [18], [2], [3] on stability in terms of states assume the control to be of static feedback type; however, more general supervisors that exercise dynamic feedback have been used here for making the systems ℓ -stable.

We have shown that the problem of determining ℓ -stability (ℓ -stabilizability) of a given language with respect to another language is equivalent to another problem posed in terms of the reversal of languages (refer to Corollary 4.10) and have provided a solution to this equivalent problem (refer to Theorems 4.12 and 4.17). We have also provided an upper bound to the value of the integer N in the definition of ℓ -stability (ℓ -stabilizability) using the solution to the equivalent problem (refer to Corollary 4.10). Next we have presented a weaker notion of language stability in which no uniform upper bound on the length of the prefix to be removed from a string in a language (for it to be ℓ -stable with respect to another language) exists and have provided the construction of the *minimally restrictive supervisor* [10], [21], [20], [11] to ℓ -stabilize a given language in this weaker sense of language stability.

The notion of ℓ -stability and ℓ -stabilizability is then generalized to describe the

notion of stability of sequential behavior of DEDSs and the notions of ω -stability and ω -stabilizability are introduced in this context. We have introduced an equivalence relation on the space of infinite strings and have obtained a necessary condition of ω -stability in terms of this relation. A necessary and sufficient condition for ω -stability is obtained in terms of ℓ -stability, which is used to arrive at tests for ω -stability and ω -stabilizability.

A. Algorithm for constructing $\Omega(\hat{X})$ and $\Lambda(\hat{X})$. As before, let

$$P \stackrel{\text{def}}{=} (X, \Sigma, \alpha, x_0, X_m)$$

be the plant and $\hat{X} \subseteq X$ be the set of legal states. The following algorithm can be used to compute $\Omega(\hat{X})$ (we assume that the plant P has finite number of states so that the algorithm terminates in finite number of steps).

ALGORITHM A.1.

1. Initiation step:

Set $\Omega_{-1}(\hat{X}) = \emptyset, \Omega_0(\hat{X}) = \hat{X}$, and $k = 0$.

2. Iteration step:

- (a) Let $X_k \subseteq X$ be the set of states from which $\Omega_k(\hat{X}) - \Omega_{k-1}(\hat{X})$ can be reached in a single transition, i.e.,

$$X_k = \{x \in X \mid \exists \sigma \in \Sigma \text{ s.t. } \alpha(\sigma, x) \in \Omega_k(\hat{X}) - \Omega_{k-1}(\hat{X})\}.$$

Determine the set X_k by considering the SM $P^{-1} \stackrel{\text{def}}{=} (X, \Sigma, \alpha^{-1}, x_0, X_m)$, where $\alpha^{-1}(\sigma, x_2) \stackrel{\text{def}}{=} \{x_1 \in X \mid \alpha(\sigma, x_1) = x_2\}$ (P^{-1} is the SM obtained by reversing all the transitions of P), and by finding the states that can be reached from $\Omega_k(\hat{X}) - \Omega_{k-1}(\hat{X})$ by a single transition in P^{-1} .

- (b) Consider $x \in X_k$. If all the transitions from x lead to $\Omega_k(\hat{X})$, then $\Omega_{k+1}(\hat{X}) = \Omega_k(\hat{X}) \cup \{x\}$. Repeat this for all $x \in X_k$. Thus, if all the transitions from a state $x \in X_k$ lead to states in $\Omega_k(\hat{X})$, then x is a strongly attractable state, i.e.,

$$\Omega_{k+1}(\hat{X}) = \Omega_k(\hat{X}) \cup \{x \in X_k \mid \alpha(\sigma, x) \in \Omega_k(\hat{X}) \text{ for all } \sigma \in \Sigma(P)(x)\},$$

where $\Sigma(P)(x) \subseteq \Sigma$ is the set of all the transitions that are defined in the state $x \in X$ in P and is given by $\Sigma(P)(x) = \{\sigma \in \Sigma \mid \alpha(\sigma, x)!\}$.

3. Termination step:

If $\Omega_{k+1}(\hat{X}) = \Omega_k(\hat{X})$, then stop and set $\Omega(\hat{X}) = \Omega_k(\hat{X})$; else set $k = k + 1$ and go to step 2.

THEOREM A.2. *Algorithm A.1 computes the region of strong attraction $\Omega(\hat{X})$ of the set of legal states $\hat{X} \subseteq X$.*

Proof. The proof that Algorithm A.1 computes $\Omega(\hat{X})$ is based on the following two facts:

First, the above algorithm computes $\Omega(\hat{X})$ if in step 2, $\Omega_k(\hat{X}) - \Omega_{k-1}(\hat{X})$ is replaced by $\Omega_k(\hat{X})$ (for proof refer to [18, Prop. 2.7]).

Second, at the end of the k th iteration, to determine the states that might be strongly attractable, we just need to consider the states that have transitions leading into the set $\Omega_{k+1}(\hat{X}) - \Omega_k(\hat{X})$ (rather than into the set $\Omega_{k+1}(\hat{X})$) in P , so that the replacement as described above is justified (see Fig. 6). In other words, we must show that at the end of k th iteration, if all the transitions in $\Sigma(P)(x)$ from the state

FIG. 6. Constructing region of strong attraction.

$x \in X - \Omega_{k+1}(\hat{X})$ lead to the set $\Omega_{k+1}(\hat{X})$, then there exists $\sigma \in \Sigma(x)$ such that $\alpha(\sigma, x) \in \Omega_{k+1}(\hat{X}) - \Omega_k(\hat{X})$. To show this, we first partition $\Sigma(P)(x)$ into the set $\Sigma_1(P)(x) \cup \Sigma_2(P)(x)$, the set $\Sigma_1(P)(x)$ of transitions leading to $\Omega_k(\hat{X})$ and the set $\Sigma_2(P)(x)$ of transitions leading to $\Omega_{k+1}(\hat{X}) - \Omega_k(\hat{X})$. Then it is enough to show that the set $\Sigma_2(x)$ is nonempty. Assume that it is empty; then $x \in \Omega(\Omega_k(\hat{X}))$; therefore it belongs to the set $\Omega_{k+1}(\hat{X})$, which is contradictory to the fact that $x \in X - \Omega_{k+1}(\hat{X})$. This proves the second claim. \square

Remark A.3. To determine the region of weak attraction $\Lambda(\hat{X})$ of \hat{X} , we replace step 2(b) in the iteration step of the previous algorithm by the following step 2(b'):

2(b') Consider $x \in X_k$. If all the uncontrollable transitions from x lead to $\Omega_k(\hat{X})$, then $\Omega_{k+1}(\hat{X}) = \Omega_k(\hat{X}) \cup \{x\}$, i.e.,

$$\Omega_{k+1}(\hat{X}) = \Omega_k(\hat{X}) \cup \{x \in X_k \mid \alpha(\sigma, x) \in \Omega_k(\hat{X}) \text{ for all } \sigma \in \Sigma_u(P)(x)\},$$

where $\Sigma_u(P)(x) = \Sigma(P)(x) \cap \Sigma_u$.

This can be tested by considering the transitions in $P|_{\Sigma_u}$ (P with all its controllable transitions deleted). Formally, $P|_{\Sigma_u} \stackrel{\text{def}}{=} (X, \Sigma_u, \alpha|_{\Sigma_u \times X}, x_0, X_m)$.

This would result in the construction of the region of weak attraction $\Lambda(\hat{X})$ of \hat{X} . Note that with an abuse of notation we have used $\Omega_k(\hat{X})$ in the algorithm for determining $\Lambda_k(\hat{X})$.

THEOREM A.4. The time complexity of Algorithm A.1 for constructing $\Omega(\hat{X})$ and $\Lambda(\hat{X})$ is $O(|\Sigma|n)$, where $|\Sigma|$ denotes the number of events in the event set Σ and n is the number of states in P .

Proof. Assume that at the end of k th iteration, the number of transitions (of length one) leading into the set $\Omega_{k+1}(\hat{X}) - \Omega_k(\hat{X})$ from $X - \Omega_{k+1}(\hat{X})$ is e_k . We show that step 2 of the algorithm can be computed in $O(e_k)$ time, as follows.

First, the states in the set X_k can be computed in $O(e_k)$ time, for to determine the states reachable from the states in the set $\Omega_{k+1}(\hat{X}) - \Omega_k(\hat{X})$ by a single transition in P^{-1} , we need consider only the e_k transitions. Second, since there could be at most

e_k such states, the states in the set $\Omega_{k+1}(\hat{X})$ can also be computed in $O(e_k)$ time. This is true because to test whether a state $x \in X_k$ belongs to $\Omega_{k+1}(\hat{X})$ requires only $O(|\Sigma|)$ time, which is constant.

Since the sets $\Omega_{k+1}(\hat{X}) - \Omega_k(\hat{X})$ for each value of k are all disjoint, the transitions (of length one) leading into them from $X - \Omega_{k+1}(\hat{X})$ are also all disjoint. Hence the computational complexity of Algorithm A.1 is of order $O(\sum_k e_k) = O(e)$, where e is the number of transitions in P . Since P is deterministic, $e \leq |\Sigma|n$; hence the theorem follows. Similarly, the complexity of the algorithm for determining $\Lambda(\hat{X})$ is also $O(|\Sigma|n)$. \square

This is significant improvement over the computational complexity of the algorithm given in [2], [3], which is $O(n^2)$. Note that our algorithm requires the construction of the SM P^{-1} , which could be nondeterministic, but has same number of transitions as P .

The above algorithm can also be used to construct the *prestable* and *prestablizable* states of a given *invariant* state set as defined in [18]. In fact, the set of prestable states and the set of prestabilizable states with respect to a given invariant or legal set of states is the same as $\Omega(\hat{X})$ and $\Lambda(\hat{X})$, respectively, where \hat{X} denotes the set of invariant states. The computational complexity of the algorithms provided in [18] is also quadratic in the number of states of P .

B. An equivalence relation on Σ^ω and ω -stability. A necessary condition for ω -stability of a given ω -language with respect to another can be obtained in terms of an equivalence relation defined on the space Σ^ω . In this appendix we define this relation and show its close relation to the notion of ω -stability.

DEFINITION B.1. For $e_1, e_2 \in \Sigma^\omega$, $e_1 \cong e_2$ if and only if there exist $m, n \in \mathcal{N}$ such that $\Pi_m(e_1) = \Pi_n(e_2)$. Note that for each $n \in \mathcal{N}$, $\Pi_n : \Sigma^\omega \rightarrow \Sigma^\omega$ is the map such that for $e \in \Sigma^\omega$, $\Pi_n(e)$ is the infinite string obtained by removing the prefix of length n from e .

THEOREM B.2. *The relation \cong as defined is an equivalence relation.*

Proof. We must show that the relation \cong is reflexive, symmetric, and transitive.

It is clear that for any vector $e_1 \in \Sigma^\omega$, $e_1 \cong e_1$, i.e., \cong is reflexive. Also, if $e_1 \cong e_2$, then clearly $e_2 \cong e_1$ for any two vectors $e_1, e_2 \in \Sigma^\omega$, i.e., \cong is symmetric. It remains to show that the relation \cong is transitive. Pick any $e_1, e_2, e_3 \in \Sigma^\omega$. We will show that $e_1 \cong e_2$ and $e_2 \cong e_3$ implies $e_1 \cong e_3$. Let $m, n, p, q \in \mathcal{N}$ be such that $\Pi_m(e_1) = \Pi_n(e_2)$ and $\Pi_p(e_2) = \Pi_q(e_3)$. We may have either $n \leq p$ or $p \leq n$. If $n \leq p$, then $\Pi_{m+(p-n)}(e_1) = \Pi_q(e_3)$, i.e., $e_1 \cong e_3$; if $p \leq n$, then $\Pi_m(e_1) = \Pi_{q+(n-p)}(e_3)$, i.e., $e_1 \cong e_3$. \square

A necessary condition for ω -stability can be obtained using the equivalence relation defined above.

PROPOSITION B.3. *If plant sequential behavior $\mathcal{L}(P)$ is ω -stable with respect to the desired eventual behavior \mathcal{K} , then for each $e \in \mathcal{L}(P)$, there exists $e' \in \mathcal{K}$ such that $e \cong e'$.*

Proof. Assume $\mathcal{L}(P)$ is ω -stable with respect to \mathcal{K} , i.e., there exist $N \in \mathcal{N}$ such that $\mathcal{L}(P) \subseteq \Sigma^{\leq N}\mathcal{K}$. Then given $e \in \mathcal{L}(P)$, there exists $n \leq N$ and $e' \in \mathcal{K}$ such that $e = e^n e'$. Thus $\Pi_n(e) = e'$, i.e. $e \cong e'$. \square

Remark B.4. Proposition B.3 gives a necessary condition for ω -stability. This condition will be a necessary as well as sufficient condition if a weaker definition of ω -stability is used. Let the projection operator be extended to the space 2^{Σ^ω} in the obvious manner, i.e., for any $n \in \mathcal{N}$, $\Pi_n : 2^{\Sigma^\omega} \rightarrow 2^{\Sigma^\omega}$ is defined to be

$$\Pi_n(\mathcal{L}) = \{e \in \Sigma^\omega \mid \exists e' \in \mathcal{L} \text{ s.t. } \Pi_n(e') = e\},$$

where $\mathcal{L} \subseteq \Sigma^\omega$. We use $\Pi_\star(\cdot)$ to denote the operator $\bigcup_{n \in \mathcal{N}} \Pi_n(\cdot)$. The plant sequential behavior $\mathcal{L}(P)$ is said to be *weakly ω -stable* with respect to the desired eventual sequential behavior \mathcal{K} if $\mathcal{L}(P) \subseteq \Sigma^\star \Pi_\star(\mathcal{K})$. Thus if $\mathcal{L}(P)$ is weakly ω -stable with respect to \mathcal{K} , then for every $e \in \mathcal{L}(P)$ there exist $n, m \in \mathcal{N}$ and $e' \in \mathcal{K}$ such that $\Pi_n(e) = \Pi_m(e')$. It is clear that ω -stability implies weak ω -stability. It can easily be verified that $\mathcal{L}(P)$ is weakly ω -stable with respect to \mathcal{K} if and only if given any $e \in \mathcal{L}(P)$ there exists $e' \in \mathcal{K}$ such that $e \cong e'$.

ASYMPTOTIC STABILITY OF INFINITE-DIMENSIONAL DISCRETE-TIME BALANCED REALIZATIONS*

RAIMUND OBER[†] AND YUANYIN WU[‡]

Abstract. The question of power and asymptotic stability of infinite-dimensional discrete-time state space systems is investigated. It is shown that every balanced realization is asymptotically stable. Conditions are given for balanced, input normal, or output normal realizations to be asymptotically and/or power stable.

Key words. linear infinite-dimensional systems, balanced realizations, stability, Hankel operator

AMS subject classifications. 93B15, 93B20, 93B28, 93D20

1. Introduction. Balanced realizations for finite-dimensional systems have received a great deal of attention. They were introduced as a means of performing model reduction in an easy fashion [7] and have subsequently been used in H^∞ control theory, for example, to evaluate the Hankel norm of a linear system [4], [5]. Recently, they have been used to study parametrization problems of certain sets of linear systems [9].

The elegant results obtained for finite-dimensional balanced systems aroused interest in the problem of the extension of the notion of a balanced realization to infinite-dimensional systems. Glover, Curtain, and Partington [5] derived continuous-time balanced realizations for a class of systems with nuclear Hankel operators. Young [13] developed a very general realization theory for infinite discrete-time systems. Similar results were obtained in the continuous-time case by Ober and Montgomery-Smith [10].

One of the fundamental problems in systems theory is the question of stability of the system. In this paper, we will address this problem in the case of infinite-dimensional balanced realizations and the closely related input and output normal realizations. We show that every balanced realization is asymptotically stable. In general, input normal and output normal realizations do not have the same stability properties as balanced realizations, but we can also give necessary and sufficient conditions for them to be asymptotically and/or power stable. The result is that an input normal or output normal realization is power stable if and only if its transfer function is rational and proper with poles inside the open unit disk, whereas the power stability of a parbalanced realization is more complicated to characterize in terms of the properties of the transfer function.

The approach we take in the proofs of the results is to relate balanced realizations and, in particular, the input and output normal realizations to restricted shift realizations. We start in §2 with the restricted and *-restricted shift realizations and study their connections with Hankel operators, shift operators, and the Douglas–Shapiro–Shields factorizations of analytical functions. In §3, using these connections and the spectral theory of shift operators, we are able to give the above-mentioned necessary and sufficient conditions for the asymptotic and power stability of the output normal

and input normal realizations. Young [13] established the existence of parbalanced realization for any function $G \in TLD^{U,Y}$. In §4 we prove that parbalanced realizations are always asymptotically stable. We also give examples that show the difficulty to analyze the power stability of a parbalanced realization in connection with its transfer function. A concluding remark is given on how to restrict ourselves to a slightly smaller class of discrete-time transfer functions and linear systems so that we can transpose all our results to the continuous-time case using a bilinear mapping (see [10]).

The following symbols are used:

\mathbb{D}	the open unit disk,
$\partial\mathbb{D}$	the unit circle,
\mathbb{D}_e	the exterior of $(\partial\mathbb{D}) \cup \mathbb{D}$,
$D_X^{U,Y}$	defined in §2,
$G^\perp(z)$	$(1/z)[G(1/z) - G(\infty)]$, $z \in \mathbb{D}$ for $G \in TLD^{U,Y}$,
H_K	the Hankel operator with symbol K ,
$H_{\mathcal{L}(U,Y)}^\infty(\mathbb{D})$	$\{F \mid F : \mathbb{D} \rightarrow \mathcal{L}(U, Y) \text{ analytic and bounded on } \mathbb{D}\}$,
$H_Y^2(\mathbb{D})$	$\{f \mid f : \mathbb{D} \rightarrow Y \text{ analytic on } \mathbb{D} \text{ and}$ $\sup_{0 < r < 1} \int_0^{2\pi} \ f(re^{it})\ ^2 dt < \infty\}$,
J	$L_U^2(\partial\mathbb{D}) \rightarrow L_Y^2(\partial\mathbb{D})$, $(Jf)(z) = f(z^{-1})$,
$\tilde{K}(z)$	$(K(\bar{z}))^*$,
$\mathcal{L}(U, Y)$	$\{A \mid A : U \rightarrow Y \text{ a bounded operator}\}$,
$L_Y^2(\partial\mathbb{D})$	$\{f \mid f : \partial\mathbb{D} \rightarrow Y \text{ square integrable on } \partial\mathbb{D}\}$,
$L_{\mathcal{L}(U,Y)}^\infty(\partial\mathbb{D})$	$\{F \mid F : \partial\mathbb{D} \rightarrow \mathcal{L}(U, Y) \text{ measurable and essentially bounded}$ on $\partial\mathbb{D}\}$,
P_+	the orthogonal projection of $L_Y^2(\partial\mathbb{D})$ onto $H_Y^2(\mathbb{D})$,
P_X	the orthogonal projection of $H_Y^2(\mathbb{D})$ onto $X \subseteq H_Y^2(\mathbb{D})$,
S	the forward shift: $(Sf)(z) = zf(z)$ for $f \in H_Y^2(\mathbb{D})$,
S^*	the backward shift: $(S^*f)(z) = z^{-1}[f(z) - f(0)]$ for $f \in H_Y^2(\mathbb{D})$,
$S(Q)$	$P_X S _X$, the compression of S to X ,
	where $X = H_Y^2(\mathbb{D}) \ominus (QH_Y^2(\mathbb{D}))$,
$S(Q)^*$	$S^* _{H_Y^2(\mathbb{D}) \ominus (QH_Y^2(\mathbb{D}))}$, the restriction of S^* to $H_Y^2(\mathbb{D}) \ominus (QH_Y^2(\mathbb{D}))$,
$\sigma(A)$	the spectrum of an operator A ,
$\sigma_p(A)$	the point spectrum of an operator A ,
$\sigma(Q)$	the spectrum of an inner function $Q \in H_Y^\infty(\mathbb{D})$ (see §3),
$\sigma_s(G)$	the set of points in \mathbb{C} where G has no analytic continuation (see Theorem 3.14),
$TLD^{U,Y}$	defined in §3,
$X \vee Y$	closed linear span of subsets X and Y of a Hilbert space,
$(F, G)_L = I_Y$	F and G are weakly left coprime (see §2),
$(F, G)_R = I_U$	F and G are weakly right coprime (see §2).

2. Hankel operators and shift realizations for discrete-time systems.

Our results will be based on the analysis of restricted shift realizations whereby the shift realizations can be analyzed in terms of Hankel operators related to the transfer functions. Here we give a brief summary of some results on Hankel operators and the restricted shift realizations of discrete-time transfer functions. We start with some basic definitions.

Let U , X , and Y be separable Hilbert spaces. The linear systems considered in this paper are of the following form:

$$\left. \begin{aligned} x_{k+1} &= Ax_k + Bu_k, \\ y_k &= Cx_k + Du_k, \end{aligned} \right\} k = 0, 1, \dots,$$

where $u_k \in U$, $x_k \in X$, and $y_k \in Y$. The system operators are assumed to be such that A is a contraction on X , $B \in \mathcal{L}(U, X)$, $C \in \mathcal{L}(X, Y)$, and $D \in \mathcal{L}(U, Y)$. This system will be denoted by (A, B, C, D) and the set of all such systems $D_X^{U,Y}$. Unless otherwise stated, the spaces U , X , and Y are assumed to be infinite-dimensional.

For $(A, B, C, D) \in D_X^{U,Y}$, the function $G(z) = C(zI - A)^{-1}B + D$ is called the *transfer function* of (A, B, C, D) and (A, B, C, D) is called a *realization* of G . The *observability operator* $\mathcal{O} : D(\mathcal{O}) \rightarrow H_Y^2(\mathbb{D})$ of the system (A, B, C, D) is defined as

$$(\mathcal{O}x)(z) = \sum_{k \geq 0} (CA^k x)z^k$$

for $x \in D(\mathcal{O}) := \{x \in X \mid \sum_{k \geq 0} (CA^k x)z^k \in H_Y^2\}$. If $D(\mathcal{O}) = X$, \mathcal{O} is bounded and $\text{Ker}(\mathcal{O}) = \{0\}$, then the system (A, B, C, D) is said to be *observable*. The *dual system* of (A, B, C, D) is defined to be (A^*, C^*, B^*, D^*) , which is, in fact, a realization of the transfer function $\tilde{G}(z) := (G(\bar{z}))^*$. The system (A, B, C, D) is said to be *reachable* if its dual system is observable, and the *reachability operator* \mathcal{R} of (A, B, C, D) is defined to be the adjoint of the observability operator of the dual system. In fact, (A, B, C, D) is reachable if and only if the range of $\mathcal{R} : H_U^2(\mathbb{D}) \rightarrow X$ is dense in X , and in this case

$$\mathcal{R} \left(\sum_{k \geq 0} u_k z^k \right) = \sum_{k \geq 0} A^k B u_k, \quad \left(\sum_{k \geq 0} u_k z^k \in H_U^2 \right).$$

Note that we define the observability operator \mathcal{O} to have range in $H_Y^2(\mathbb{D})$ instead of l_Y^2 . Accordingly the domain of the reachability operator \mathcal{R} is in $H_U^2(\mathbb{D})$ instead of l_U^2 . The definitions adapted here are found to be more convenient in our context.

We write $LD_X^{U,Y}$ for the class of reachable and observable systems with state space X . The set of $\mathcal{L}(U, Y)$ -valued transfer functions that have reachable and observable realizations is denoted by $TLD^{U,Y}$. Note that $(A, B, C, D) \in LD_X^{U,Y}$ if and only if $(A^*, C^*, B^*, D^*) \in LD_X^{Y,U}$. Correspondingly, $G \in TLD^{U,Y}$ if and only if $\tilde{G} \in TLD^{Y,U}$, where $\tilde{G}(z) = (G(\bar{z}))^*$, $(z \in \mathbb{D}_e)$.

For an observable and reachable system (A, B, C, D) with observability operator \mathcal{O} and reachability operator \mathcal{R} , the *observability gramian* is defined to be $\mathcal{M} := \mathcal{O}^* \mathcal{O} : X \rightarrow X$, and the *reachability gramian* is $\mathcal{W} := \mathcal{R} \mathcal{R}^* : X \rightarrow X$. If $\mathcal{M} = \mathcal{W}$, then the system is said to be *parbalanced*.

Let G be in $TLD^{U,Y}$; i.e., G has a reachable and observable realization $(A, B, C, D) \in LD_X^{U,Y}$ for some state space X . Let \mathcal{R} be the reachability operator and \mathcal{O} the observability operator of the realization. Hence the operator $\mathcal{OR} : H_U^2(\mathbb{D}) \rightarrow H_Y^2(\mathbb{D})$ is

bounded. By the fact that

$$G^\perp(z) = z^{-1}[G(z^{-1}) - G(\infty)] = C(I - zA)^{-1}B = \sum_{n \geq 0} CA^n Bz^n, \quad z \in \mathbb{D},$$

it can be verified that, for any polynomial $f(z) = \sum_{k=0}^n u_k z^k$, $u_k \in U$,

$$\mathcal{O}Rf = P_+ G^\perp Jf,$$

where $(Jg)(z) = g(z^{-1})$ for any $g \in H_U^2(\mathbb{D})$. In this way $P_+ G^\perp J : H_U^2(\mathbb{D}) \rightarrow H_Y^2(\mathbb{D})$ defines a bounded operator. It is called the *Hankel operator with symbol G^\perp* and is denoted by H_{G^\perp} .

Conversely, let G be a $\mathcal{L}(U, Y)$ -valued function, analytic on \mathbb{D}_e and at infinity such that the Hankel operator $H_{G^\perp} = P_+ G^\perp J : H_U^2(\mathbb{D}) \rightarrow H_Y^2(\mathbb{D})$ is defined for every polynomial $f(z) = \sum_{k=0}^n u_k z^k$, ($u_k \in U$) and can be extended to a bounded operator. Then G has reachable and observable realizations. In fact, G has the restricted shift realization, which was first introduced by Fuhrmann [2] and Helton [6] (see also [13]).

THEOREM 2.1. *Let G be a $\mathcal{L}(U, Y)$ -valued function analytic on \mathbb{D}_e and at infinity such that $H_{G^\perp} : H_U^2(\mathbb{D}) \rightarrow H_Y^2(\mathbb{D})$ defines a bounded operator. Then G has a state space realization (A, B, C, D) with state space X , i.e., for $z \in \mathbb{D}_e$,*

$$G(z) = C(zI - A)^{-1}B + D,$$

which is given in the following way:

The state space X is given by

$$X = \overline{\text{range}} H_{G^\perp} \subseteq H_Y^2(\mathbb{D}).$$

The state propagation operator $A : X \rightarrow X$, the input operator $B : U \rightarrow X$, the output operator $C : X \rightarrow Y$ and the feedthrough operator $D : U \rightarrow Y$ are given by the following, for $f \in X$ and $u \in U$:

$$\begin{aligned} (Af)(z) &:= (S^*f)(z) = \frac{f(z) - f(0)}{z}, \\ (Bu)(z) &:= G^\perp(z)u, \\ Cf &:= f(0), \\ Du &:= G(\infty)u, \end{aligned}$$

where S is the (forward) shift operator: $(Sf)(z) = zf(z)$, $f \in H_Y^2(\mathbb{D})$. The realization (A, B, C, D) is called the restricted shift realization of the transfer function G .

The following proposition shows that the restricted shift realization is reachable and observable.

PROPOSITION 2.2 (see [3] or [13]). *Assume the notation of Theorem 2.1. Then the system (A, B, C, D) is in $LD_X^{U,Y}$; i.e., it is observable and reachable. The observability operator \mathcal{O} and reachability operator \mathcal{R} of (A, B, C, D) are, respectively, given by*

$$\mathcal{O} = I_X : X \rightarrow H_Y^2(\mathbb{D}) \quad \text{and} \quad \mathcal{R} = H_{G^\perp} : H_U^2(\mathbb{D}) \rightarrow X.$$

Therefore the class $TL D^{U,Y}$ of transfer functions can be characterized as the set of $\mathcal{L}(U, Y)$ -valued functions analytic on \mathbb{D}_e and at infinity such that the Hankel operator H_{G^\perp} is bounded. For such transfer functions, the restricted shift realization exists. We emphasize these points by the following corollary.

COROLLARY 2.3. *The following statements are equivalent:*

1. G is in $TLD^{U,Y}$, i.e. G has a reachable and observable realization in some state space X ;
2. G has the restricted shift realization that is reachable and observable;
3. G is analytic on \mathbb{D}_e and at infinity such that the Hankel operator H_{G^\perp} is bounded.

Note that, if $G^\perp \in H_{\mathcal{L}(U,Y)}^\infty(\mathbb{D})$, then $G \in TLD^{U,Y}$, since, in this case, H_{G^\perp} is bounded.

As a next step, we construct another realization, which is the dual realization of the restricted shift realization. Let G be in $TLD^{U,Y}$. Then $\tilde{G}(z) = (G(\bar{z}))^*$, ($z \in \mathbb{D}_e$) is in $TLD^{Y,U}$. Moreover, if $(\tilde{A}, \tilde{B}, \tilde{C}, \tilde{D})$ is the restricted shift realization of \tilde{G} , then the dual system $(\tilde{A}^*, \tilde{C}^*, \tilde{B}^*, \tilde{D}^*)$ is a realization of G , called the **-restricted shift realization* of G .

A concrete representation of the *-restricted shift realization can be obtained.

THEOREM 2.4. *Let G be in $TLD^{U,Y}$. The state space representation (A_*, B_*, C_*, D_*) of the *-restricted shift realization is given by the following:*

The state space X_ is $X_* = \overline{\text{range}} H_{\tilde{G}^\perp}$, where*

$$\tilde{G}^\perp(z) = (G^\perp(\bar{z}))^*.$$

The operators A_, B_*, C_* , and D_* are defined as*

$$\begin{aligned} A_* &= P_{X_*} S|_{X_*}, \\ B_* u &= P_{X_*} u, \quad (u \in U) \\ C_* f &= (H_{G^\perp} f)(0), \quad (f \in X_*), \\ D_* &= G(\infty), \end{aligned}$$

where P_{X_} is the orthogonal projection of $H_U^2(\mathbb{D})$ onto X_* , and the space U is considered as the subspace $\{u + 0z + 0z^2 + 0z^3 + \dots \mid u \in U\}$ of $H_U^2(\mathbb{D})$.*

The system (A^, C^*, B^*, D^*) is observable and reachable. The reachability and observability operators \mathcal{R}_* and \mathcal{O}_* are, respectively, given by*

$$\mathcal{R}_* = P_{X_*} : H_U^2(\mathbb{D}) \rightarrow X_* \quad \text{and} \quad \mathcal{O}_* = H_{\tilde{G}^\perp}^*|_{X_*} = H_{G^\perp}|_{X_*}.$$

Proof. Replacing G by \tilde{G} in Theorem 2.1, we obtain the restricted shift realization of \tilde{G} , and the dual of this realization is the *-restricted shift realization stated in the theorem. Here we just verify the formula for the output operator C_* , which is the adjoint of the input operator \tilde{B} of the restricted shift realization of \tilde{G} . Hence $C_* = \tilde{B}^*$. So by Theorem 2.1 we have

$$C_*^* y = \tilde{B} y = \tilde{G}^\perp y \in X_*, \quad y \in Y.$$

From this, we obtain that, for $f \in X_* \subseteq H_U^2(\mathbb{D})$ and $y \in Y$,

$$\begin{aligned} \langle C_* f, y \rangle_Y &= \langle f, C_*^* y \rangle_{H_U^2(\mathbb{D})} \\ &= \frac{1}{2\pi} \int_0^{2\pi} \langle f(e^{it}), \tilde{G}^\perp(e^{it}) y \rangle_U dt \\ &= \frac{1}{2\pi} \int_0^{2\pi} \langle (\tilde{G}^\perp(e^{it}))^* f(e^{it}), y \rangle_U dt \\ &= \langle \frac{1}{2\pi} \int_0^{2\pi} (\tilde{G}^\perp(e^{it}))^* f(e^{it}) dt, y \rangle_U. \end{aligned}$$

Hence, using a change of variable $z = e^{-it}$, we have

$$\begin{aligned} C_*f &= \frac{1}{2\pi} \int_0^{2\pi} \left(\tilde{G}^\perp(e^{it}) \right)^* f(e^{it}) dt \\ &= \frac{1}{2\pi i} \int_{\partial\mathbb{D}} \bar{z} (\tilde{G}^\perp(\bar{z}))^* f(\bar{z}) dz \\ &= \frac{1}{2\pi i} \int_{\partial\mathbb{D}} \bar{z} G^\perp(z) f(\bar{z}) dz. \end{aligned}$$

Note that the last integral is the zeroth Fourier coefficient of $G^\perp(z)f(\bar{z})$, which is the same as the zeroth Fourier coefficient of $P_+G^\perp(z)f(\bar{z}) = H_{G^\perp}f$. This is $(H_{G^\perp}f)(0)$, since $H_{G^\perp}f \in H_Y^2(\mathbb{D})$. \square

From these results, we see that the state space for the restricted shift realization is given as the closed range of the Hankel operator whose symbol is the transfer function mapped to the unit disk. The state propagation operator is just the backward shift restricted to the state space. For the $*$ -restricted shift realization, the state space is also the closed range of a Hankel operator, while the state propagation operator is the forward shift compressed to this state space. It is well known and readily verified that the closure of the range of a Hankel operator H_G is the orthogonal complement of a right invariant subspace of $H_Y^2(\mathbb{D})$ [3], [8]. A vector-valued version of Beurling's theorem (see, e.g., [3, Thm. 12.22, p. 186]) asserts that a right invariant space in $H_Y^2(\mathbb{D})$ can only be either the trivial space $\{0\}$ or $QH_Y^2(\mathbb{D})$, where $Q \in H_{\mathcal{L}(Y)}^\infty(\mathbb{D})$ is such that $\|Q\|_\infty \leq 1$ and $Q(e^{it})$ is for almost every $t \in [0, 2\pi)$ a partial isometry with a fixed nonzero initial space. Such a function Q is called a *rigid* function. A rigid function Q is called *inner* if $Q(e^{it})$ is a unitary operator for almost all $t \in [0, 2\pi)$.

This discussion leads to the cyclicity of functions defined as follows (see [3]).

DEFINITION 2.1. Let $G \in TLD^{U,Y}$. Then G^\perp is called

1. *cyclic* if $(\text{range } H_{G^\perp})^\perp = \{0\}$,
2. *noncyclic* if $(\text{range } H_{G^\perp})^\perp = QH_Y^2(\mathbb{D})$ for some rigid function $Q \in H_{\mathcal{L}(Y)}^\infty(\mathbb{D})$,
3. *strictly noncyclic* if $(\text{range } H_{G^\perp})^\perp = QH_Y^2(\mathbb{D})$ for some inner function $Q \in H_{\mathcal{L}(Y)}^\infty(\mathbb{D})$.

It should be noted that the inner function Q in statement 3 of the above definition is unique up to right multiplication by a constant unitary operator on Y . Also, if G^\perp is scalar, then G^\perp is noncyclic if and only if it is strictly noncyclic. It is important to have characterizations for matrix-valued functions to be strictly noncyclic. To this end, we introduce some definitions. Let K be in $H_{\mathcal{L}(U,Y)}^\infty(\mathbb{D})$. The function \hat{K} defined on \mathbb{D}_e with values in $\mathcal{L}(U, Y)$ is called a *meromorphic pseudocontinuation of bounded type* of K if \hat{K} is of bounded type, i.e.,

$$\hat{K}(z) = \frac{F(z)}{h(z)}, \quad z \in \mathbb{D}_e,$$

where F is a $\mathcal{L}(U, Y)$ -valued function and h is a scalar-valued function, both bounded and analytic in \mathbb{D}_e ; K and \hat{K} have the same strong radial limits on $\partial\mathbb{D}$.

Let $F_1 \in H_{\mathcal{L}(U,Y)}^\infty(\mathbb{D})$ and $F_2 \in H_{\mathcal{L}(Z,Y)}^\infty(\mathbb{D})$. We say that F_1 and F_2 are *left weakly coprime* and write

$$(F_1, F_2)_L = I_Y$$

if $F_1 H_U^2(\mathbb{D}) \vee F_2 H_Z^2(\mathbb{D}) = H_Y^2(\mathbb{D})$, where \vee stands for the closed linear span.

Analogously, we say that $K_1 \in H_{\mathcal{L}(U,Y)}^\infty(\mathbb{D})$ and $K_2 \in H_{\mathcal{L}(U,Z)}^\infty(\mathbb{D})$ are *weakly right coprime* and write $(K_1, K_2)_R = I_U$ if \tilde{K}_1 and \tilde{K}_2 are weakly left coprime.

Using these notations, we have the following theorem ([3, Thm. 3.5, p. 254]).

THEOREM 2.5. *For $K \in H_{\mathcal{L}(U,Y)}^\infty(\mathbb{D})$ with U and Y finite-dimensional, the following statements are equivalent:*

1. K is strictly noncyclic,
2. On $\partial\mathbb{D}$ the function K can be factored as

$$K = Q_1(zF_1)^* = (zF_2)^*Q_2.$$

Q_1 and Q_2 are inner functions in $H_{\mathcal{L}(Y)}^\infty(\mathbb{D})$ and $H_{\mathcal{L}(U)}^\infty(\mathbb{D})$, respectively. The functions F_1 and F_2 are in $H_{\mathcal{L}(Y,U)}^\infty(\mathbb{D})$ and in $H_{\mathcal{L}(U,Y)}^\infty(\mathbb{D})$, respectively, and the coprimeness conditions $(Q_1, F_1)_R = I_Y$, $(Q_2, F_2)_L = I_U$ hold. Here Q_1 (respectively, Q_2) is unique up to right (respectively, left) multiplication by a constant unitary operator,

3. K has a meromorphic pseudocontinuation of bounded type on \mathbb{D}_e .

If statement 2 holds, then $Q_1H_Y^2(\mathbb{D}) = (\text{range } H_K)^\perp$ and $\tilde{Q}_2H_U^2(\mathbb{D}) = (\text{range } H_{\tilde{K}})^\perp$.

We will call the factorization of K in the theorem the Douglas–Shapiro–Shields factorization. In fact, this is the generalization due to Fuhrmann [3] of the result on scalar functions of Douglas, Shapiro, and Shields [1].

By Theorem 2.5, we immediately have the following corollary.

COROLLARY 2.6. *In the notation of the theorem with U and Y finite-dimensional, K is strictly noncyclic if and only if \tilde{K} is strictly noncyclic.* \square

From Theorems 2.1, 2.4, 2.5, and Definition 2.1, we see that the state space of a restricted shift realization of a transfer function G is the orthogonal complement of an invariant subspace, which is characterized by a rigid function Q . The state propagation operator A is the backward shift S^* restricted to the state space $(QH_Y^2(\mathbb{D}))^\perp$, i.e., $A = S^*_{|(QH_Y^2(\mathbb{D}))^\perp}$, which we will denote by $S(Q)^*$. One of the important points in our context is that the function Q can be determined from the transfer function G , if G^\perp is strictly noncyclic.

For the $*$ -restricted shift realization, the state space can be determined in a similar way to the derivation of the restricted shift realization. In this case, the state propagation operator is the forward shift operator S compressed to the orthogonal complement of an invariant subspace that is determined by a rigid function Q_* , i.e., $P_{(Q_*H_U^2(\mathbb{D}))^\perp}S|_{(Q_*H_U^2(\mathbb{D}))^\perp}$, which we denote by $S(Q_*)$.

We summarize these results in the following proposition.

PROPOSITION 2.7. *Let G be in $TLD^{U,Y}$ with U and Y finite-dimensional and let $(A, B, C, D) \in LD_X^{U,Y}$ be its restricted shift realization and $(A_*, B_*, C_*, D_*) \in LD_{X_*}^{U,Y}$ its $*$ -restricted shift realization. Then*

1. If G^\perp is cyclic we have that (a) $A = S^*$ and $X = H_Y^2(\mathbb{D})$, and (b) $A_* = S$ and $X_* = H_U^2(\mathbb{D})$;
2. If G^\perp is noncyclic, we have that (a) $A = S(Q)^*$, where $Q \in H_{\mathcal{L}(Y)}^\infty(\mathbb{D})$ is a rigid function such that

$$X = \overline{\text{range}} H_{G^\perp} = (QH_Y^2(\mathbb{D}))^\perp.$$

If G^\perp is in $H_{\mathcal{L}(U,Y)}^\infty(\mathbb{D})$ and is strictly noncyclic with factorization $G^\perp = Q_1(zF_1)^*$, where $Q_1 \in H_{\mathcal{L}(Y)}^\infty(\mathbb{D})$ is inner and $F_1 \in H_{\mathcal{L}(Y,U)}^\infty(\mathbb{D})$ such that $(Q_1, F_1)_R = I_Y$, then $Q = Q_1V_1$ for some unitary operator V_1 on Y , and (b) $A_* = P_{X_*}S|_{X_*} = S(Q_*)$, where $Q_* \in H_{\mathcal{L}(U)}^\infty(\mathbb{D})$ is a rigid function such that

$$X_* = \overline{\text{range}} H_{\tilde{G}^\perp} = (Q_*H_U^2(\mathbb{D}))^\perp.$$

If G^\perp is in $H_{\mathcal{L}(U,Y)}^\infty(\mathbb{D})$ and is strictly noncyclic and \tilde{G}^\perp has a factorization $\tilde{G}^\perp = Q_2(zF_2)^*$, where $Q_2 \in H_{\mathcal{L}(U)}^\infty(\mathbb{D})$ is inner and $F_2 \in H_{\mathcal{L}(U,Y)}^\infty(\mathbb{D})$ such that $(Q_2, F_2)_L = I_U$, then $Q_* = Q_2 V_2$ for some unitary operator V_2 on U .

Proof. The proposition follows from Theorems 2.1, 2.4, 2.5, and Definition 2.1.

□

3. Stability and spectral minimality of input normal and output normal realizations. In this section, we discuss the stability and questions of spectral minimality of input normal and output normal realizations using the results on restricted and *-restricted shift realizations studied in §2.

The following definition recalls the notion of an input normal and output normal system as defined by Moore [7] for finite-dimensional state space realizations. The definitions in the infinite-dimensional case are natural extensions of the finite-dimensional notions (see, e.g., [13]).

DEFINITION 3.1. Let (A, B, C, D) be in $LD_X^{U,Y}$. Then the system is

1. *output normal* if $\mathcal{M} = I$,
2. *input normal* if $\mathcal{W} = I$,
3. *parbalanced* if $\mathcal{M} = \mathcal{W}$,

4. *balanced* if $\mathcal{M} = \mathcal{W}$ and there is an orthonormal basis of the state space with respect to which \mathcal{M} (and hence \mathcal{W}) has a diagonal matrix representation.

From our results on the restricted and the *-restricted shift realization we immediately have examples for input and output normal realizations.

PROPOSITION 3.1. Let $G \in TLD^{U,Y}$. Then the restricted shift realization is output normal whereas the *-restricted shift realization is input normal.

Proof. The proof follows from Proposition 2.2 and Theorem 2.4 □

Next, we quote a result that establishes a reachable output-normal realization of a transfer function is unitarily equivalent to its restricted shift realization

Two systems $(A_1, B_1, C_1, D_1) \in D_{X_1}^{U,Y}$ and $(A_2, B_2, C_2, D_2) \in D_{X_2}^{U,Y}$ are called *equivalent* (*unitarily equivalent*) if there exists a bounded and boundedly invertible operator (a unitary operator) V mapping the state space X_1 onto the state space X_2 , such that

$$(A_1, B_1, C_1, D_1) = (V^{-1}A_2V, V^{-1}B_2, C_2V, D_2).$$

In this case, V is called an equivalence (unitary) transformation.

THEOREM 3.2 (see [13]). Let $(A_1, B_1, C_1, D_1) \in LD_{X_1}^{U,Y}$ and $(A_2, B_2, C_2, D_2) \in LD_{X_2}^{U,Y}$ be two output normal realizations of a transfer function in $TLD^{U,Y}$. Then (A_1, B_1, C_1, D_1) and (A_2, B_2, C_2, D_2) are unitarily equivalent.

By a duality argument, we have as a corollary that the same result holds for input normal realizations; i.e., an input normal realization is unitarily equivalent to the *-restricted shift realization.

COROLLARY 3.3. Let $(A_1, B_1, C_1, D_1) \in LD_{X_1}^{U,Y}$ and $(A_2, B_2, C_2, D_2) \in LD_{X_2}^{U,Y}$ be two input normal realizations of a transfer function in $TLD^{U,Y}$. Then (A_1, B_1, C_1, D_1) and (A_2, B_2, C_2, D_2) are unitarily equivalent.

We now turn to the study of stability. We introduce a classification of contractions according to their stability properties [12], which will simplify our notation.

DEFINITION 3.2. Let T be a contraction on the Hilbert space H . Then

1. $T \in C_0$ if $\lim_{n \rightarrow \infty} T^n h = 0$, for all $h \in H$,
2. $T \in C_0$ if $\lim_{n \rightarrow \infty} (T^*)^n h = 0$, for all $h \in H$,
3. $T \in C_1$ if $\lim_{n \rightarrow \infty} T^n h \neq 0$, for all $h \in H$, $h \neq 0$,

4. $T \in C_{\cdot 1}$ if $\lim_{n \rightarrow \infty} (T^*)^n h \neq 0$, for all $h \in H$, $h \neq 0$.

We further set $C_{ij} = C_{\cdot i} \cap C_{\cdot j}$, $i, j = 0, 1$.

Now we define the two notions of stability we will consider in the remainder of the paper.

DEFINITION 3.3. A discrete time system $(A, B, C, D) \in D_X^{U, Y}$ or the state propagation operator A is called

1. *asymptotically stable* if for every $x \in X$,

$$A^k x \rightarrow 0 \quad \text{as } k \rightarrow \infty,$$

i.e., if A is of class $C_{0\cdot}$,

2. *power stable* if $r < 1$, where

$$r := \inf\{\bar{r} \mid \text{there is } M_{\bar{r}} > 0 \text{ such that } \|A^k\| \leq M_{\bar{r}} \bar{r}^k, k \geq 0\}.$$

The number r is called the *degree of power stability*.

It is easy to see that stability and observability, as well as reachability properties of discrete time systems, are preserved under equivalence transformations, whereas input and output normality are preserved under unitary equivalence. Moreover, two equivalent power stable systems have the same degree of power stability.

Therefore, by Theorem 3.2 and its corollary, we can establish all stability and other important results concerning input normal and output normal realizations by restricting ourselves to $*$ -restricted and restricted shift realizations. Henceforth, when we prove statements about input normal or output normal reachable and observable realizations, we must only prove them in the case of restricted or $*$ -restricted realization.

From Proposition 2.7, we can see that the study of stability and spectral properties of the restricted and $*$ -restricted realizations reduces to the study of the operators $S(Q)^*$ and $S(Q_*)$, where Q and Q_* are rigid functions. We will need the following lemma (see [8, Cor., p. 43]).

LEMMA 3.4. Let $Q \in H_{\mathcal{L}(Y)}^\infty(\mathbb{D})$ be a rigid function. Denote by P_X the projection on $X := (QH_Y^2(\mathbb{D}))^\perp$. Then, for $f \in H_Y^2(\mathbb{D})$, $\lim_{n \rightarrow \infty} \|P_X S^n f\|^2 = \|f\|^2 - \|Q^* f\|^2$.

The following theorem shows that an output normal realization of a transfer function in $TLD^{U, Y}$ is always asymptotically stable.

THEOREM 3.5. Let $G \in TLD^{U, Y}$ and let (A, B, C, D) be an output normal reachable realization of G . Then

1. $A \in C_{0\cdot}$; i.e., A is asymptotically stable,
2. $A \in C_{00}$ if G^\perp is strictly noncyclic,
3. $A \in C_{01}$ if G^\perp is cyclic.

Proof. By Proposition 3.1, we can assume without loss of generality that (A, B, C, D) is the restricted shift realization.

1. The state propagation operator A of the restricted shift realization is the restriction of the backward shift to a subspace of $H_Y^2(\mathbb{D})$. The backward shift S^* is such that for every $x_0 \in H_Y^2(\mathbb{D})$,

$$(S^*)^k x_0 \rightarrow 0, \quad \text{as } k \rightarrow \infty.$$

This immediately implies statement 1.

2. This follows from Proposition 2.7 and Lemma 3.4.

3. If G^\perp is cyclic, then A is the backward shift S^* on the space $H_Y^2(\mathbb{D})$, and therefore $A \in C_{01}$. \square

In the case of input normal realizations, the situation is, however, such that we cannot, in general, expect that the realization is asymptotically stable, since the state propagation operator of the $*$ -restricted shift realization is the forward shift operator, compressed to a subspace of $H_U^2(\mathbb{D})$. The forward shift on $H_U^2(\mathbb{D})$ is not asymptotically stable. The following corollary states that, at least for an important class of transfer functions, input normal realizations are asymptotically stable.

COROLLARY 3.6. *Let $G \in \text{TLD}^{U,Y}$ and let (A, B, C, D) be an input normal observable realization of G . Then*

1. $A \in C_0$,
2. $A \in C_{00}$ if \tilde{G}^\perp is strictly noncyclic,
3. $A \in C_{10}$ if \tilde{G}^\perp is cyclic.

Proof. Let (A, B, C, D) be the $*$ -restricted realization of G . Recall that by definition (A, B, C, D) is the dual system of the restricted shift realization of \tilde{G} . Hence the result follows by duality from Theorem 3.5 \square

We now proceed to power stability. The following result gives a characterization of power stability (see, e.g., Przyluski [11]).

PROPOSITION 3.7. *Let T be a contraction. Then the spectral radius $r(T)$ of T , i.e.,*

$$r(T) = \sup\{|\lambda| \mid \lambda \in \sigma(T)\},$$

is given by

$$r(T) = \inf\{0 \leq \bar{r} \leq 1 \mid \text{there exists } M_{\bar{r}} \geq 0 \text{ such that } \|T^k\| \leq M_{\bar{r}} \bar{r}^k, k \geq 0\}.$$

Hence, if T is power-stable, then the degree of power stability equals the spectral radius.

Proof. The proof follows from an application of the well-known formula

$$\sup\{|\lambda| \mid \lambda \in \sigma(T)\} = \lim_{n \rightarrow \infty} \|T^n\|^{1/n}. \quad \square$$

To establish whether the output normal and input normal realizations are power-stable, it is therefore important to determine the spectral radius of its state propagation operator. To this end, we must introduce C_0 contractions, which play an important role in the theory of contractive operators. C_0 contractions are defined via the H^∞ calculus for contractions and are a special class of completely nonunitary contractions (see [12]). Specifically, a contraction T on a Hilbert space H is *completely nonunitary* if there is no subspace $V \subseteq H$ such that $TV = V$ and $T|_V$ is unitary. For such T , the operator $u(T) := \lim_{r \rightarrow 1} u(rT)$ is a well-defined bounded operator for any $u \in H^\infty$ and satisfies $\|u(T)\| \leq \|u\|_{H^\infty}$. In particular, $u(T)$ is a contraction if u is an inner function.

A completely nonunitary contraction is a C_0 contraction if there exists an inner function m such that $m(T) = 0$. The least common divisor of all such inner functions is called the *minimal function* m_T of T . For the minimal function m_T , we also have that $m_T(T) = 0$. Therefore the minimal function of a C_0 contraction can be seen to be a generalization of the minimal polynomials for matrices.

As in the case of matrices, the spectrum of C_0 operators is given by the “zeros” of the minimal function in the following sense. We define the *spectrum* $\sigma(Q)$ of an inner function $Q \in H_{\mathcal{L}(Y)}^\infty(\mathbb{D})$ to be

$$\sigma(Q) = \left\{ \lambda \in \overline{\mathbb{D}} \mid \lim_{\substack{\delta > 0 \\ \delta \rightarrow 0}} \inf_{\substack{\xi \in \mathbb{D} \\ |\xi - \lambda| < \delta}} \inf_{\substack{\|y\|=1 \\ y \in Y}} \|Q(\xi)y\| = 0 \right\}.$$

Then we have the following proposition (see [8, p. 75]),

PROPOSITION 3.8. *If T is a C_0 operator, then*

$$\sigma(T) = \sigma(m_T) \quad \text{and} \quad \sigma_p(T) = \sigma(m_T) \cap \mathbb{D}.$$

Now we use these results to analyze the spectrum of the operators $S(Q)$ and $S(Q)^*$. First the following proposition [8, p. 73] shows when $S(Q)$ is a C_0 contraction.

PROPOSITION 3.9. *If $\dim(U) < \infty$ and $Q \in H_{\mathcal{L}(U)}^\infty(\mathbb{D})$ is a rigid function, then the determinant $d = \det(Q)$ is such that $d(S(Q)) = 0$. Therefore, when Q is an inner function and U has finite dimension, the operator $S(Q)$ is a C_0 contraction.*

In fact, $S(Q)$ and $S(Q)^*$ are both C_0 contractions when Q is inner and U is finite dimensional, as shown by the following result (see [3, Thm, 13.2, p. 191] or [8, p. 75]).

PROPOSITION 3.10. *For a given inner function $Q \in H_{\mathcal{L}(U)}^\infty(\mathbb{D})$, the operators $S(Q)$ and $S(\tilde{Q})^*$ are unitarily equivalent.*

More precisely, $S(Q) = \tau_Q^{-1} S(\tilde{Q})^* \tau_Q$, where the unitary operator τ_Q is given by

$$\begin{aligned} \tau_Q : L_U^2(\partial\mathbb{D}) &\rightarrow L_U^2(\partial\mathbb{D}) \\ f &\mapsto e^{-it} \tilde{Q} J f. \end{aligned}$$

One of the important results in the theory of the backward shift operator $S(Q)^*$ restricted to an invariant subspace is that its spectrum can be completely characterized by the associated inner function Q . Note that, if σ is a set of complex numbers, then σ^* is used to denote the set of the complex conjugates of the elements in σ .

THEOREM 3.11 (see [8, p. 75]). *The following statements hold:*

1. (a) *Let S^* be the backward shift on $H_Y^2(\mathbb{D})$. Then*

$$\sigma(S^*) = \overline{\mathbb{D}}, \quad \sigma_p(S^*) = \mathbb{D},$$

- (b) *Let S be the forward shift on $H_Y^2(\mathbb{D})$. Then*

$$\sigma(S) = \overline{\mathbb{D}}, \quad \sigma_p(S) = \emptyset;$$

2. (a) *Let Q be an inner function in $H_Y^\infty(\mathbb{D})$ with Y finite dimensional. Then*

$$\sigma(S(Q)^*) = \sigma(Q)^* = \sigma(m_{S(Q)^*}),$$

$$\sigma_p(S(Q)^*) = \sigma(S(Q)^*) \cap \mathbb{D} = \{\bar{\lambda} \in \mathbb{D} \mid \text{Ker} Q(\lambda)^* \neq \{0\}\},$$

- (b)

$$\sigma(S(Q)) = \sigma(Q) = \sigma(m_{S(Q)}),$$

$$\sigma_p(S(Q)) = \sigma(S(Q)) \cap \mathbb{D} = \{\lambda \in \mathbb{D} \mid \text{Ker} Q(\lambda) \neq \{0\}\}.$$

The next result shows that we must only be concerned with inner functions if we are interested in the case when the spectral radius of the restricted backward shift is less than 1 (see [3, p. 194]).

THEOREM 3.12. *Let U be finite-dimensional and Q a rigid function that is not inner. Then $\sigma_p(S(Q)^*)$ is equal to the open unit disk \mathbb{D} .*

In terms of the restricted and *-restricted shift realizations, Theorems 3.11 and 3.12 can be translated into the following result.

PROPOSITION 3.13. *Let (A, B, C, D) and (A_*, B_*, C_*, D_*) be, respectively, the restricted and *-restricted shift realizations of a transfer function $G \in TLD^{U,Y}$ where U and Y have finite dimensions.*

1. *If G^\perp is cyclic, then $\sigma(A) = \overline{\mathbb{D}}$, $\sigma_p(A) = \mathbb{D}$ and $\sigma(A_*) = \overline{\mathbb{D}}$, and $\sigma_p(A) = \emptyset$.*
2. *If G^\perp is noncyclic but not strictly noncyclic, then $\sigma(A) = \overline{\mathbb{D}}$, $\sigma(A_*) = \overline{\mathbb{D}}$.*
3. *If G^\perp is in $H_{\mathcal{L}(U,Y)}^\infty(\mathbb{D})$ and is strictly noncyclic with factorization $G^\perp = Q_1(zF_1)^*$ and $\tilde{G}^\perp = Q_2(zF_2)^*$, where $Q_1 \in H_{\mathcal{L}(Y)}^\infty(\mathbb{D})$ and $Q_2 \in H_{\mathcal{L}(U)}^\infty(\mathbb{D})$ are inner, and where Q_1 and $F_1 \in H_{\mathcal{L}(Y,U)}^\infty(\mathbb{D})$ are right weakly coprime, and Q_2 and $F_2 \in H_{\mathcal{L}(U,Y)}^\infty(\mathbb{D})$ are also right weakly coprime, then*

$$\sigma(A) = \sigma(Q_1)^* = \sigma(m_A),$$

$$\sigma_p(A) = \sigma(Q_1)^* \cap \mathbb{D} = \{\bar{\lambda} \in \mathbb{D} \mid \text{Ker} Q_1(\lambda)^* \neq \{0\}\}$$

and

$$\sigma(A_*) = \sigma(Q_2) = \sigma(m_{A_*}),$$

$$\sigma_p(A_*) = \sigma(Q_2) \cap \mathbb{D} = \{\lambda \in \mathbb{D} \mid \text{Ker} Q_2(\lambda) \neq \{0\}\}.$$

Proof. The proposition follows from Theorems 3.11 and 3.12 and Proposition 2.7. \square

A very important property of finite-dimensional systems is that the eigenvalues of the state propagation matrix correspond exactly to the poles of the transfer function. For infinite-dimensional systems, it is desirable to have the analogous property. This was shown to be true for strictly noncyclic transfer functions by Fuhrmann ([3, Chap. III]).

DEFINITION 3.4. Let $G \in TLD^{U,Y}$ be such that G^\perp has a meromorphic pseudocontinuation of bounded type on \mathbb{D}_e . Then we extend the definition of G^\perp onto \mathbb{D}_e to be this unique meromorphic pseudocontinuation and hence define G on \mathbb{D} . The set $\sigma_s(G)$ is defined to be the set of points z such that the extended G cannot be analytically continued to z .

A realization $(A, B, C, D) \in LD_X^{U,Y}$ of G is said to be *spectrally minimal* if $\sigma(A) = \sigma_s(G)$.

We note that a more general definition of spectral minimality can be made for a larger class of transfer functions (see [3]). However, the definition suffices for our discussion here. It turns out that, if $G \in TLD^{U,Y}$ is strictly noncyclic, then both the restricted and *-restricted shift realizations are spectrally minimal.

THEOREM 3.14. *Let G be in $TLD^{U,Y}$, where U and Y have finite dimensions. If G^\perp is in $H_{\mathcal{L}(U,Y)}^\infty(\mathbb{D})$ and is strictly noncyclic, then*

1. *Every output normal realization (A, B, C, D) is spectrally minimal, i.e.,*

$$\sigma(A) = \sigma_s(G),$$

2. *Every input normal realization (A_*, B_*, C_*, D_*) is spectrally minimal.*

Proof. 1. See, [3, Thm. 4.11, p. 267] for the case of the restricted shift realization.

2. Without loss of generality, we assume (A, B, C, D) is the $*$ -restricted shift realization of G .

Recall from Corollary 2.6 that G^\perp is strictly noncyclic if and only if \tilde{G}^\perp is strictly noncyclic. By statement 1 and the construction of the $*$ -restricted shift realization, we have that $\sigma(A_\star^*) = \sigma_s(\tilde{G})$. Since

$$\sigma_s(G) = (\sigma_s(\tilde{G}))^* = \sigma(A_\star^*)^* = \sigma(A_\star),$$

we have the spectral minimality of the $*$ -restricted shift realization. \square

We now show that an input normal or output normal system is power-stable if and only if it is finite-dimensional.

THEOREM 3.15. *Let G be in $TLD^{U,Y}$ such that $G^\perp \in H_{\mathcal{L}(U,Y)}^\infty(\mathbb{D})$ and let U and Y be finite-dimensional. Then an output normal (respectively, input normal) realization of G is power-stable if and only if G is rational.*

Proof. Let G be rational. Since $G^\perp \in H_{\mathcal{L}(U,Y)}^\infty(\mathbb{D})$, there is a number $0 < r < 1$ such that the poles of G are contained in the set $\{\lambda : |\lambda| \leq r\}$. Being rational, G^\perp has a meromorphic pseudocontinuation of bounded type and hence by Theorem 2.5 is strictly noncyclic. Theorem 3.14 then implies that the propagation operator of any output normal (respectively, input normal) realization of G has spectral radius less than 1. Now Proposition 3.7 shows that it is power-stable.

Conversely, assume that an output normal realization of G is power stable. Then the restricted shift realization is power stable. Let A be its propagation operator. We have by Proposition 3.7 that $r(A)$, the spectral radius of A , is less than 1. By Proposition 3.13, this implies that G^\perp is strictly noncyclic. Then, by Theorem 3.14, any output normal realization of G is spectrally minimal, and hence G can be analytically continued across $\partial\mathbb{D}$. Being strictly noncyclic, G^\perp has a meromorphic pseudocontinuation on \mathbb{D}_e , and thus G has a meromorphic pseudocontinuation on \mathbb{D} . Since a meromorphic pseudocontinuation is unique, the pseudocontinuation is an analytic continuation. Thus G is a meromorphic function on the extended complex plane. Hence it is rational.

If an input normal realization is assumed to be power-stable, a similar argument will also show that G is rational. \square

4. Balanced realizations. This section is devoted to the study of the stability properties of balanced realizations with infinite-dimensional state space.

Balanced realizations of finite-dimensional systems have played an important role in model reduction and Hankel norm approximation of linear systems [7], [4]. In finite dimensions, it is straightforward to construct a balanced realization from input normal or output normal realizations. In infinite dimensions, it is not trivial to guarantee that this can be done, since the state space transformation that is involved, in general, has an unbounded inverse. That this is nevertheless possible was shown by Young [13]. Note that, in the following theorem, the subscripts o and i signify output normal and input normal realizations, respectively.

THEOREM 4.1. *Let $G \in TLD^{U,Y}$. Let (A_o, B_o, C_o, D_o) be the restricted shift realization of G with state space $X_o = \overline{\text{range}} H_{G^\perp}$ and let (A_i, B_i, C_i, D_i) be the $*$ -restricted realization with state space $X_i = \overline{\text{range}} H_{\tilde{G}^\perp}$. Set*

$$\mathcal{W}_o = H_{G^\perp} H_{G^\perp}^*|_{X_o}, \quad \mathcal{M}_i = H_{\tilde{G}^\perp} H_{\tilde{G}^\perp}^*|_{X_i}.$$

1. There exist parbalanced realizations $(A_{b1}, B_{b1}, C_{b1}, D_{b1}) \in D_{X_o}^{U,Y}$ and $(A_{b2}, B_{b2}, C_{b2}, D_{b2}) \in D_{X_i}^{U,Y}$ of G that satisfy

$$\begin{aligned} \mathcal{W}_o^{1/4} A_{b1} &= A_o \mathcal{W}_o^{1/4}, & \mathcal{W}_o^{1/4} B_{b1} &= B_o, \\ C_{b1} &= C_o \mathcal{W}_o^{1/4}, & D_{b1} &= D_o \end{aligned}$$

and

$$\begin{aligned} A_{b2} \mathcal{M}_i^{1/4} &= \mathcal{M}_i^{1/4} A_i, & B_{b2} &= \mathcal{M}_i^{1/4} B_i, \\ C_{b2} \mathcal{M}_i^{1/4} &= C_i, & D_{b2} &= D_i. \end{aligned}$$

2. All parbalanced realizations of G are unitarily equivalent.

3. If $G \in TLD^{U,Y}$ is continuous on $\partial\mathbb{D}$ with values in the set of compact operators, then there exists a balanced realization whose state space is equal to the closure of the range of the Hankel operator with symbol G^\perp . The gramian has a matrix representation with respect to a basis such that its diagonal entries are the singular values of the Hankel operator with symbol G^\perp .

Proof. Statements 2 and 3 and the existence of the first parbalanced realization of statement 1 can be found in [13]. The second realization of statement 1 can be obtained by taking the dual of the parbalanced realization of \bar{G} constructed by the method of the first realization. \square

We have the following proposition concerning the transformation from the restricted ($*$ -restricted) shift realization to the parbalanced realization in Theorem 4.1.

PROPOSITION 4.2. In the notation of Theorem 4.1, the operators $\mathcal{W}_o^{1/2}$ and $\mathcal{W}_o^{1/4}$ are bounded positive definite with dense ranges in X_o ; the operators $\mathcal{M}_i^{1/2}$ and $\mathcal{M}_i^{1/4}$ are bounded positive definite with dense ranges in X_i .

Proof. Clearly, \mathcal{W}_o is a bounded positive definite operator on X_o . Similarly, \mathcal{M}_i is a positive definite operator on X_i . Since

$$\mathcal{W}_o^{1/2}(\mathcal{W}_o^{1/2})^* = H_{G^\perp} H_{G^\perp}^*$$

and $H_{G^\perp} H_{G^\perp}^* X_o$ is dense in X_o , $\mathcal{W}_o^{1/2}$ has dense range in X_o . Hence so does $\mathcal{W}_o^{1/4}$. Similarly, $\mathcal{M}_i^{1/2}$ and $\mathcal{M}_i^{1/4}$ also have dense ranges. \square

Combining Theorem 4.1 and Proposition 4.2, we have, in the terminology of [12], that A_{b1} is a quasi-affine transform of A_o and A_i a quasi-affine transform of A_{b2} .

Theorem 4.1 has some by-products that may be of interest in their own right. First, since two parbalanced realizations are unitarily equivalent, their state spaces must be unitarily equivalent.

COROLLARY 4.3. The spaces $\overline{H_{G^\perp}(H_U^2)}$ and $\overline{H_{\bar{G}^\perp}(H_Y^2)}$ are unitarily equivalent, with a unitary transformation given by

$$V = \mathcal{W}_o^{-1/4} H_{G^\perp} \mathcal{M}_i^{-1/4} : \overline{H_{G^\perp}(H_U^2)} \rightarrow \overline{H_{\bar{G}^\perp}(H_Y^2)}.$$

Before stating the second consequence of Theorem 4.1, we quote from [3, p. 248] the following result regarding the closedness of the range of a Hankel operator.

PROPOSITION 4.4. Let $K \in H_{\mathcal{L}(U,Y)}^\infty(\mathbb{D})$ with U and Y finite-dimensional. Then $H_K(H_U^2(\mathbb{D}))$ is closed in $H_Y^2(\mathbb{D})$ if and only if there are functions $Q \in H_{\mathcal{L}(Y)}^\infty(\mathbb{D})$, $F \in H_{\mathcal{L}(Y,U)}^\infty(\mathbb{D})$, $P_1 \in H_{\mathcal{L}(Y)}^\infty(\mathbb{D})$, and $P_2 \in H_{\mathcal{L}(U,Y)}^\infty(\mathbb{D})$ such that, for almost all $z \in \partial\mathbb{D}$,

$$K(z) = Q(z)(zF(z))^*, \quad P_1(z)Q(z) + P_2(z)F(z) = I_Y$$

and Q is inner. Note that the last equality means that Q and F are strongly right coprime [3].

We have the following characterization of when the state space transformation in Theorem 4.1 that maps an input normal (respectively, output normal) realization to a (par-) balanced realization is an equivalence transformation.

PROPOSITION 4.5. *Let $G \in \text{TLD}^{U,Y}$. A parbalanced realization is equivalent to an output normal (or input normal) realization if and only if H_{G^\perp} has closed range.*

Proof. If H_{G^\perp} has closed range, then \mathcal{W}_o in Theorem 4.1 has bounded inverse and $\mathcal{W}_o^{-1/4}$ is an equivalence transformation from the restricted shift realization to a parbalanced realization.

Conversely, if T is an equivalence transformation from a parbalanced realization to the restricted shift realization, then it will follow that $TT^*TT^* = \mathcal{W}_o$. Hence \mathcal{W}_o has bounded inverse. Since $\mathcal{W}_o = H_{G^\perp}H_{G^\perp}^*$, H_{G^\perp} must have closed range. Note that H_{G^\perp} has closed range if and only if $H_{\tilde{G}^\perp}$ has closed range. This completes the proof. \square

In fact, the state space isomorphism theorem holds when H_{G^\perp} has closed range.

COROLLARY 4.6. *Let $G \in \text{TLD}^{U,Y}$. Then all reachable and observable realizations of G are equivalent if and only if H_{G^\perp} has closed range.*

Proof. If all reachable and observable realizations of G are equivalent, then, in particular, the output normal and the parbalanced realizations are equivalent. By Proposition 4.5, H_{G^\perp} has closed range.

Conversely, assume that H_{G^\perp} has closed range. Let $(A, B, C, D) \in \text{LD}_X^{U,Y}$ be a reachable and observable realization of G with state space X . We show that it is equivalent to an output normal realization. Then, by Theorem 3.2, this shows that all reachable and observable realizations of G are equivalent.

Let \mathcal{O} and \mathcal{R} be, respectively, the observability and reachability operators of (A, B, C, D) . It is easily verified that $H_{G^\perp} = \mathcal{O}\mathcal{R} : H_V^2(\mathbb{D}) \rightarrow H_Y^2(\mathbb{D})$ (see the beginning of § 2). Hence $\mathcal{O}\mathcal{R}(H_V^2(\mathbb{D}))$ is closed in $H_Y^2(\mathbb{D})$. By reachability, $\mathcal{R}(H_V^2(\mathbb{D})) \subseteq X$ is dense in X . Thus

$$\mathcal{O}(X) \subseteq \overline{\mathcal{O}\mathcal{R}(H_V^2(\mathbb{D}))} = \mathcal{O}\mathcal{R}(H_V^2(\mathbb{D})) \subseteq \mathcal{O}(X).$$

It follows that $\mathcal{O}(X) = \mathcal{O}\mathcal{R}(H_V^2(\mathbb{D}))$, and hence $\mathcal{O}(X)$ is closed in $H_Y^2(\mathbb{D})$. Since by observability \mathcal{O} is injective, the operator $\mathcal{O} : X \rightarrow \mathcal{O}(X)$ has bounded inverse. Consequently, the operator $\mathcal{O}^*\mathcal{O} : X \rightarrow X$ has bounded inverse on X . Now let $V = (\mathcal{O}^*\mathcal{O})^{-1/2}$, then V is bounded and is boundedly invertible. It is routine to verify that the realization $(V^{-1}AV, V^{-1}B, CV, D)$, which is equivalent to (A, B, C, D) , is output normal. \square

The main result in this section is that all parbalanced realizations are asymptotically stable. We need two lemmas in the proof.

LEMMA 4.7 (see [3, p. 124]). *Let $A : H_1 \rightarrow H$ and $B : H_2 \rightarrow H$ be two linear operators from Hilbert spaces H_1 and H_2 , respectively, into a Hilbert space H . Then $AA^* \leq BB^*$ if and only if there exists a contraction $V : H_1 \rightarrow H_2$ such that $A = BV$. Moreover, $AA^* = BB^*$ if and only if V is a partial isometry with final space equal to $\text{range}(B^*)$.*

LEMMA 4.8. *Let $G \in \text{TLD}^{U,Y}$. Let (A, B, C, D) be a realization of G and let (A^*, C^*, B^*, D^*) be its dual system. Then (A, B, C, D) is a parbalanced realization of G if and only if (A^*, C^*, B^*, D^*) is a parbalanced realization of \tilde{G} .*

THEOREM 4.9. *Let $G \in \text{TLD}^{U,Y}$ and let (A_b, B_b, C_b, D_b) be a parbalanced realization of G . Then $A_b \in C_{00}$.*

Proof. Here we use the notation and result of Theorem 4.1 and first prove that A_{b1} is asymptotically stable. Note that $A_o^* = P_{X_o} S|_{X_o}$ and $X_o^\perp \subseteq \ker(H_{G^\perp}^*)$. It is easy to verify that

$$H_{G^\perp}^* A_o^* = H_{G^\perp}^* S|_{X_o} = S^*|_{X_o} H_{G^\perp}^*|_{X_o} = A_o H_{G^\perp}^*|_{X_o}.$$

Hence we have

$$\begin{aligned} \langle A_o \mathcal{W}_o A_o^* x, x \rangle &= \langle A_o H_{G^\perp} H_{G^\perp}^* A_o^* x, x \rangle \\ &= \langle H_{G^\perp}^* A_o^* x, H_{G^\perp}^* A_o^* x \rangle \\ &= \langle A_o H_{G^\perp}^* x, A_o H_{G^\perp}^* x \rangle \\ &\leq \langle H_{G^\perp}^* x, H_{G^\perp}^* x \rangle \\ &= \langle \mathcal{W}_o x, x \rangle, \end{aligned}$$

i.e., $A_o \mathcal{W}_o A_o^* \leq \mathcal{W}_o$. Thus by Lemma 4.7 there exists a contraction V on X_o such that

$$A_o \mathcal{W}_o^{1/2} = \mathcal{W}_o^{1/2} V,$$

and hence for any positive integer n

$$A_o^n \mathcal{W}_o^{1/2} = \mathcal{W}_o^{1/2} V^n.$$

Let x be any element in $\mathcal{W}_o^{1/2} X_o$, i.e., $x = \mathcal{W}_o^{1/2} z$ for some $z \in X$. Then the element $y = \mathcal{W}_o^{1/4} z \in X_o$ is such that $y = \mathcal{W}_o^{-1/4} x$. The above equality applied to y yields

$$A_o^n \mathcal{W}_o^{1/4} x = \mathcal{W}_o^{1/2} V^n y.$$

Since the right-hand side of the last equality is in $\mathcal{W}_o^{1/2} X_o$, the operator $\mathcal{W}_o^{-1/4}$ can be applied to both sides to lead to

$$\mathcal{W}_o^{-1/4} A_o^n \mathcal{W}_o^{1/4} x = \mathcal{W}_o^{1/4} V^n y.$$

Now, noting that $\mathcal{W}_o^{1/4}$ is selfadjoint and, from Theorem 4.1, $A_{b1}^n x = \mathcal{W}_o^{-1/4} A_o^n \mathcal{W}_o^{1/4} x$, we have that

$$\begin{aligned} \|A_{b1}^n x\|^2 &= \langle A_{b1}^n x, A_{b1}^n x \rangle \\ &= \langle \mathcal{W}_o^{-1/4} A_o^n \mathcal{W}_o^{1/4} x, \mathcal{W}_o^{-1/4} A_o^n \mathcal{W}_o^{1/4} x \rangle \\ &= \langle \mathcal{W}_o^{-1/4} A_o^n \mathcal{W}_o^{1/4} x, \mathcal{W}_o^{1/4} V^n y \rangle \\ &= \langle \mathcal{W}_o^{1/4} \mathcal{W}_o^{-1/4} A_o^n \mathcal{W}_o^{1/4} x, V^n y \rangle \\ &= \langle A_o^n \mathcal{W}_o^{1/4} x, V^n y \rangle \\ &\rightarrow 0 \end{aligned}$$

as $A_o^n z \rightarrow 0$ for any z and $\|V^n y\| \leq \|y\|$.

We thus have proved $\|A_{b1}^n x\| \rightarrow 0$ for any $x \in \mathcal{W}_o^{1/2} X_o$. Let $z \in X_o$ and $\epsilon > 0$. Since $\mathcal{W}_o^{1/2} X_o$ is dense in X_o , there exists $x \in \mathcal{W}_o^{1/2} X_o$ such that $\|z - x\| < \epsilon/2$. Choosing N such that $\|A_{b1}^n x\| < \epsilon/2$ whenever $n \geq N$ and using the fact that A_{b1} is a contraction, we obtain, for $n \geq N$

$$\|A_{b1}^n z\| \leq \|A_{b1}^n (z - x)\| + \|A_{b1}^n x\| < \|A_{b1}^n\| \|z - x\| + \epsilon/2 \leq \epsilon/2 + \epsilon/2 = \epsilon.$$

This shows that A_{b1} is asymptotically stable. Since, by statement 2 of Theorem 4.1, all observable and reachable parbalanced realizations are unitarily equivalent, A_b must be asymptotically stable. Hence any parbalanced realization of any transfer function in $TLD^{U,Y}$ is asymptotically stable. Since by Lemma 4.8 $(A_b^*, C_b^*, B_b^*, D_b^*)$ is a parbalanced realization of the transfer function $\tilde{G} \in TLD^{Y,U}$, we can apply this statement to $(A_b^*, C_b^*, B_b^*, D_b^*)$ to get the asymptotic stability of A_b^* . Therefore we have proved that $A_b \in C_{00}$. \square

We discuss the spectral properties of a parbalanced realization and relate these properties to the characterization of power-stability of parbalanced realizations.

PROPOSITION 4.10. *Let (A_b, B_b, C_b, D_b) , (A_i, B_i, C_i, D_i) , and (A_o, B_o, C_o, D_o) be, respectively, a parbalanced, an input normal and an output normal realization of $G \in TLD^{U,Y}$ with U and Y finite-dimensional. If G^\perp is in $H_{\mathcal{L}(U,Y)}^\infty$ and is strictly noncyclic, then A_b, A_i, A_o are all C_0 operators. Moreover, they have the same minimal function.*

Proof. By Theorem 3.5, Corollary 3.6, and Theorem 4.9, the assumption in the proposition implies that A_i, A_o , and A_b are all in C_{00} . Hence they are all completely nonunitary (see [12] or [8]). Furthermore, as noted after Proposition 4.2, A_{b1} is a quasi-affine transform of A_o and A_i a quasi-affine transform of A_{b2} . The result now follows from Proposition 3.13 and [12, Prop. 4.6, p. 125], which shows the following: For two completely nonunitary operators A and B on a Hilbert space H , if there is a bounded injective operator C on H with dense range in H such that $AC = CB$ (i.e., B is a quasi-affine transform of A), then A is a C_0 operator if and only if B is, and in this case they both have the same minimal function. \square

For the spectrum of the state propagation operators, we obtain the following result.

COROLLARY 4.11. *Under the assumption of Proposition 4.10, we have*

$$\sigma(A_b) = \sigma(A_i) = \sigma(A_o) \quad \text{and} \quad \sigma_p(A_b) = \sigma_p(A_i) = \sigma_p(A_o).$$

Proof. The proof is an immediate consequence of Propositions 4.10 and 3.8. \square

For the question of the spectral minimality, we have the same result as for input normal and output normal realizations in the case of finite-dimensional U and Y .

COROLLARY 4.12. *Under the assumption of Proposition 4.10, the systems (A_b, B_b, C_b, D_b) , (A_i, B_i, C_i, D_i) , and (A_o, B_o, C_o, D_o) are spectrally minimal, i.e.,*

$$\sigma_s(G) = \sigma(A_b) = \sigma(A_i) = \sigma(A_o).$$

Proof. Combining Theorems 3.14 with 3.2, we have that

$$\sigma_s(G) = \sigma(A_i) = \sigma(A_o).$$

Corollary 4.11 now implies the result. \square

The criteria for power-stability are also identical to those in the input normal and output normal case if G^\perp is strictly noncyclic.

COROLLARY 4.13. *Let (A_b, B_b, C_b, D_b) be a parbalanced realization of $G \in TLD^{U,Y}$ with U and Y finite-dimensional. Assume that G^\perp is in $H_{\mathcal{L}(U,Y)}^\infty(\mathbb{D})$ and is strictly noncyclic. Then A_b is power-stable if and only if G is rational.*

Proof. The proof follows from Corollary 4.11 and Theorem 3.15. \square

This corollary shows that a parbalanced realization of $G \in TLD^{U,Y}$, with G^\perp nonrational and strictly noncyclic, cannot be power-stable. When G^\perp is not strictly

noncyclic the situation is complicated. Here we give an example of a power-stable parbalanced realization of a cyclic function with l_2 as its state space.

Example. Let S and S^* be the right and left shifts on the space l_2 . Let $A = \frac{1}{5}(I + S + S^*)$. Clearly, $\|A\| \leq \frac{3}{5}$. Define $B : \mathbb{C} \rightarrow l_2$ as

$$B(\lambda) = (\lambda, 0, 0, \dots)^T, \quad \lambda \in \mathbb{C}$$

and $C : l_2 \rightarrow \mathbb{C}$ as

$$C(x_k)_{k \geq 1} = x_1, \quad (x_k)_{k \geq 1} \in l_2.$$

We take D to be zero. We have $\|B\| = 1$ and $\|C\| = 1$. Now consider $e_i = (\delta_{ij})_{j \geq 1}$, where δ_{ij} is the Kronecker delta. Then $\{e_i\}_{i \geq 1}$ forms a basis of l_2 . With respect to this basis, we have the following matrix representations of A , B , and C :

$$A = \frac{1}{5} \begin{bmatrix} 1 & 1 & 0 & 0 & 0 & \cdots \\ 1 & 1 & 1 & 0 & 0 & \cdots \\ 0 & 1 & 1 & 1 & 0 & \cdots \\ 0 & 0 & 1 & 1 & 1 & \cdots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix}, \quad B = \begin{bmatrix} 1 \\ 0 \\ 0 \\ 0 \\ \vdots \end{bmatrix}, \quad \text{and} \quad C = [1 \ 0 \ 0 \ 0 \ \cdots].$$

We show that (A, B, C, D) is an observable and reachable system. Let \mathcal{O} and \mathcal{R} be, respectively, the observability and reachability operators. For $x = (x_k)_{k \geq 0} \in l^2$, we have

$$\|\mathcal{O}x\|^2 = \|(CA^k x)_{k \geq 0}\|^2 = \sum_{k \geq 0} \|CA^k x\|^2 \leq \sum_{k \geq 0} \|A\|^{2k} \|x\|^2 \leq \sum_{k \geq 0} \left(\frac{3}{5}\right)^{2k} \|x\|^2.$$

Hence \mathcal{O} is bounded. Let $x = (x_k)_{k \geq 0} \in l^2$ be such that $\mathcal{O}x = 0$, i.e., $CA^k x = 0$ for $k = 0, 1, \dots$. Then it follows that $x_1 = CA^0 x = 0$, and hence $x_2 = 0$ because $0 = CAx = (x_1 + x_2)/5$, and so on. So we have $x = 0$. This shows that the system is observable. Note that $\mathcal{R} = \mathcal{O}^*$. Hence the system is reachable. It is obviously parbalanced. Also, the transfer function $g(z) = C(zI - A)^{-1}B$ is such that $g^\perp \in H^\infty$ due to the fact that $\|A\| < 1$. Since this is a power-stable realization, by Corollary 4.13, g must be cyclic. Thus there exists a cyclic transfer function that has power-stable parbalanced realizations.

5. Concluding remarks. We have shown the asymptotic stability of parbalanced realizations and have given conditions for an input normal or output normal realization to be asymptotically stable. An input normal or output normal realization cannot be power-stable unless the transfer function is rational. This is also true for parbalanced realizations when the transfer functions are assumed to be strictly noncyclic. If the transfer function is cyclic, the problem of finding a full characterization for power stability of parbalanced realizations remains open.

Concluding the paper, we point out that the results here can be translated to continuous-time systems by the bilinear mapping defined in [10]. However, to use that mapping, we restrict the discrete-time transfer functions to be *admissible*. A function G is said to be an admissible discrete-time transfer function if G is in $TL D^{U,Y}$ and the limit

$$\lim_{\substack{\lambda < -1, \lambda \rightarrow -1 \\ \lambda \in \mathbb{R}}} G(\lambda)$$

exists in the norm topology. Correspondingly, the discrete-time linear systems (A, B, C, D) must be *admissible*, also; that is, in addition to A being contractive, B, C , and D being bounded, the limit

$$\lim_{\substack{\lambda \rightarrow -1, \lambda > -1 \\ \lambda \in \mathbb{R}}} C(\lambda I + A)^{-1} B$$

must exist in the norm topology and $-1 \notin \sigma_p(A)$. It can be easily verified that the restricted and *-restricted shift realizations of admissible transfer functions are admissible systems. Moreover, the dual system of an admissible system is admissible, and any reachable and observable parbalanced realization of an admissible transfer function is an admissible system. Since the class of admissible transfer functions (linear systems) is smaller than the class of transfer functions (linear systems) considered in this paper, all the results of this paper are also valid for the smaller class.

WEAK SHARP MINIMA IN MATHEMATICAL PROGRAMMING*

J. V. BURKE[†] AND M. C. FERRIS[‡]

Abstract. The notion of a *sharp*, or *strongly unique*, minimum is extended to include the possibility of a nonunique solution set. These minima will be called *weak sharp minima*. Conditions necessary for the solution set of a minimization problem to be a set of weak sharp minima are developed in both the unconstrained and constrained cases. These conditions are also shown to be sufficient under the appropriate convexity hypotheses. The existence of weak sharp minima is characterized in the cases of linear and quadratic convex programming and for the linear complementarity problem. In particular, a result of Mangasarian and Meyer is reproduced that shows that the solution set of a linear program is always a set of weak sharp minima whenever it is nonempty. Consequences for the convergence theory of algorithms are also examined, especially conditions yielding finite termination.

Key words. finite termination, strongly unique minima, sharp minima

AMS subject classifications. 90C20, 90C30, 65K05

1. Introduction. Let $f: X \mapsto \bar{\mathbf{R}} := \mathbf{R} \cup \{-\infty, \infty\}$; we say that f has a sharp minimum at $\bar{x} \in \mathbf{R}^n$ if $f(x) \geq f(\bar{x}) + \alpha \|x - \bar{x}\|$, for all x near \bar{x} and some $\alpha > 0$. The notion of a sharp minimum, or equivalently, a strongly unique local minimum, has far reaching consequences for the convergence analysis of many iterative procedures [1], [8], [11], [12], [17], [18]. In this article, we extend the notion of a sharp minimum to include the possibility of a nonunique solution set. We say that $\bar{S} \subset \mathbf{R}^n$ is a set of *weak sharp minima* for the function f relative to the set $S \subset \mathbf{R}^n$ where $\bar{S} \subset S$ if there is an $\alpha > 0$ such that

$$(1) \quad f(x) \geq f(y) + \alpha \text{dist}(x | \bar{S}),$$

for all $x \in S$ and $y \in \bar{S}$ where

$$\text{dist}(x | \bar{S}) := \inf_{z \in \bar{S}} \|x - z\|.$$

The constant α and the set \bar{S} are called the modulus and domain of sharpness for f over S , respectively. Clearly, \bar{S} is a set of global minima for f over S . The notion of weak sharp minima is easily localized. We will say that $\bar{x} \in \mathbf{R}^n$ is a local weak sharp minimum for f on $S \subset \mathbf{R}^n$ if there exists a set $\bar{S} \subset S$ and a parameter $\delta > 0$ with $\bar{x} \in \bar{S}$ such that the set $\bar{S} \cap \{x : \|x - \bar{x}\| \leq \delta\}$ is a set of weak sharp minima for the function

$$f_\delta(x) := \begin{cases} f(x), & \text{if } \|x - \bar{x}\| \leq \delta, \\ +\infty, & \text{otherwise,} \end{cases}$$

relative to the set S . Since the restriction to the local setting is straightforward, we will concentrate on the global definition.

The study of weak sharp minima is motivated primarily by applications in convex and convex composite programming, where such minima commonly occur. For example, such minima frequently occur in linear programming, linear complementarity,

and least distance or projection problems. The goals of this study are to quantify this property, investigate its geometric structure, characterize its occurrence in simple convex programming problems, and, finally, to analyze its impact on the convergence of algorithms. Furthermore, although our primary interest is with convex programming, we also investigate the significance of weak sharp minima for nonconvex problems. However, in the latter case, rather strong regularity conditions are required to yield significant extensions of the convex case. Nonetheless, we do obtain some very interesting and significant results for differentiable problems with convex constraints. These results extend and refine earlier work of Al-Khayyal and Kyparisis [1] on the finite termination of algorithms at sharp minima. In a later study, we also show how these results can be applied to convex composite optimization problems to establish the quadratic rate of convergence of a variety of algorithms. This study builds on the work initiated in [9].

Our study begins in §2 with the derivation of first-order necessary conditions for the solution set of a problem to be a set of weak sharp minima. The unconstrained ($S = \mathbb{R}^n$) and constrained cases are treated separately. When the problem data is convex, it is shown that these conditions are also sufficient. In the third section these results are applied to three important classes of convex programs: quadratic programming, linear programming, and the linear complementarity problem. In the final section we examine certain tools for studying the convergence of algorithms in the presence of weak sharp minima. In particular, it is shown how we can attain finite convergence to weak sharp minima.

The notation that we employ is for the most part standard; however, a partial list is provided for the readers' convenience. The *inner product* on \mathbb{R}^n is defined as the bilinear form

$$\langle y, x \rangle := \sum_{i=1}^n y_i x_i.$$

We denote a *norm* on \mathbb{R}^n by $\|\cdot\|$. Each norm defines a norm dual to it and is given by

$$\|x\|_o := \sup_{\|y\| \leq 1} \langle y, x \rangle.$$

The associated closed unit balls for these norms are denoted by B and B° , respectively. The 2-norm plays a special role in our development and is denoted by

$$\|x\|_2 := \sqrt{\langle x, x \rangle}.$$

If it is understood from the context that we are speaking of the 2-norm, then we will drop the subscript "2" from this notation.

Given two subsets A and B of \mathbb{R}^n and $\beta \in \mathbb{R}$, we define

$$A \pm \beta B := \{a \pm \beta b : a \in A, b \in B\}.$$

On the other hand,

$$A \setminus B := \{a \in A : a \notin B\}.$$

If $A \subset \mathbb{R}^n$ then the *polar* of A is defined to be the set

$$A^\circ := \{x^* \in \mathbb{R}^n : \langle x^*, x \rangle \leq 1 \ \forall x \in A\}.$$

This notation is consistent with the definition of the dual unit ball B° . The *indicator* and *support* functions for A are given by

$$\psi(x \mid A) := \begin{cases} 0 & \text{if } x \in A, \\ +\infty & \text{otherwise} \end{cases}$$

and

$$\psi^*(x \mid A) := \sup\{\langle x^*, x \rangle : x^* \in A\},$$

respectively. Moreover, we write $\text{int } A$ for the interior of A , $\text{cl } A$ for the closure of A , and $\text{span } A$ for the linear span of the elements of A . The *relative interior* of A , denoted $\text{ri } A$, is the interior of A relative to the *affine hull* of A , which is given by

$$\text{aff } A := \left\{ \sum_{k=1}^s \lambda_k x_k \mid \begin{array}{l} s \in \{1, 2, \dots\}, x_k \in A \text{ and } \lambda_k \in \mathbb{R} \\ \text{for } k = 1, 2, \dots, s, \text{ with } \sum_{k=1}^s \lambda_k = 1 \end{array} \right\}.$$

The subspace *perpendicular* to A is defined to be

$$A^\perp := \{y \in \mathbb{R}^n : \langle y, x \rangle = 0 \text{ for all } x \in A\}.$$

If A is closed, then we define the *projection* of a point $x \in \mathbb{R}^n$ onto the set A as the set of all points in A that are closest to x in a given norm. In this paper, we will only speak of the projection with respect to the 2-norm; it is denoted by

$$P(x \mid A) := \{\bar{y} \in A : \|x - \bar{y}\|_2 = \inf_{y \in A} \|x - y\|_2\}.$$

The projection is an example of a multivalued mapping on \mathbb{R}^n . The set A is said to be *convex* if the line segment connecting any two points in A is also contained in A . The *convex hull* of the set A , denoted $\text{co}(A)$, is the smallest convex set that contains A ; that is, $\text{co}(A)$ is the intersection of all convex sets that contain A . It is interesting to note that the projection operator can be used to characterize the closed convex subsets of \mathbb{R}^n . That is, the set A is closed and convex if and only if the projection operator for A , $P(\cdot \mid A)$, is single valued on all of \mathbb{R}^n [2], [16].

Given $x \in A$, we define the *normal cone* to A at x , denoted $N(x \mid A)$, to be the closure of the convex hull of all limits of the form

$$\lim_k t_k^{-1}(x_k - p_k),$$

where the sequences $\{t_k\} \subset \mathbb{R}$, $\{p_k\} \subset A$, and $\{x_k\} \subset \mathbb{R}^n$ satisfy $t_k \downarrow 0$, $p_k \in P(x_k \mid A)$, and $p_k \rightarrow x$. If A is convex, we can show that this definition implies that

$$N(x \mid A) = \{x^* \in \mathbb{R}^n : \langle x^*, y - x \rangle \leq 0 \ \forall y \in A\}.$$

The *tangent cone* to A at x is defined dually by the relation

$$T(x \mid A) := N(x \mid A)^\circ.$$

If A is convex, we have the relation

$$T(x \mid A) = \text{cl} [\cup_{\lambda \geq 0} \lambda(A - x)].$$

The *contingent cone* to A at x plays a role similar to that of the tangent cone but is, in general, larger. The contingent cone to A at x is given by

$$K(x | A) := \{d \in \mathbb{R}^n : \exists t_k \downarrow 0, d^k \rightarrow d, \text{ with } x + t_k d^k \in A\}.$$

The set A is said to be *regular* at $x \in A$ if $T(x | A) = K(x | A)$. In particular, every convex set is regular.

Let $f: X \mapsto \overline{\mathbb{R}} := \mathbb{R} \cup \{+\infty\}$. The *domain* and *epigraph* of f are given by

$$\text{dom } f := \{x \in \mathbb{R}^n : f(x) < +\infty\}$$

and

$$\text{epi } f := \{(x, \lambda) \in \mathbb{R}^n \times \mathbb{R} : f(x) \leq \lambda\},$$

respectively. Observe that f is lower semicontinuous if and only if $\text{epi } f$ is closed. For $x \in \text{dom } f$, we define the *subdifferential* of f at x to be the set

$$\partial f(x) := \{x^* : (x^*, -1) \in N((x, f(x)) | \text{epi } f)\},$$

and the *singular subdifferential* of f at x to be the set

$$\partial^\infty f(x) := \{x^* : (x^*, 0) \in N((x, f(x)) | \text{epi } f)\}.$$

The mappings ∂f and $\partial^\infty f$ are further examples of multivalued mappings on \mathbb{R}^n . We observe that the set $\partial f(x) \cup \partial^\infty f(x)$ is always nonempty even though ∂f may be empty at certain points. Moreover, the function f is locally Lipschitzian on \mathbb{R}^n if and only if ∂f is nonempty and compact valued on all of \mathbb{R}^n . The domain of ∂f is the set

$$\text{dom } \partial f := \{x^* \in \mathbb{R}^n : \partial f(x) \neq \emptyset\}.$$

If f is convex, then this subdifferential coincides with the usual subdifferential from convex analysis. The *generalized directional derivative* of f is the support function of $\partial f(x)$,

$$f^\circ(x; d) := \psi^*(d | \partial f(x)),$$

and the *contingent directional derivative* of f at x in the direction d is given by

$$f^-(x; d) := \liminf_{\substack{u \rightarrow d \\ t \downarrow 0}} \frac{f(x + tu) - f(x)}{t}.$$

The relation $f^-(x; d) \leq f^\circ(x; d)$ always holds. The function f is said to be *regular* at x if $f^\circ(x; d) = f^-(x; d)$ in which case the usual directional derivative,

$$f'(x; d) := \lim_{t \downarrow 0} \frac{f(x + td) - f(x)}{t},$$

exists and equals this common value. See [7] for further details of subdifferential calculus.

2. Subdifferential geometry. We begin with a study of some geometric consequences of weak sharp minima. Specifically, we are interested in first-order necessary conditions. The general unconstrained ($S = \mathbb{R}^n$) and constrained cases are treated separately. In both cases, it is shown that the necessary conditions are also sufficient under appropriate convexity hypotheses. The following preliminary result is required.

LEMMA 2.1. *Suppose $f: \mathbb{R}^n \mapsto \bar{\mathbb{R}}$ is closed, proper, and convex, the sets $\bar{S} := \arg \min \{f(x) : x \in \mathbb{R}^n\}$ and C are nonempty, closed, and convex subsets of \mathbb{R}^n with $C \subseteq \bar{S}$, and $\alpha > 0$. The following are equivalent:*

1. $\alpha B^\circ \cap N(x \mid \bar{S}) \subseteq \partial f(x)$, for all $x \in C$,
2. $\alpha B^\circ \cap \bigcup_{x \in C} N(x \mid \bar{S}) \subseteq \bigcup_{x \in C} \partial f(x)$.

Proof. [1 \implies 2]. Trivial.

[2 \implies 1]. Let $z \in C$ and $z^* \in \alpha B^\circ \cap N(z \mid \bar{S})$. Then by hypothesis, $z^* \in \partial f(u)$ for some $u \in C$. Since $C \subseteq \bar{S}$ implies that $\partial f(u) \subseteq N(u \mid \bar{S})$, hence $z^* \in N(u \mid \bar{S})$, it follows from $z^* \in N(z \mid \bar{S})$ that

$$(2) \quad \langle z^*, u \rangle = \langle z^*, z \rangle.$$

However, $z^* \in \partial f(u)$ is by definition $f(y) - f(u) \geq \langle z^*, y - u \rangle$, for all y . Since $u, z \in \bar{S}$, $f(u) = f(z)$ so that (2) gives $f(y) - f(z) \geq \langle z^*, y - z \rangle$, for all y , or equivalently, $z^* \in \partial f(z)$. \square

Necessary conditions for weak sharp minima in the unconstrained case now follow.

THEOREM 2.2. *Let $f: \mathbb{R}^n \mapsto \bar{\mathbb{R}}$ be lower semicontinuous and $\alpha > 0$. Consider the following statements:*

1. *The set \bar{S} is a set of weak sharp minima for the function f on \mathbb{R}^n with modulus α .*
2. *For all $d \in \mathbb{R}^n$,*

$$f^-(x; d) \geq \alpha \text{dist}(d \mid K(x \mid \bar{S})).$$

3. *For all $d \in \mathbb{R}^n$*

$$f^\circ(x; d) \geq \alpha \text{dist}(d \mid T(x \mid \bar{S})).$$

4. *The inclusion*

$$\alpha B^\circ \cap N(x \mid \bar{S}) \subseteq \partial f(x)$$

holds.

5. *The inclusion*

$$\alpha B^\circ \cap \left[\bigcup_{x \in \bar{S}} N(x \mid \bar{S}) \right] \subseteq \bigcup_{x \in \bar{S}} \partial f(x)$$

holds.

6. *For all $y \in \mathbb{R}^n$,*

$$f'(p; y - p) \geq \alpha \text{dist}(y \mid \bar{S}),$$

where $p \in P(y \mid \bar{S})$.

Statement 1 implies statement 2 for all $x \in \bar{S}$. Statement 2 implies statement 3 at points $x \in \bar{S}$ at which \bar{S} is regular. Statements 3 and 4 are equivalent. If f is closed proper and convex and the set \bar{S} is nonempty closed and convex, then statements 1–6 are equivalent with 2, 3, and 4 holding at every point of \bar{S} .

Proof.

[1 \implies 2]. Let $x \in \bar{S}$. The hypothesis guarantees that for all t and d'

$$f(x + td') - f(x) \geq \alpha \text{dist}(x + td' \mid \bar{S}),$$

which implies that

$$\frac{f(x + td') - f(x)}{t} \geq \alpha \frac{\text{dist}(x + td' \mid \bar{S}) - \text{dist}(x \mid \bar{S})}{t}.$$

By taking lim infs of both sides as $d' \rightarrow d$ and $t \downarrow 0$ and applying [4, Thm. 4], we obtain the result.

[(2 plus regularity) \implies 3]. Simply observe that regularity at $x \in \bar{S}$ implies the equivalence $T(x \mid \bar{S}) = K(x \mid \bar{S})$ and by definition $f^\circ(x; \cdot) \geq f^-(x; \cdot)$.

[3 \iff 4]. We recall from [5, Thm. 3.1] that if $K \subset \mathbb{R}^n$ is a nonempty closed convex cone, then

$$\text{dist}(x \mid K) = \psi^*(x \mid K^\circ \cap B^\circ).$$

The result now follows from the fact that $f^\circ(x; \cdot) = \psi^*(\cdot \mid \partial f(x))$.

Observe that if f is closed proper and convex, and \bar{S} is nonempty closed and convex, then f is regular on its domain and \bar{S} is regular at each of its elements. Hence either one of the statements 1 or 2 implies both 3 and 4 for all $x \in \bar{S}$.

[(4 holds for all $x \in \bar{S}$) \implies 5]. Trivial.

[(5 plus convexity) \implies 4]. Convexity and Lemma 2.1 combine to establish that 5 implies 4.

[(5 plus convexity) \implies 1]. Given $y \in \mathbb{R}^n$, Theorem 1 in [4] implies the existence of a $x^* \in \alpha B^\circ \cap N(P(y \mid \bar{S}) \mid \bar{S})$ such that $\alpha \text{dist}(y \mid \bar{S}) = \langle x^*, y \rangle - \psi^*(x^* \mid \bar{S})$. Thus, by hypothesis, there exists a $x \in \bar{S}$ with $x^* \in \partial f(x)$. Hence

$$\begin{aligned} f(y) &\geq f(x) + \langle x^*, y - x \rangle \\ &\geq f(x) + \langle x^*, y \rangle - \langle x^*, x \rangle \\ &\geq f(x) + \langle x^*, y \rangle - \psi^*(x^* \mid \bar{S}) \\ &= f(x) + \alpha \text{dist}(y \mid \bar{S}). \end{aligned}$$

Since $y \in \mathbb{R}^n$ is arbitrary, the result is obtained.

[(1 plus convexity) \implies 6]. Let y be given and define $p := P(y \mid \bar{S})$ so that $f(y) \geq f(p) + \alpha \text{dist}(y \mid \bar{S}) = f(p) + \alpha \|y - p\|$. Let $z = \lambda y + (1 - \lambda)p$ for $\lambda \in [0, 1]$. Then $p = P(z \mid \bar{S})$ and

$$f(z) \geq f(p) + \alpha \|z - p\| = f(p) + \alpha \lambda \|y - p\|$$

implying that

$$\frac{f(p + \lambda(y - p)) - f(p)}{\lambda} \geq \alpha \|y - p\|.$$

The result now follows in the limit.

[(6 plus convexity) \implies 1]. Since f is convex it follows that for all x and y

$$f'(x; y - x) = \inf_{t>0} \left[\frac{f(x + t(y - x)) - f(x)}{t} \right]$$

so that for any y we may take $x = P(y \mid \bar{S}) = p$, $t = 1$ and

$$f(p + y - p) - f(p) \geq f'(p; y - p) \geq \alpha \text{dist}(y \mid \bar{S}). \quad \square$$

COROLLARY 2.3. *Suppose f is closed proper and convex and has a set of weak sharp minima \bar{S} that is nonempty, closed, convex, and compact. Then*

$$0 \in \text{int} \bigcup_{\bar{x} \in \bar{S}} \partial f(\bar{x}).$$

Proof. The corollary follows if we can show that

$$\bigcup_{x \in \bar{S}} N(x \mid \bar{S}) = \mathbf{R}^n.$$

Clearly, $\bigcup_{x \in \bar{S}} N(x \mid \bar{S}) \subset \mathbf{R}^n$, so let $y \in \mathbf{R}^n$. By continuity of $\langle y, \cdot \rangle$ and compactness of \bar{S}

$$z^* \in \arg \max_{z \in \bar{S}} \langle y, z \rangle$$

so that $\langle y, z - z^* \rangle \leq 0$, for all $z \in \bar{S}$. Hence $y \in N(z^* \mid \bar{S})$. \square

In the constrained case, we must introduce a constraint qualification to guarantee the validity of the type of first-order optimality conditions that are required for our analysis. For the problem

$$(3) \quad \begin{array}{ll} \text{minimize} & f(x), \\ & x \in S \end{array}$$

these optimality conditions take the form

$$(4) \quad 0 \in \partial f(x) + N(x \mid S).$$

Condition (4) is not always guaranteed to be valid even in the fully convex case, so a constraint qualification is required.

Example 2.4. Consider (3), where $f: \mathbf{R} \mapsto \bar{\mathbf{R}}$ is given by

$$f(x) := \begin{cases} -\sqrt{1+x^2}, & \text{for } x \in [-1, 1] \\ +\infty, & \text{otherwise,} \end{cases}$$

and $S := \{x : x \leq -1\}$. This is a convex program with a closed proper convex objective function having unique global solution $\bar{x} = -1$. However, (4) does not hold since $\partial f(\bar{x}) = \emptyset$.

For this reason we introduce the following constraint qualification due to Rockafellar [20].

DEFINITION 2.5. We say that the *basic constraint qualification* (BCQ) for (3) is satisfied at $x \in S$ if for every $u \in \partial^\infty f(x)$ and $v \in N(x \mid S)$ such that $u + v = 0$ it must be the case that $u = v = 0$. The BCQ is said to be satisfied on a set $\bar{S} \subset S$ if it is satisfied at every point of \bar{S} .

From Rockafellar [20, Cor. 5.2.1], we know that the optimality condition (4) is satisfied at every local solution to (3) at which the BCQ holds. In particular, if f is locally Lipschitzian on \mathbb{R}^n , then $\partial^\infty f(x) = \{0\}$ on all of \mathbb{R}^n ; hence the BCQ is vacuously satisfied on all of S , so (4) holds at every local minima for (3).

THEOREM 2.6. *Suppose $f: \mathbb{R}^n \mapsto \bar{\mathbb{R}}$ is lower semicontinuous and $\bar{S} \subset S$ are nonempty closed subsets of \mathbb{R}^n .*

(a) *The inclusion*

$$(5) \quad \alpha B \subset \partial f(\bar{x}) + \left[T(\bar{x} \mid S) \bigcap N(\bar{x} \mid \bar{S}) \right]^\circ.$$

holds at $\bar{x} \in \bar{S}$ if and only if

$$(6) \quad f^\circ(\bar{x}; z) \geq \alpha \|z\| \quad \forall z \in T(\bar{x} \mid S) \bigcap N(\bar{x} \mid \bar{S}).$$

(b) *If \bar{S} is a set of weak sharp minima for f over S with modulus $\alpha > 0$ such that the BCQ holds at every point of \bar{S} , then for each $\bar{x} \in \bar{S}$ at which f , S , and \bar{S} are regular, we have the inclusion (5).*

(c) *If we further assume that f is closed proper and convex and the sets \bar{S} and S are nonempty closed and convex, then \bar{S} is a set of weak sharp minima for f over S with modulus $\alpha > 0$ if and only if the inclusion (5) holds for all $\bar{x} \in \bar{S}$.*

Proof. (a) We show that (5) and (6) are equivalent. Clearly, both statements are false if $\partial f(\bar{x})$ is empty, so we assume it to be nonempty. First note that (6) is equivalent to

$$(7) \quad \sup \{ \langle x^*, z \rangle \mid x^* \in \partial f(\bar{x}) \} \geq \alpha \|z\| \quad \forall z \in T(\bar{x} \mid S) \bigcap N(\bar{x} \mid \bar{S}).$$

We show this is equivalent to

$$(8) \quad \sup \left\{ \langle x^*, z \rangle \mid x^* \in \partial f(\bar{x}) + \left[T(\bar{x} \mid S) \bigcap N(\bar{x} \mid \bar{S}) \right]^\circ \right\} \geq \alpha \|z\| \quad \forall z \in \mathbb{R}^n.$$

This is accomplished in two parts. First, it is shown that the supremum in (8) is infinite if $z \notin T(\bar{x} \mid S) \bigcap N(\bar{x} \mid \bar{S})$ and then it is shown that the suprema in (7) and (8) are equal if $z \in T(\bar{x} \mid S) \bigcap N(\bar{x} \mid \bar{S})$. Suppose $z \notin T(\bar{x} \mid S) \bigcap N(\bar{x} \mid \bar{S})$. Then there exists $z^* \in \left[T(\bar{x} \mid S) \bigcap N(\bar{x} \mid \bar{S}) \right]^\circ$ such that $\langle z^*, z \rangle > 0$. Let $x^* \in \partial f(\bar{x})$, which is nonempty by assumption, and consider $x^* + \lambda z^*$ as $\lambda \rightarrow \infty$. Since $\langle x^* + \lambda z^*, z \rangle \uparrow +\infty$ as $\lambda \uparrow +\infty$, we see that the supremum in (8) is infinite. Suppose that $z \in T(\bar{x} \mid S) \bigcap N(\bar{x} \mid \bar{S})$. Then

$$\begin{aligned} & \sup \{ \langle x^*, z \rangle \mid x^* \in \partial f(\bar{x}) \} \\ & \leq \sup \left\{ \langle x^*, z \rangle \mid x^* \in \partial f(\bar{x}) + \left[T(\bar{x} \mid S) \bigcap N(\bar{x} \mid \bar{S}) \right]^\circ \right\} \end{aligned}$$

since $0 \in \left[T(\bar{x} \mid S) \bigcap N(\bar{x} \mid \bar{S}) \right]^\circ$. However

$$\begin{aligned} & \sup \left\{ \langle x^*, z \rangle \mid x^* \in \partial f(\bar{x}) + \left[T(\bar{x} \mid S) \bigcap N(\bar{x} \mid \bar{S}) \right]^\circ \right\} \\ & = \sup \left\{ \langle y^* + z^*, z \rangle \mid y^* \in \partial f(\bar{x}), z^* \in \left[T(\bar{x} \mid S) \bigcap N(\bar{x} \mid \bar{S}) \right]^\circ \right\} \\ & \leq \sup \{ \langle y^*, z \rangle \mid y^* \in \partial f(\bar{x}) \} \end{aligned}$$

by the definition of a polar cone.

Note that (8) is equivalent to

$$\psi^*(z \mid \alpha B) \leq \psi^*(z \mid \partial f(\bar{x}) + [T(\bar{x} \mid S) \cap N(\bar{x} \mid \bar{S})]^\circ),$$

which is equivalent to

$$\alpha B \subseteq \partial f(\bar{x}) + [T(\bar{x} \mid S) \cap N(\bar{x} \mid \bar{S})]^\circ,$$

which establishes the result.

(b) The definitions imply that \bar{S} is a set of weak sharp minima for f over S with modulus $\alpha > 0$ if and only if \bar{S} is a set of weak sharp minima for the function $h(x) := f(x) + \psi(x \mid S)$ over \mathbb{R}^n with modulus $\alpha > 0$. We will show that this implies (6) for every $\bar{x} \in \bar{S}$ at which f , \bar{S} and S are regular.

Let $\bar{x} \in \bar{S}$ be a point at which f , \bar{S} , and S are regular. Since \bar{S} is a set of weak sharp minima for h over \mathbb{R}^n with modulus $\alpha > 0$, Theorem 2.2 implies that

$$h'(\bar{x}; d) \geq \alpha \text{dist}(d \mid T(\bar{x} \mid \bar{S})) \quad \text{for all } d.$$

Now, by the BCQ, [20, Cor. 8.1.2], and the regularity of S , we know that

$$(9) \quad h'(\bar{x}; d) \leq f'(\bar{x}; d) + \psi(\cdot \mid S)'(\bar{x}; d) = f'(\bar{x}; d) + \psi(d \mid T(\bar{x} \mid S)).$$

Therefore,

$$f'(\bar{x}; d) \geq \alpha \text{dist}(d \mid T(\bar{x} \mid \bar{S})) \quad \text{for all } d \in T(\bar{x} \mid S).$$

This last inequality implies (6) since

$$\text{dist}(d \mid T(\bar{x} \mid \bar{S})) = \|d\|$$

for every $d \in N(\bar{x} \mid \bar{S})$.

(c) Since convexity implies regularity, half of this result has already been established in part (b). It remains to show that (5) holding for all $\bar{x} \in \bar{S}$ implies that \bar{S} is a set of weak sharp minima for f over S with modulus α .

Let $\bar{x} \in \bar{S}$. It was shown in part (a) that the statement (5) is equivalent to the statement (6). Thus we need only show that if (6) holds for all $\bar{x} \in \bar{S}$, then \bar{S} is a set of weak sharp minima for f over S with modulus α . To this end, let $x \in \mathbb{R}^n$ be given and set $\bar{x} = P(x \mid \bar{S})$. By (9) we only need consider cases where $x - \bar{x} \in T(\bar{x} \mid S)$. From the definition of projection it follows that $x - \bar{x} \in N(\bar{x} \mid \bar{S})$. Therefore, $f'(\bar{x}; x - \bar{x}) \geq \alpha \|x - \bar{x}\|$, for all x and hence $h'(\bar{x}; x - \bar{x}) \geq \alpha \text{dist}(x \mid \bar{S})$, for all x . By Theorem 2.2, \bar{S} is a set of weak sharp minima for f over S with modulus α . \square

COROLLARY 2.7. *Suppose $f: \mathbb{R}^n \mapsto \mathbb{R}$ is differentiable and $\bar{S} \subset S$ are nonempty closed subsets of \mathbb{R}^n .*

(a) *The inclusion*

$$(10) \quad \alpha B \subset \nabla f(\bar{x}) + [T(\bar{x} \mid S) \cap N(\bar{x} \mid \bar{S})]^\circ$$

holds at $\bar{x} \in \bar{S}$ if and only if

$$\langle \nabla f(\bar{x}), z \rangle \geq \alpha \|z\| \quad \forall z \in T(\bar{x} \mid S) \cap N(\bar{x} \mid \bar{S}).$$

(b) If \bar{S} is a set of weak sharp minima for f over S with modulus $\alpha > 0$, then for each $\bar{x} \in \bar{S}$ at which S and \bar{S} are regular, we have the inclusion (10).

(c) If we further assume that f is closed proper and convex and the sets \bar{S} and S are nonempty closed and convex, then \bar{S} is a set of weak sharp minima for f over S with modulus $\alpha > 0$ if and only if

$$-\nabla f(\bar{x}) \in \text{int} \bigcap_{x \in \bar{S}} [T(x | S) \cap N(x | \bar{S})]^\circ.$$

Remark. The corollary given above is a strengthening of [1, Prop. 2.2]. In particular, the equivalence in part (a) is proven without assumptions on convexity of S . In fact, under the convexity assumptions in part (c), the condition given in [1] is equivalent to strong uniqueness. By relaxing strong uniqueness to the assumption of a weak sharp minimum, all the results of [1, Prop. 2.2] still follow, with the exception of uniqueness.

3. Some special cases. We now examine three important classes of convex programming problems and characterize when these problems possess weak sharp minima. The problem classes considered are linear and quadratic programming and the linear complementarity problem.

3.1. Quadratic programming. We will use the results on weak sharp minima from §2 to obtain a necessary and sufficient condition for weak sharp minima to occur in convex quadratic programs.

The quadratic programming problem is

$$(11) \quad \begin{array}{ll} \text{minimize} & \frac{1}{2} \langle x, Qx \rangle + \langle c, x \rangle, \\ & x \in S \end{array}$$

where S is polyhedral and $Q \in \mathbb{R}^{n \times n}$ is symmetric and positive semidefinite. The key to our characterization of when problem (11) has weak sharp minima is the relation (6) in Theorem 2.6. To apply this result, we must first obtain a tractable description of the tangent cone to the solution set of (11). This is accomplished by using the description of the solution set of a convex program given in [3], [14].

THEOREM 3.1. *Let \bar{S} be the set of solutions to the problem $\min\{f(x) : x \in S\}$ where both $f: \mathbb{R}^n \mapsto \mathbb{R}$ and $S \subset \mathbb{R}^n$ are taken to be convex and choose $\bar{x} \in \bar{S}$. Then*

$$\bar{S} = \{x \in S \mid \nabla f(x) = \nabla f(\bar{x}), \langle \nabla f(\bar{x}), x - \bar{x} \rangle = 0\}.$$

It is clear that for convex quadratic programs this gives the solution set as

$$\bar{S} = S \cap \{x \mid \langle \nabla f(\bar{x}), x - \bar{x} \rangle = 0\} \cap \{x \mid \nabla^2 f(\bar{x})(x - \bar{x}) = 0\}$$

and since S is polyhedral

$$(12) \quad T(x \mid \bar{S}) = T(x \mid S) \cap (\nabla f(\bar{x}))^\perp \cap \ker(\nabla^2 f(\bar{x})).$$

Note that $\nabla f(\bar{x})$ is constant on the solution set of a convex program and $\nabla^2 f(\bar{x})$ is constant for the problem (11). In the rest of this paper, we will use the notation $\nabla f(\bar{x})$, $\nabla^2 f(\bar{x})$ for these constants and $\text{span}(d)$, $\ker(A)$ to represent the subspace generated by d and the nullspace of the matrix A , respectively.

THEOREM 3.2. Let \bar{S} be the set of solutions to (11) and assume that \bar{S} is non-empty. Then \bar{S} is a set of weak sharp minima for f over S if and only if

$$(\ker(\nabla^2 f(\bar{x})))^\perp \subseteq \text{span}(\nabla f(\bar{x})) + N(x | S), \quad \forall x \in \bar{S},$$

or, equivalently,

$$(\nabla f(\bar{x}))^\perp \cap T(x | S) \subseteq \ker(\nabla^2 f(\bar{x})), \quad \forall x \in \bar{S},$$

where \bar{x} is any element of \bar{S} .

Proof.

(\Leftarrow) We show that (6) holds. Let $x \in \bar{S}$ and $d \in T(x | S)$. Note that (12) and the hypothesis gives

$$\begin{aligned} K &:= T(x | \bar{S})^\circ = N(x | S) + \text{span}(\nabla f(\bar{x})) + (\ker(\nabla^2 f(\bar{x})))^\perp \\ &= N(x | S) + \text{span}(\nabla f(\bar{x})). \end{aligned}$$

Therefore

$$\begin{aligned} \alpha \text{dist}(d | T(x | \bar{S})) &= \alpha \psi^*(d | \mathbf{B} \cap T(x | \bar{S})^\circ) \\ &= \alpha \sup \left\{ \langle z, d \rangle \mid z \in \mathbf{B} \cap K \right\}. \end{aligned}$$

It follows from [21, p. 65] that $K = \text{span}(\nabla f(\bar{x})) + (K \cap (\nabla f(\bar{x}))^\perp)$, hence, $z \in \mathbf{B} \cap K$ implies $z = \lambda \nabla f(\bar{x}) + y$ with $|\lambda| \leq \eta$, where

$$\eta := \begin{cases} 1/\|\nabla f(\bar{x})\|, & \text{if } \|\nabla f(\bar{x})\| \neq 0, \\ 0 & \text{otherwise,} \end{cases}$$

and $y \in K \cap (\nabla f(\bar{x}))^\perp$. Therefore

$$\begin{aligned} \alpha \text{dist}(d | T(x | \bar{S})) &= \alpha \sup \left\{ \langle \lambda \nabla f(\bar{x}) + y, d \rangle \mid |\lambda| \leq \eta, y \in N(x | S) \cap (\nabla f(\bar{x}))^\perp \right\} \\ &\leq \alpha \eta \langle \nabla f(\bar{x}), d \rangle \\ &\leq \langle \nabla f(\bar{x}), d \rangle = \langle \nabla f(x), d \rangle = f'(x; d) \end{aligned}$$

as required. The last two inequalities follow since d and y are polar to each other and by choosing $\alpha \leq \|\nabla f(\bar{x})\|$ when $\nabla f(\bar{x}) \neq 0$.

(\Rightarrow) Suppose that for some $x \in \bar{S}$, $T(x | S) \cap (\nabla f(\bar{x}))^\perp \not\subseteq \ker(\nabla^2 f(\bar{x}))$. Then there exists $d \in T(x | S) \cap (\nabla f(\bar{x}))^\perp$ with $d \notin \ker(\nabla^2 f(\bar{x}))$. Thus from (12), $d \notin T(x | \bar{S})$ and so

$$\alpha \text{dist}(d | T(x | \bar{S})) > 0 = \langle \nabla f(\bar{x}), d \rangle = f'(x; d),$$

which, using (6), implies that (11) does not have a weak sharp minimum. \square

It is possible to illustrate the theorem by means of adapting a simple example given in [18, p. 206].

Example 3.3. The problem is

$$\begin{aligned} &\text{minimize}_{x \in \mathbb{R}^3} && \frac{1}{2}x_1^2 + \frac{1}{2}x_2^2 \\ &\text{subject to} && x_i \in [a_i, b_i], i = 1, 2, 3 \end{aligned}$$

for given $a, b \in \mathbb{R}^3$ with $a \leq b$. We let $S = [a_1, b_1] \times [a_2, b_2] \times [a_3, b_3]$. Note that

$$\bar{S} = \{(P(0 \mid [a_1, b_1]), P(0 \mid [a_2, b_2]), x_3) \mid x_3 \in [a_3, b_3]\}$$

and for each $\bar{x} \in \bar{S}$, $\nabla f(\bar{x}) = (\bar{x}_1, \bar{x}_2, 0)$. Also,

$$\nabla^2 f(\bar{x}) = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{bmatrix} \text{ so that } \ker \nabla^2 f(\bar{x}) = \{0\} \times \{0\} \times \mathbb{R}.$$

Furthermore, for $\bar{x} \in S$ we have

$$T(\bar{x} \mid S) = I_1(\bar{x}_1) \times I_2(\bar{x}_2) \times I_3(\bar{x}_3),$$

where

$$I_j(x_j) = \begin{cases} [0, +\infty) & \text{if } x_j = a_j, \\ \mathbb{R} & \text{if } a_j < x_j < b_j, \\ (-\infty, 0] & \text{if } x_j = b_j. \end{cases}$$

It follows that the second equivalence of Theorem 3.2 is satisfied exactly when $0 > b_i$ or $0 < a_i$ for $i = 1, 2$; that is, the box does not straddle the x_1 or x_2 axis. This is precisely when the problem has a weak sharp minimum.

A generalization of this result that does not require the set S to be polyhedral is easily obtained. Observe that the argument given above only employs the polyhedrality of S to establish that (12) holds. However, (12) also holds under the assumption

$$\text{ri}(S - \bar{x}) \cap (\nabla f(\bar{x}))^\perp \cap \ker(\nabla^2 f(\bar{x})) \neq \emptyset$$

(see [21, Cors. 23.8.1 and 16.4.2]), so the following result is immediate.

THEOREM 3.4. *Let \bar{S} be the solution set for (11) where it is no longer assumed that S is polyhedral. Suppose $\bar{x} \in \bar{S}$ is such that*

$$\text{ri}(S - \bar{x}) \cap (\nabla f(\bar{x}))^\perp \cap \ker(\nabla^2 f(\bar{x})) \neq \emptyset.$$

Then \bar{S} is a set of weak sharp minima for f over S if and only if

$$(\ker(\nabla^2 f(\bar{x})))^\perp \subseteq \text{span}(\nabla f(\bar{x})) + N(x \mid S) \quad \forall x \in \bar{S}.$$

3.2. Linear programming. It was shown in [15] that the solution set of a linear program is a set of weak sharp minima. We show below how it can be obtained as a corollary to Theorem 3.2.

The linear programming problem is

$$(13) \quad \begin{array}{ll} \text{minimize} & \langle c, x \rangle \\ & x \in S \end{array}$$

where S is polyhedral.

THEOREM 3.5. *If (13) has a solution, then the set of solutions is a set of weak sharp minima for this problem.*

Proof. Let \bar{x} be a solution of (13). We note that for linear programming $f(x) = \langle c, x \rangle$ so that

$$(\ker(\nabla^2 f(\bar{x})))^\perp = \{0\}.$$

It follows that

$$(\ker(\nabla^2 f(\bar{x})))^\perp \subseteq \text{span}(\nabla f(\bar{x}) + N(x \mid S)) \quad \forall x \in \bar{S},$$

so by Theorem 3.2, (13) has a weak sharp minimum. \square

As was done in Theorem 3.4, we can generalize this result to the case where S is not assumed to be polyhedral.

Remark. It is tempting to consider parametric results for weak sharp minima. In fact, the following example shows that this is not too fruitful. Consider the linear programs $P(i)$, for $i = 1, \dots, \infty$, given by

$$\begin{array}{ll} \text{minimize} & x_1/i + x_2 \\ \text{subject to} & x \geq 0 \end{array}$$

Then, as shown above, each of these problems has a weak sharp minimum. However, it is easy to show that there is no constant $\alpha > 0$ that will work for all of them.

As a simple application of this result, we have the following corollary.

COROLLARY 3.6. *Suppose $f: \mathbb{R}^n \mapsto \bar{\mathbb{R}}$ is a proper polyhedral convex function and the problem*

$$(14) \quad \min_{x \in \mathbb{R}^n} f(x)$$

has a nonempty solution set, \bar{S} . Then \bar{S} is a set of weak sharp minima for (14).

Proof. It follows from the definition of a polyhedral convex function that

$$f(x) = h(x) + \psi(x \mid C),$$

where

$$h(x) := \max\{\langle x, b_1 \rangle - \beta_1, \dots, \langle x, b_k \rangle - \beta_k\}$$

and

$$C := \{x : \langle x, b_{k+1} \rangle \leq \beta_{k+1}, \dots, \langle x, b_m \rangle \leq \beta_m\}.$$

It is clear that (14) is equivalent to

$$(15) \quad \begin{array}{ll} \text{minimize}_x & h(x) \\ \text{subject to} & x \in C, \end{array}$$

which in turn is equivalent to the linear program

$$(16) \quad \begin{array}{ll} \text{minimize}_{(x, \psi)} & \psi \\ \text{subject to} & \begin{array}{l} \psi \geq \langle x, b_i \rangle - \beta_i \quad i = 1, \dots, k \\ x \in C \end{array} \end{array}$$

and that the solution set of (16) is $\bar{S} \times \{h(\bar{x})\}$ for any $\bar{x} \in \bar{S}$. Theorem 3.5 implies the existence of $\alpha > 0$ such that

$$\begin{aligned} \psi - h(\bar{x}) &\geq \alpha \text{dist}((x, \psi) \mid \bar{S} \times \{h(\bar{x})\}) \\ &\geq \alpha \text{dist}(x \mid \bar{S}) \end{aligned}$$

for all (x, ψ) feasible for (16). It then follows that

$$h(x) - h(\bar{x}) \geq \alpha \text{dist}(x \mid \bar{S})$$

for all $x \in C$ since $(x, h(x))$ is feasible for (16). Thus (15) has a weak sharp minimum as required. \square

3.3. Sharpness for linear complementarity problems. We will use the analysis given previously to show that nondegenerate monotone linear complementarity problems have weak sharp minima. This was proved in [13].

The linear complementarity problem is to find an $x \geq 0$ with $Mx + q \geq 0$ satisfying $\langle x, Mx + q \rangle = 0$. To study this we consider the related optimization problem

$$(17) \quad \begin{array}{ll} \text{minimize} & \langle x, Mx + q \rangle \\ \text{subject to} & Mx + q \geq 0, x \geq 0. \end{array}$$

Given any feasible point x for (17), we define the sets

$$I(x) = \{i \mid M_i x + q_i = 0\} \quad \text{and} \quad J(x) = \{j \mid x_j = 0\}.$$

It is clear that any solution of (17) satisfies

$$I(x) \cup J(x) = \{1, \dots, n\}.$$

We make a convexity(monotone) assumption that M is positive semidefinite and a nondegeneracy assumption that there is a solution of (17), \hat{x} , which satisfies

$$I(\hat{x}) \cap J(\hat{x}) = \emptyset.$$

Under these assumptions, it can be shown that any other solution of (17) satisfies $I(\hat{x}) \subseteq I(x)$ and $J(\hat{x}) \subseteq J(x)$, (see for instance [13, Lemma 2.2]).

THEOREM 3.7. *The solution set of a nondegenerate monotone linear complementarity problem (17) is a set of weak sharp minima for the problem (17).*

Proof. Let x be any solution of (17) and let \hat{x} be the nondegenerate solution. By Theorem 3.2 we must show

$$(\nabla f(\hat{x}))^\perp \cap T(x \mid S) \subseteq \ker(\nabla^2 f(\hat{x})),$$

which, for this problem, means

$$\left\langle (M + M^T)\hat{x} + q, d \right\rangle = 0, \quad \begin{array}{l} M_{I(x)} d \geq 0 \\ d_{J(x)} \geq 0 \end{array} \Bigg\rangle \implies (M + M^T)d = 0.$$

We note that

$$\begin{aligned} 0 &= \langle (M + M^T)\hat{x} + q, d \rangle \\ &= \langle M\hat{x} + q, d \rangle + \langle \hat{x}, Md \rangle \\ &= \sum_{i \in J(\hat{x})} (M\hat{x} + q)_i d_i + \sum_{j \in I(\hat{x})} \hat{x}_j (Md)_j. \end{aligned}$$

Since $I(\hat{x}) \subseteq I(x)$ and $J(\hat{x}) \subseteq J(x)$ and $M_{I(x)} d \geq 0$ and $d_{J(x)} \geq 0$ we see that

$$\sum_{i \in J(\hat{x})} (M\hat{x} + q)_i d_i = 0 \quad \text{and} \quad \sum_{j \in I(\hat{x})} \hat{x}_j (Md)_j = 0.$$

It now follows that $d_{J(\hat{x})} = 0$ and $(Md)_{I(\hat{x})} = 0$ so that $\langle d, Md \rangle = 0$. This is equivalent to $(M + M^T)d = 0$ as required. \square

Note that in this result, we assume that the related optimization problem (17) has a weak sharp minimum, as opposed to an assumption of the form

$$(18) \quad -M\hat{x} - q \in \text{int } N(\hat{x} \mid \mathbf{R}_+^n)$$

as made in [1]. Using Theorem 3.7 it is easy to construct examples that are sharp in the sense given above, but do not satisfy (18).

4. Finite termination of algorithms. In this section we study the convergence properties of algorithms for solving problems of the form

$$(19) \quad \begin{array}{ll} \text{minimize} & f(x) \\ & x \in S \end{array}$$

where it is assumed that $f: \mathbf{R}^n \mapsto \mathbf{R}$ is differentiable and S is a nonempty closed convex subset of \mathbf{R}^n . Under the assumption that the solution set for (19), \bar{S} , is a set of weak sharp minima, we will examine certain tools for identifying an element of \bar{S} in a finite number of iterations. Our approach is based on the techniques developed in [6]. Consequently, we need to introduce some elementary facts concerning the face structure of convex sets.

Recall that a nonempty convex subset \hat{C} of a closed convex set C in \mathbf{R}^n is said to be a face of C if every convex subset of C whose relative interior meets \hat{C} is contained in \hat{C} (e.g., see [21, §18]). In fact, the relative interiors of the faces of C form a partition of C [21, Thm. 18.2]. Thus every point $x \in C$ can be associated with a unique face of C denoted by $F(x|C)$ such that $x \in \text{ri}(F(x|C))$. A face \hat{C} of C is said to be exposed if there is a vector $x^* \in \mathbf{R}^n$ such that $\hat{C} = E(x^* \mid C)$ where

$$E(x^* \mid C) := \arg \max\{\langle x^*, y \rangle : y \in C\}.$$

The vector x^* is said to expose the face $E(x^* \mid C)$. It is well known and elementary to show that every face \hat{C} of a polyhedron is exposed and that the exposing vectors are precisely the elements of $\text{ri}(N(x|C))$ for any $x \in \text{ri } \hat{C}$.

With these notions in mind, we have the following key result.

THEOREM 4.1. *If \bar{S} is a set of weak sharp minima for problem (19) that is regular, then the set*

$$K := \bigcap_{x \in \bar{S}} [T(x \mid S) \cap N(x \mid \bar{S})]^\circ$$

has nonempty interior and for each $z \in \text{int } K$ we have the inclusion $E(z \mid S) \subset \bar{S}$. If it is further assumed that the function f is convex, then \bar{S} is an exposed face of S with exposing vector $-\nabla f(\bar{x})$ for any $\bar{x} \in \bar{S}$.

Proof. The fact that the set K has nonempty interior follows immediately from Corollary 2.7, in particular, $-\nabla f(\bar{x}) \in \text{int } K$ for any $\bar{x} \in \bar{S}$. Let $z \in \text{int } K$ and choose $\delta > 0$ so that $z + \delta B \subset K$. Then for each $\bar{x} \in \bar{S}$

$$\langle z + \delta B, d \rangle \leq 0 \text{ for all } d \in T(\bar{x} \mid S) \bigcap N(\bar{x} \mid \bar{S}),$$

or, equivalently,

$$\langle z, d \rangle \leq -\delta \|d\| \text{ for all } d \in T(\bar{x} \mid S) \bigcap N(\bar{x} \mid \bar{S}).$$

Hence, given $x \in S$ and $p \in P(x \mid \bar{S})$ we have

$$\langle z, x - p \rangle \leq -\delta \|x - p\|$$

since $(x - p) \in T(p \mid S) \cap N(p \mid \bar{S})$. Consequently, $E(z \mid S) \subset \bar{S}$.

It only remains to show that if f is convex, then $E(-\nabla f(\bar{x}) \mid S) = \bar{S}$ for any $\bar{x} \in \bar{S}$. First observe that

$$(20) \quad \nabla f(x) = \nabla f(y) \text{ for every } x, y \in \bar{S}$$

by Theorem 3.1. Moreover, it has been established that $E(-\nabla f(\bar{x}) \mid S) \subset \bar{S}$. Hence the result will follow if we can show that $\langle \nabla f(x), x \rangle = \langle \nabla f(x), y \rangle$ for any choice of $x, y \in \bar{S}$. But this follows immediately from Theorem 3.1. \square

Remark. In Theorem 4.1, the nonemptiness of the set $\text{int } K$ followed from the differentiability hypothesis on f . In the absence of such a differentiability hypothesis, the result would, in general, be false. Indeed, we need only consider the case $f(x) := \text{dist}(x \mid \bar{S})$, where \bar{S} is any nonempty closed set and S is any set that properly contains \bar{S} in its interior.

In [10], the notion of minimum principle sufficiency was introduced. Assuming $\bar{x} \in \bar{S}$, we define

$$\hat{S} := \arg \min \{ \nabla f(\bar{x})x \mid x \in S \}.$$

Minimum principle sufficiency (MPS) is the equality of the sets \hat{S} and \bar{S} . Note that in the notation above $\hat{S} \equiv E(-\nabla f(\bar{x}) \mid S)$. Solodov [22] pointed out the following interesting corollary to Theorem 4.1.

THEOREM 4.2. *Suppose f is convex and differentiable and $S \subset \mathbb{R}^n$ is a closed convex set. If \bar{S} is a set of weak sharp minima for (19) then MPS is satisfied. If S is polyhedral, then MPS is equivalent to \bar{S} being a set of weak sharp minima for (19).*

Proof. The first statement of the theorem follows from Theorem 4.1. For the second part, note that for all $x \in S$

$$\begin{aligned} f(x) - f(P(x \mid \bar{S})) &\geq \nabla f(P(x \mid \bar{S}))(x - P(x \mid \bar{S})) && \text{by convexity of } f, \\ &= \nabla f(\bar{x})(x - P(x \mid \bar{S})) && \text{by Theorem 3.1,} \\ &= \nabla f(\bar{x})(x - P(x \mid \hat{S})) && \text{by MPS,} \\ &\geq \alpha \|x - P(x \mid \hat{S})\| && \text{by Theorem 3.5,} \\ &= \alpha \|x - P(x \mid \bar{S})\| && \text{by MPS,} \end{aligned}$$

where $\alpha > 0$ as required. \square

The following simple example shows that the assumption of polyhedrality cannot be removed in the above.

Example 4.3. The problem

$$\begin{aligned} &\text{minimize} && x_1 \\ &\text{subject to} && (x_1 - 1)^2 + x_2^2 \leq 1 \end{aligned}$$

has a unique solution $(0, 0)$. It is easy to see that MPS is satisfied. However, for the problem to have a weak sharp minimum would require the existence of $\alpha > 0$ such that

$$x_1 \geq \alpha \sqrt{x_1^2 + x_2^2}$$

for all feasible points x . If we consider points x on the boundary of the circle, then it follows that

$$x_1^2 \geq 2\alpha^2 x_1,$$

which is not true for x_1 sufficiently small.

Another simple application of Theorem 4.1 results in the following strong upper semicontinuity result for linear programs that was first proven in [19, Lemma 3.5].

COROLLARY 4.4. *Let S be a polyhedral convex set in \mathbb{R}^n . Let $c \in \mathbb{R}^n$ and $\bar{S} := \arg \max_{x \in S} \langle \bar{c}, x \rangle$. Then there is a neighborhood U of \bar{c} such that if $c \in U$ then*

$$\arg \max_{x \in S} \langle c, x \rangle = \arg \max_{x \in \bar{S}} \langle c, x \rangle.$$

Proof. If $\bar{S} = \emptyset$, the result follows from the fact that a polyhedral set has a finite number of faces and the graph of the subdifferential of a closed proper convex function is closed. Otherwise, it follows from Theorem 3.5 that \bar{S} is a set of weak sharp minima for

$$\max_{x \in S} \langle \bar{c}, x \rangle.$$

By Theorem 4.1, it follows that $\bar{S} = E(\bar{c} | S)$ and that for all c in a neighborhood of \bar{c} that $E(c | S) \subset E(\bar{c} | S)$. The required equality $E(c | S) = E(c | \bar{S})$ now follows easily. \square

As another immediate consequence of Theorem 4.1, we obtain the following generalization of a result found in [1].

COROLLARY 4.5. *Suppose \bar{S} is a set of weak sharp minima for the problem (19) and let $\{x^k\} \subset \mathbb{R}^n$. If either*

(a) *f is convex and $\{x^k\}$ is any sequence for which $\text{dist}(x^k | \bar{S}) \rightarrow 0$ and ∇f is uniformly continuous on an open set containing $\{x^k\}$, or*

(b) *the sequence $\{x^k\}$ converges to some $\hat{x} \in \bar{S}$, ∇f is continuous and \bar{S} is regular,*

then there is a positive integer k_0 such that any solution of

$$(21) \quad \begin{array}{l} \text{minimize} \quad \langle \nabla f(x^k), x \rangle \\ x \in S \end{array}$$

solves (19).

Proof. Let us first assume that (a) holds. By Theorem 2.6,

$$(22) \quad -\nabla f(\bar{x}) + \alpha B \in \bigcap_{x \in \bar{S}} [T(x | S) \cap N(x | \bar{S})]^\circ$$

for every $\bar{x} \in \bar{S}$, where $\alpha > 0$ is the modulus of weak sharp minimization for the set \bar{S} . Also, by Theorem 3.1, $\nabla f(x) = \nabla f(y)$ for all $x, y \in \bar{S}$. Consequently, the hypotheses imply the existence of an integer k_0 such that $\|\nabla f(x^k) - \nabla f(\bar{x})\| < \alpha$ for all $k \geq k_0$. Therefore, by Theorem 4.1, $E(\nabla f(x^k) | S) = \bar{S}$.

If (b) holds, then (22) is still valid for every point $\bar{x} \in \bar{S}$. The result follows just as it did under assumption (a) since $\|\nabla f(x^k) - \nabla f(\hat{x})\| \rightarrow 0$. \square

The proof of this result only requires the assumption (22) to hold. Part b) of the above corollary can then be proven under the hypothesis that (22) holds only at \hat{x} . This is a weakening of the hypotheses that $-\nabla f(\hat{x}) \in \text{int } N(\hat{x} | S)$ in [1, Thm. 2.1].

Assuming that we can solve (21), Corollary 4.5 can be employed to construct hybrid iterative algorithms for solving problem (19) that will terminate finitely at weak sharp minima. All that needs to be done is to solve the problem (21) occasionally and if an optima is found, then stop. However, some algorithms do not require such a "fix" to locate weak sharp minima finitely. We show that when the objective function f is convex, we can characterize those algorithms that can identify weak sharp minima finitely. We begin with a result that relates the optimality condition given in Theorem 2.6 to the structure of convex subsets of the constraint region S .

LEMMA 4.6. *Let F be any nonempty closed convex subset of the closed convex set $S \subset \mathbb{R}^n$. Then*

$$(23) \quad F + \bigcap_{x \in F} [T(x | S) \cap N(x | F)]^\circ \subset \bigcup_{x \in F} [x + N(x | S)] =: K.$$

Proof. Let $\bar{x} \in F$. We need only show that

$$\bar{K} := \bar{x} + \bigcap_{x \in F} [T(x | S) \cap N(x | F)]^\circ \subset K.$$

Let $y \in \bar{K}$ and let \bar{y} be the projection of $P(y | S)$ onto F . Since $y \in \bar{K}$, there is a $z \in [T(\bar{y} | S) \cap N(\bar{y} | F)]^\circ$ such that $y = \bar{x} + z$. Hence

$$\begin{aligned} 0 &= \langle y - y, P(y | S) - \bar{y} \rangle \\ &= \langle P(y | S) + (y - P(y | S)) - \bar{x} - z, P(y | S) - \bar{y} \rangle \\ &= \langle (P(y | S) - \bar{y}) + (y - P(y | S)) + (\bar{y} - \bar{x}) - z, P(y | S) - \bar{y} \rangle \\ &= \|P(y | S) - \bar{y}\|_2^2 + \langle y - P(y | S), P(y | S) - \bar{y} \rangle \\ &\quad + \langle \bar{y} - \bar{x}, P(y | S) - \bar{y} \rangle + \langle -z, P(y | S) - \bar{y} \rangle. \end{aligned}$$

Observe that each of the terms in the final sum is nonnegative. The second term is nonnegative since $(y - P(y | S)) \in N(P(y | S) | S)$ and $-(P(y | S) - \bar{y}) \in T(P(y | S) | S)$. The third term is nonnegative since $\bar{x} - \bar{y} \in T(\bar{y} | F)$ while $(P(y | S) - \bar{y}) \in N(\bar{y} | F)$. Finally, the fourth term is nonnegative since $(P(y | S) - \bar{y}) \in [T(\bar{y} | S) \cap N(\bar{y} | F)]$. Hence each term is zero so that $\bar{y} = P(y | S)$; that is, $y \in \bar{y} + N(\bar{y} | S) \subset K$. \square

Remarks. 1. It should be noted that one can easily generate examples in which the inclusion (23) is strict.

2. In the fully convex and differentiable case, it was shown in Theorem 4.1 that the set of weak sharp minima \bar{S} is an exposed face of the constraint region S . Consequently, the set F in the above lemma may be taken to be the set \bar{S} . In this case we may write

$$K = \bigcup_{x \in \bar{S}} [F(x | S) + N(x | S)].$$

Lemma 4.6 is now employed to show that the characterization given in [6] of those algorithms that identify the optimal face of S in a finite number of steps also characterizes those algorithms that identify weak sharp minima finitely.

THEOREM 4.7. *Suppose f is convex and let $\bar{S} \subset S$ be a set of weak sharp minima for (19). If $\{x^k\} \subset S$ is such that $\text{dist}(x^k | \bar{S}) \rightarrow 0$ and ∇f is uniformly continuous on an open set containing $\{x^k\}$, then $x^k \in \bar{S}$ for all k sufficiently large if and only if*

$$(24) \quad P(-\nabla f(x^k) | T(x^k | S)) \rightarrow 0.$$

Proof. If $x^k \in \bar{S}$ for all k sufficiently large, then $-\nabla f(x^k) \in N(x^k | S)$ for all k sufficiently large so that (24) holds trivially. On the other hand, suppose (24) is satisfied. The Moreau decomposition of $-\nabla f(x^k)$ yields

$$-\nabla f(x^k) = P(-\nabla f(x^k) | T(x^k | S)) + P(-\nabla f(x^k) | N(x^k | S)).$$

From Theorem 3.1, we have that ∇f is constant on \bar{S} . Thus for any $\bar{x} \in \bar{S}$, the hypotheses imply that

$$\|\nabla f(\bar{x}) + P(-\nabla f(x^k) | N(x^k | S))\| \rightarrow 0,$$

so

$$\text{dist}(x^k + P(-\nabla f(x^k) | N(x^k | S)) | \bar{S} - \nabla f(\bar{x})) \rightarrow 0.$$

However, by Theorem 2.6,

$$\bar{S} - \nabla f(\bar{x}) \subset \text{int} \left[\bar{S} + \bigcap_{x \in \bar{S}} [T(x | S) \cap N(x | \bar{S})]^\circ \right].$$

Thus Lemma 4.6 implies that

$$\begin{aligned} x^k + P(-\nabla f(x^k) | N(x^k | S)) &\in \text{int} \left[\bar{S} + \bigcap_{x \in \bar{S}} [T(x | S) \cap N(x | \bar{S})]^\circ \right] \\ &\subset \bigcup_{x \in \bar{S}} [x + N(x | S)] \end{aligned}$$

for all k sufficiently large. Therefore,

$$\begin{aligned} x^k &= P(x^k + P(-\nabla f(x^k) | N(x^k | S)) | S) \\ &\in P \left(\bigcup_{x \in \bar{S}} [x + N(x | S)] \middle| S \right) \\ &\subset \bigcup_{x \in \bar{S}} \{x\} \\ &= \bar{S} \end{aligned}$$

for all k sufficiently large. \square

In [6], it was shown that the condition (24) is simple to check in certain cases. In particular, it was established that the standard sequential quadratic programming method and the gradient projection method both satisfy (24) and so will automatically generate sequences that terminate finitely at weak sharp minima. We should also note that Polyak[18, Exer. 2, p. 209] indicates that the gradient projection method terminates finitely at weak sharp minima.

AN INTERIOR-POINT METHOD FOR MINIMIZING THE MAXIMUM EIGENVALUE OF A LINEAR COMBINATION OF MATRICES*

FLORIAN JARRE†

Abstract. An algorithm for minimizing the largest eigenvalue of an affine combination of symmetric matrices is presented. The nonsmooth problem is transformed into an equivalent smooth constrained problem, which is solved by a predictor-corrector interior-point method taking full advantage of the differentiability and convexity. Some promising numerical results obtained from a preliminary implementation are included.

Key words. convex program, eigenvalue, implementation

1. Introduction.

1.1. The problem. Problems in mechanics and systems analysis can often be expressed in the following (or a closely related) form: Find

$$(1) \quad \lambda^{\text{opt}} := \inf_{x \in \mathbb{R}^m} \{ \lambda_{\max}(A(x)) \}$$

and an optimal solution x^{opt} if it exists. Here $\lambda_{\max}(A(x))$ is the largest eigenvalue of the matrix

$$(2) \quad A(x) := A^{(0)} + \sum_{i=1}^m x_i A^{(i)},$$

for given symmetric matrices $A^{(i)} \in \mathbb{R}^{n \times n}$, $0 \leq i \leq m$.

Since $\lambda_{\max}(A(x))$ is convex, problem (1) is a convex but nondifferentiable optimization problem. It arises in a variety of applications; for example, the stability analysis of dynamical systems [2], [3], or in combinatorial applications [1]; see also [5], [26], [28] for further applications.

Below, we state some simple facts that illustrate the nature of problem (1) and are easily verified.

- If $\lambda^{\text{opt}} > -\infty$, it lies in the interval $[\lambda_{\min}(A^{(0)}), \lambda_{\max}(A^{(0)})]$,
- There is no x such that $\sum_i x_i A^{(i)}$ is positive definite if and only if λ^{opt} is finite,
- There is no $x \neq 0$ such that $\sum_i x_i A^{(i)}$ is semidefinite if and only if problem (1) has a nonempty and bounded set of optimal solutions

1.2. Basic assumptions. Without loss of generality, we assume that the matrices $I, A^{(i)}$, $0 \leq i \leq m$ are linearly independent, i.e., $r_0 I + \sum_{i \geq 1} r_i A^{(i)} = 0$ if and only if $r_i = 0$, $0 \leq i \leq m$. We further assume that $\lambda_{\min}(A^{(0)}) = 0$ (by adding a suitable multiple of the identity to $A^{(0)}$). For convenience, we also assume that all $A^{(i)}$ have Frobenius norm 1.

2. Relationship to other methods. The need for efficient methods for solving minimax eigenvalue problems like (1) is expressed, for example, in [28]. In this section, we briefly introduce different methods for solving (1) and outline the development that led to the method of this paper.

2.1. “Classical” methods. Standard methods for nondifferentiable optimization, e.g., Shor’s subgradient method, Shor’s ellipsoid method, or Kelly’s cutting plane method, can be used for solving (1); for a survey of these methods, refer to [2, Chaps. 13–14]. Other papers on methods for nondifferentiable optimization include [17], [21], [31], [38]. Specialized methods for (1) are developed in, e.g., [3], [8], [14], [15], [25], [26], [27], [29].

Overton’s method [25], [26] is locally quadratically convergent. His method builds on earlier work of Fletcher [5] for semidefinite programming. Goh and Teo’s method [8] is most closely related to the approach of this paper, since it involves transforming (1) into a smooth nonlinear programming problem by means of determinants.

2.2. Development of interior-point methods. The present paper was motivated by the recent developments of interior-point methods that started with the work of Karmarkar [16] in 1984. Karmarkar presented a method for solving linear programs. Both his proof showing that the method was polynomial (and of much lower complexity than the ellipsoid method) as well as his claim that an implementation of his method was superior to the programs based on the simplex method received great attention (and skepticism). It was soon recognized that Karmarkar’s original method could easily be modified (and improved) to handle nonlinear convex constraints (see Sonnevend [32]), and analyses that proved that the rate of convergence for programs with certain nonlinear convex constraints is the same as in the case of linear constraints were given in [9], [10], [19].

Of particular interest for this paper is the application of interior-point methods for optimization problems over the cone of positive semidefinite matrices, as suggested by Sonnevend [32], [33] (implementational aspects were not considered). In [34] he compared different barrier functions for the cone of positive definite matrices and showed why the barrier function $-\log \det X$ is the “principal actor” for such optimization problems. A detailed complexity analysis of interior-point methods for convex optimization problems based on the notion of self-concordance is given in Nesterov and Nemirovsky’s work [22]. Their analysis also applies to the function $-\log \det X$ and provides the main theoretical tools for our results in §3.

During the writing of this paper, we learned of two other papers [1], [30] that also present implementations of interior-point methods for solving eigenvalue problems and are closely related to this one. In [1] Alizadeh gives an elegant proof for a duality result concerning minimax eigenvalue problems and applies this result to solve combinatorial problems. His method is based on the same theoretical framework as ours, and solves the dual problem. It is particularly attractive for the case where $m \gg n$. In [30] Ringertz describes an implementation of a barrier method for minimizing the largest eigenvalue of a matrix subject to nonlinear equality and inequality constraints. His problems arise in the optimal design of shell structures for airplanes. They are not convex and hence more difficult in nature than problem (1). Ringertz does not touch the topic of estimating the complexity of his method but presents numerical experiments on a Cray XMP with several thousand nonlinear constraints. His results support the obvious conjecture (see also [12]) that interior-point methods are also very efficient for much more difficult problems than the one analyzed here and for which a complexity analysis is not yet possible. Nevertheless, the complexity analysis

of interior-point algorithms is an integral part of the method, not only since it led to their development, but also since it explains their behaviour (weak dependence on the data, affine invariance) and gives important conclusions for implementational aspects (line search, stopping test).

As in [8], problem (1) is transformed to a nonlinear optimization problem that is solved by an interior-point method taking full advantage of the structure (differentiability and convexity) of the transformed problem. The efficiency of the interior-point method is what makes the approach attractive. The algorithm presented here is globally linearly convergent and the guaranteed rate of convergence depends only on the dimension of the problem and not on the data of the matrices $A^{(i)}$. More precisely, there is a theoretical worst-case bound of at most $O(\sqrt{n})$ iterations to reduce the error $\lambda_{\max}(A(x)) - \lambda^{\text{opt}}$ by a factor of 2. Furthermore, recent analyses of interior point methods for linear programs by Ye et al. in [37] showed that predictor-corrector methods similar to the one presented here are quadratically convergent under weak assumptions.

2.3. Implementations of interior-point methods. An early implementation of a barrier method, the SUMT program [4] by Fiacco and McCormick, did not prove to be competitive, and barrier methods were subsequently largely ignored. The recent theoretical developments led to a deeper understanding of the method, and soon after Karmarkar's original work, a number of implementations of his method and its variants for solving linear programs were presented. For certain problems, these implementations were clearly superior to the simplex method. However, numerical implementation of interior-point methods for solving nonlinearly constrained problems has been very slow. A simple program for problems with quadratic constraints is presented in [13]. Recently, Nesterov and Nemirovsky also distributed a software package [24] with an implementation of an interior-point method for solving a class of convex programming problems, including problem (1). Their package is based on a projective algorithm that is closely related to Karmarkar's original algorithm. The package is easy to use, but it is quite sensitive to ill conditioning, even for the small test problems provided with the package (see §5.3). As motivated in §4, the implementation of this paper may be attractive for the case where n is large and m is moderate, and the matrices A_i are sparse or of low rank. Very promising also is the recent implementation of Alizadeh [1] (for large m and moderate n) and the one by Ringertz [30] that is tailored to the solution of more general problems.

3. General barrier approach. It is our goal to present a fairly self-contained article that provides some encouragement (supported by numerical experiments) that interior-point methods are an ideal tool for solving minimax eigenvalue problems. However, the algorithm described below requires improvement (to exploit sparsity or low-rank structure of the matrices $A^{(i)}$ and to allow for more general problems) to be really efficient.

3.1. An equivalent problem. We rewrite problem (1) as another convex differentiable problem with a positive definite constraint. In the following, we write $A > 0$ ($A \geq 0$) if the matrix A is positive definite (positive semidefinite). Positive definiteness can easily be verified numerically (via Cholesky decomposition). Moreover, the cone of positive definite matrices $A > 0$ is characterized by the domain of the smooth convex barrier function $-\log \det_+(A)$. Here, \det_+ of a symmetric matrix

is simply defined as

$$(3) \quad \det_+(A) := \begin{cases} \det(A) & \text{if } A \text{ is positive definite,} \\ -\infty & \text{otherwise.} \end{cases}$$

Let us introduce an $(m+1)$ th variable λ and denote

$$(4) \quad \tilde{x} := (x^T, \lambda)^T \in \mathbb{R}^{m+1}.$$

Note that a number λ is larger than $\lambda_{\max}(A(x))$ if and only if $\lambda I - A(x)$ is positive definite. This observation can be used to rewrite (1) and (2) as

$$(5) \quad \inf_{\tilde{x} \in \mathbb{R}^{m+1}} \{\lambda \mid \det_+(\lambda I - A(x)) > 0\}.$$

The domain of problem (5) is denoted by the open set S° . The efficiency of a barrier method for solving (5) as given below strongly depends on the properties of the barrier function for S° . We use the barrier function

$$(6) \quad \phi(\tilde{x}) := -\log \det_+(\lambda I - A(x)).$$

Under the basic assumptions of §1, we can further show that this function is strictly convex.

LEMMA 1. *The function $-\log \det_+(\lambda I - A(x))$ is strictly convex in x, λ .*

Proof. For the proof, see Appendix A. \square

3.2. A conceptual barrier method. In the following, we briefly recall the principle of a barrier method. Modifications like bounds on the variables, linear equality constraints, or additional convex constraints are easy to implement but are omitted here for clarity.

Suppose that a function $f_0(\tilde{x})$ (which in our case is simply the $(m+1)$ th variable λ) is to be minimized over some convex feasible set S (e.g., the set where $\lambda I - A(x)$ is positive semidefinite), and we are given a “barrier function” for the set S (i.e., a smooth convex function $\phi(\tilde{x})$ that tends to infinity as x approaches the boundary of S and is finite in its interior S°).

We consider a family of unconstrained subproblems. For $\mu \rightarrow 0$ ($\mu > 0$), find

$$(7) \quad \tilde{x}(\mu) := \arg \min \{f_0(\tilde{x}) + \mu \phi(\tilde{x})\}.$$

The minimizers $\tilde{x}(\mu)$ are unique if, for example, S is bounded, ϕ is strictly convex, and f_0 is convex. As the perturbation $\mu \phi(\tilde{x})$ of the objective function is “phased out,” i.e., as $\mu \rightarrow 0$, we can show under weak assumptions that $\tilde{x}(\mu)$ converges to an optimal solution of the original problem. Moreover, $\tilde{x}(\mu)$ is a smooth curve and the tangent to $\tilde{x}(\mu)$ is easily computable; see, e.g., [4]. These properties motivate the following conceptual barrier method.

Given $\mu_0 = 1$ and $\tilde{x}(\mu_0)$, set $k := 0$

Do until convergence

- Compute the tangent $\tilde{x}'(\mu_k)$.
- Select an appropriate $\mu_{k+1} < \mu_k$.
- Predict the next iterate by $\hat{x}(\mu_{k+1}) := \tilde{x}(\mu_k) + (\mu_{k+1} - \mu_k)\tilde{x}'(\mu_k)$.
- Find $\tilde{x}(\mu_{k+1})$ by Newton’s method starting from $\hat{x}(\mu_{k+1})$.
- Set $k := k + 1$.

End

3.3. Barrier methods and self-concordance. The reason we expect barrier methods for problem (5) to work well depends on the properties of the barrier function ϕ . In particular, the property of *self-concordance*, which is defined by Nesterov and Nemirovsky in [23], plays an important role for the analysis of Newton's method. In its simplest form, the condition that a function ϕ be self-concordant is as follows.

DEFINITION. Let $S \subset \mathbb{R}^n$ be convex, $x \in S^\circ$, and $h \in \mathbb{R}^n$ be arbitrary and define the restriction of a convex function $\phi : S^\circ \rightarrow \mathbb{R}$ in direction h through x by the function $\psi : J \rightarrow \mathbb{R}$, where $\psi(t) := \psi_{x,h}(t) := \phi(x + th)$ and J is some open interval containing 0. The function ϕ is called self-concordant, with self-concordance parameter α if, for any x and h , its restriction ψ satisfies the inequality

$$(8) \quad |\psi'''(0)| \leq \frac{2}{\sqrt{\alpha}} \psi''(0)^{3/2}.$$

A self-concordant function $\phi : S^\circ \rightarrow \mathbb{R}$ is called *strongly self-concordant* if $\phi(x) \rightarrow \infty$ as x approaches the boundary ∂S of S . Thus self-concordant barrier functions are strongly self-concordant.

Discussion. Intuitively, this condition may be interpreted as follows. The third derivative ψ''' is a measure of how fast the second derivative ψ'' is changing, and this condition implies that the *relative* change of ψ'' is locally¹ bounded by some Lipschitz constant $2/\sqrt{\alpha}$. Since the condition holds for any $h \in \mathbb{R}^n$, an analogous statement also holds for the second and third derivatives $D^2\phi$ and $D^3\phi$ of ϕ at x .

For the derivation of an equivalent condition, a “relative Lipschitz condition” on the Hessian of ϕ , and for a simplified analysis we refer to [10], [11].

Nesterov and Nemirovsky showed in [23] that this condition is satisfied by a class of *logarithmic* barrier functions. In particular, it is satisfied with $\alpha = 1$ for the barriers of linear or convex quadratic constraint functions and the function “ $-\log \det_+(A)$.” They further show that, if some function Θ is self-concordant on a convex subset of \mathbb{R}^l and if L is an affine mapping into \mathbb{R}^l (its range intersecting at least part of the domain of Θ), then $\phi(y) := \Theta(L(y))$ is also self-concordant. This implies the following lemma.

LEMMA 2. *The barrier function $-\log \det_+(\lambda I - A(x))$ is self-concordant in x, λ with $\alpha = 1$.*

Results. Denote the Hessian of ϕ by $H(x) := D^2\phi(x)$. The main result about self-concordance in [23] is that Newton's method when applied to minimizing a strongly self-concordant function ϕ defined on a set S° is quadratically convergent (with constant less than 2) if the first Newton step Δx exists and has length less than $\sqrt{\alpha}/4$ measured in the “right” norm

$$(9) \quad \|\Delta x\|_{H(x)} := (\Delta x^T H(x) \Delta x)^{1/2} = \psi''_{x,\Delta x}(0)^{1/2}.$$

The importance of this statement is that it only depends on α and that the set of points x for which the Newton step Δx (starting at x) satisfies $\|\Delta x\|_{H(x)} \leq \sqrt{\alpha}/4$ is a “fixed portion” of the whole set S . More precisely, let ϕ be a self-concordant logarithmic barrier function of some convex constraint functions² f_1, \dots, f_m ,

$$\phi(x) = - \sum_{i=1}^m \log(-f_i(x));$$

¹ Here, “locally” means that $t\psi''(0)^{1/2}$ is small.

² Note that $-\sqrt[n]{\det_+(\lambda I - A(x))}$ is convex; so this statement applies to the function $\phi(\bar{x}) = -\frac{1}{n} \log \det_+(\lambda I - A(x))$ with $m = 1$ and $\alpha = 1/n$.

let the domain $S = \{x \mid f_i(x) \leq 0\}$ of ϕ be bounded, \bar{x} be the minimum of ϕ , and $E = 0.2\{h \mid h^T D^2 \phi(\bar{x}) h \leq 1\}$. Then, $\bar{x} + E$ is within the domain of quadratic convergence of Newton's method and

$$(10) \quad \bar{x} + 5\sqrt{\alpha}E \subset S \subset \bar{x} + \frac{5(m+2\sqrt{m})}{\sqrt{\alpha}}E$$

(see [11] and also [35] for a similar result for quadratic constraints). Applied to the set S of problem (1), this implies that the ratio of inner and outer ellipsoid only depends on the dimension of the matrices $A^{(i)}$ but not on the matrices themselves. This statement implies further that all subproblems (7) from §3.2 are of the same “difficulty”; that is, no matter how small μ is, the domain of convergence of Newton's method for finding $\tilde{x}(\mu_{k+1})$ is always a “fixed percentage” of the previous level set $\{\tilde{x} \mid \tilde{x} \in S, f_0(\tilde{x}) \leq f_0(\tilde{x}(\mu_k))\}$, and the “percentage” depends only on n and μ_k/μ_{k+1} . This fact guarantees polynomial convergence (independent of the data matrices $A^{(i)}$) of the barrier method in §3.2, and it does not hold for other barrier functions such as $1/\det(A(x))$.

4. A specific barrier method.

4.1. Notation and initialization. The ideas outlined above will now be applied to problem (5) in more detail. Recall the definition (4) of \tilde{x} and define

$$(11) \quad A(\tilde{x}) := \lambda I - A(x) = \lambda I - A^{(0)} - \sum_{i=1}^m x_i A^{(i)}.$$

For a given vector \tilde{w} in \mathbb{R}^{m+1} and for $\mu \in (0, 1]$, consider the barrier function

$$(12) \quad \varphi(\tilde{x}, \mu) := \frac{\rho}{\mu} \lambda - \log \det_+(A(\tilde{x})) - \tilde{w}^T \tilde{x}$$

with some constant $\rho > 0$. Note that the feasible domain of (5) is given by the domain of φ , $S^\circ = \{\tilde{x} \mid \varphi(\tilde{x}, \mu) < \infty\}$.

The vector \tilde{w} is a linear perturbation to the barrier function and does not influence self-concordance of φ . We will choose \tilde{w} so that our initial point is a minimizer of $\varphi(\cdot, 1)$.

To initialize the algorithm, let $\lambda_0 = 2\lambda_{\max}(A^{(0)}) > 0$ (recall $\lambda_{\min}(A^{(0)}) = 0$) and let $x^0 = 0 \in \mathbb{R}^m$. This implies that $\tilde{x}^0 = (0, \dots, 0, 2\lambda_{\max}(A^{(0)}))^T$ is a strictly feasible starting point (and that $\text{cond}(A(\tilde{x}^0)) = 2$). Set $\mu = 1$ and choose ρ as $\rho = n/\lambda_{\max}(A^{(0)})$ for example. The vector \tilde{w} is chosen such that

$$(13) \quad D_{\tilde{x}} \varphi(\tilde{x}^0, 1) = 0$$

and is constant throughout our algorithm. Let $e_{m+1} := (0, \dots, 0, 1)^T \in \mathbb{R}^{m+1}$. Then another representation of φ is given by

$$(14) \quad \varphi(\tilde{x}, \mu) = \left(\frac{\rho}{\mu} e_{m+1} - \tilde{w} \right)^T \tilde{x} - \log \det_+(A(\tilde{x})).$$

4.2. The derivatives of φ . Adopting the notation in [1], we define the “symmetric scalar product” of two matrices by

$$(15) \quad A \bullet B := \sum_{i,j} A_{ij} B_{ij} = \text{trace}(A^T B).$$

The first and second derivatives of φ are defined in terms of

$$(16) \quad B(\tilde{x}) := A(\tilde{x})^{-1}.$$

To abbreviate the notation, we refer to $\tilde{x}_{m+1} = \lambda$ and $A^{(m+1)} = -I$. It is known (and easy to verify) that the partial derivatives of “log det” are

$$\frac{\partial}{\partial X_{ij}} \log \det(X) = (X^{-T})_{ij}$$

(for $X \in \mathbb{R}^{n \times n}$ with $\det(X) > 0$ [6]), so that the derivative $D \log \det X = X^{-T}$, where X^{-T} is to be interpreted as a linear functional via the scalar product (15), $X^{-T}[A] := X^{-T} \bullet A$. Thus, by the chain rule, we obtain

$$\hat{g}_i := \hat{g}_i(\tilde{x}) := \frac{\partial}{\partial \tilde{x}_i} \log \det_+(A(\tilde{x})) = B(\tilde{x}) \bullet \left(\frac{d}{d\tilde{x}_i} A(\tilde{x}) \right).$$

Hence

$$(17) \quad \hat{g}_i = -B(\tilde{x}) \bullet A^{(i)}, \quad 1 \leq i \leq m+1.$$

The derivative $g(\tilde{x}, \mu) = D_{\tilde{x}} \varphi(\tilde{x}, \mu)^T$ of φ now follows from (14):

$$(18) \quad g(\tilde{x}, \mu) = \frac{\rho}{\mu} e_{m+1} - \hat{g}(\tilde{x}) - \tilde{w}.$$

The derivative $D_{\tilde{x}} g(\tilde{x}, \mu)$ of g , in turn, is given by the partial derivatives

$$\frac{\partial}{\partial \tilde{x}_j} (A^{(i)} \bullet B(\tilde{x})) = \sum_{k,l} A_{kl}^{(i)} \frac{\partial}{\partial \tilde{x}_j} B_{kl}(\tilde{x}) = \sum_{k,l} A_{kl}^{(i)} (-B_{kq} B_{rl})_{qr} \bullet \left(\frac{\partial}{\partial \tilde{x}_j} A(\tilde{x}) \right)$$

for $1 \leq i, j \leq m+1$. (Here and in the following, we occasionally omit the argument of $B = B(\tilde{x})$.) Summarizing, we find that

$$\frac{\partial}{\partial \tilde{x}_j} g_i(\tilde{x}, \mu) = \sum_{k,l,q,r} A_{kl}^{(i)} A_{qr}^{(j)} B_{kq} B_{rl} = B A^{(i)} \bullet A^{(j)} B = \text{trace}(A^{(i)} B A^{(j)} B).$$

It is straightforward to compute the Hessian

$$(19) \quad H(\tilde{x}) := D_{\tilde{x}} g(\tilde{x}, \mu) = \left(\frac{\partial}{\partial \tilde{x}_j} g_i(\tilde{x}, \mu) \right)_{ij}$$

in $O(mn^3 + m^2n^2)$ multiplications. For our examples below, with $m, n < 100$, this was sufficient; we note, however, that, if the $A^{(i)}$ are sparse or of low rank (and n is large, while m is moderate), this can be done much more efficiently. In this case, the Hessian is a dense (m by m) matrix, even if the (n by n) matrix $A(\tilde{x})$ is sparse. Also, note that the Hessian does not depend on μ , ρ , or \tilde{w} .

4.3. Perturbed centers.

DEFINITION. A minimizing point of the function $\varphi(\cdot, \mu)$ will be called the *perturbed center* is denoted by $\tilde{x}(\mu)$. If it exists, the perturbed center with perturbation $\tilde{w} = 0$ is the *analytic center*, as defined in [32].

LEMMA 3. *The following conditions hold:*

(i) Let some point $x^0 \in S^o$ be given and \tilde{w} be such that $D\varphi(x^0, 1) = 0$. Then the functions $\varphi(\cdot, \mu)$ have unique minimizers $\tilde{x}(\mu)$ for all $\mu \in (0, 1]$ if and only if λ^{opt} is finite;

(ii) The analytic center exists for $\mu = 1$ if and only if it exists for all $\mu \geq 0$, or, equivalently, if and only if the set of optimal solutions for (1) is nonempty and bounded.

Proof. For the proof, see Appendix A. \square

(Note that, if λ^{opt} is finite, the set of optimal solutions for (1) can be empty or unbounded.)

It is intuitive (and has been shown, e.g., in [4], [12]) that, if (1) has an optimal solution, the perturbed centers $\tilde{x}(\mu)$ converge to a solution \tilde{x}^{opt} as $\mu \rightarrow 0$. This result holds for any strictly feasible starting point \tilde{x}^0 and the corresponding \tilde{w} . Thus Lemma 3 describes a whole family of curves of perturbed centers, each of which starts somewhere in S^o and leads to an optimal solution.

For the analytic center, a number of nice properties can be shown. In particular, the center is affine invariant and “far away” from the boundary of the feasible set in the sense that for $\tilde{w} = 0$ the points $\tilde{x}(\mu)$ allow two-sided ellipsoidal approximations of the level sets $\{\tilde{x} \in S \mid f_0(\tilde{x}) \leq \tau\}$ for a suitable $\tau = \tau(\mu)$ as already stated in (10). The inner ellipsoid also describes the domain in which the path of centers $\tilde{x}(\mu)$ is well approximated by its tangent. Furthermore, points on the path of analytic centers define dual feasible variables that can be used in a stopping test. Similar results hold in a somewhat weaker form for the perturbed center if the perturbation \tilde{w} is small. For large perturbations \tilde{w} (for $\tilde{w}^T D_{\tilde{x}}^2 \varphi(\tilde{x}^0, 1)^{-1} \tilde{w} \geq 1$), however, this is no longer true. The vector \tilde{w} guarantees the existence of the perturbed center and that the method below is well defined even if the set of optimal solutions is unbounded. However, it is our goal to keep \tilde{w} small. To decrease the norm of \tilde{w} , it is advantageous in some instances to perform a phase one and to introduce an additional bound, for example, $\|\tilde{x}\|_2 \leq 10^6$. Then find the *analytic* center of this set (the existence of it is guaranteed by the additional bound) and define \tilde{w} as in (13) for this starting point after deleting the additional bound again.

The algorithm in this paper is a modification of that described in [12]. The situation here is particularly simple, since a strictly feasible starting point can easily be constructed. Below, we explain one iteration of the method.

4.4. One iteration of the algorithm. The following description is a more detailed and specialized version of the barrier method outlined in §3. At the beginning of each iteration, we assume that a strictly feasible current iterate \tilde{x}^k and an associated parameter μ_k are given, where \tilde{x}^k is considered as an approximation to $\tilde{x}(\mu_k)$. We repeat the following iteration until some convergence criterion is satisfied.

1) Determine the tangent to the curve of perturbed centers $\tilde{x}^k(\mu)$, that passes through \tilde{x}^k . The tangent to the curve $\tilde{x}(\mu)$ is easily obtained by differentiating the characteristic equation

$$(20) \quad g(\tilde{x}(\mu), \mu) \equiv 0$$

with respect to μ . The differentiation yields

$$D_{\tilde{x}} g(\tilde{x}(\mu), \mu)^T \tilde{x}'(\mu) + \frac{\partial}{\partial \mu} g(\tilde{x}(\mu), \mu)^T = H(\tilde{x}(\mu)) \tilde{x}'(\mu) - \frac{\rho}{\mu^2} e_{m+1} = 0.$$

The tangent can thus be computed from a Cholesky decomposition of the Hessian. Note that the direction of the tangent $\tilde{x}'(\mu)$ does not depend on the vector \tilde{w} or on

μ , but only on the current point \tilde{x} . Thus the above computation precisely yields the direction of the tangent to the (unique) curve of perturbed centers starting at \tilde{x} and ending in an optimal solution. Also, the last component (i.e., λ) of $\tilde{x}'(\mu)$ is positive (since H is positive definite), so that $-\tilde{x}'(\mu)$ is obviously a descent direction for the objective value λ .

2) Perform a linear extrapolation in the direction of the tangent, as follows:

$$\hat{x}^{k+1} := \tilde{x}^k - \beta_k \tilde{x}'(\mu).$$

The steplength β_k for the extrapolation is chosen as r_k times the maximum steplength β_{\max} such that $A(\tilde{x}^k - \beta_{\max} \tilde{x}'(\mu))$ is still positive semidefinite. (The exact computation of β_{\max} involves computing the maximum eigenvalue of a matrix.) Here, $r_k \in (0, 1)$ can be chosen adaptively: Set $r_1 = 0.9$, and, (for $k \geq 2$) if Newton's method (in step 4), below) converged in less than three steps in the previous iteration, increase r (as $r_k = (1 + r_{k-1})/2$); if it converged in more than four Newton steps, decrease r (as $r_k = \max\{r_{k-1}/2, 2r_{k-1} - 1\}$).

3) The parameter μ is controlled as follows. Given the k th iterate \tilde{x}^k , an associated parameter μ_k , and an extrapolated point $\hat{x}^{k+1} \in \mathbb{R}^{m+1}$ for the $(k+1)$ th iterate, determine the (unique) value $\hat{\mu}_{k+1}$ that “best fits” \hat{x}^{k+1} , i.e., such that the last component of the gradient g at \hat{x}^{k+1} is zero. Set $\mu_{k+1} = \min\{\mu_k/2, \hat{\mu}_{k+1}\}$.

Remark. For a moderate stepsize β for the (linear) extrapolation, we can show that $\hat{\mu}_{k+1} < \mu_k$ (for a more precise statement and a proof, we refer to Appendix A).

4) Perform Newton's method (with line search) to minimize the barrier function $\varphi(\cdot, \mu_{k+1})$. The stopping criterion for Newton's method is $\|\Delta\tilde{x}\|_{H(\tilde{x})} \leq 0.2$, i.e., the H -norm of the Newton step (9) must be less than 0.2.

In our program, below, we implement a simple modification of Newton's method by using the “old” factorization of the Hessian that was computed for the last Newton step (or in the extrapolation) for four further “inexact” Newton steps with line search before recomputing the new Hessian for the next true Newton step.

4.5. Stopping test. The following lemma may be used for determining when to stop.

LEMMA 4. *As in (9), we define, for a positive definite matrix H , the H -norm of a vector v by $\|v\|_H^2 = v^T H v$. If, for a given point \tilde{x}^k , there is a μ such that the Newton step $\Delta\tilde{x}$ for finding the analytic center $\tilde{x}(\mu)$ (with $\tilde{w} = 0$) satisfies*

$$\|\Delta\tilde{x}\|_H \leq \frac{\sqrt{\alpha}}{4}$$

with $H := H(\tilde{x}^k)$, then (1) has a bounded optimal solution set, and \tilde{x}^k is almost optimal in the following sense: $\lambda - \lambda^{\text{opt}} \leq 2n\mu/\rho$.

The assumption that there is such a μ can be interpreted as \tilde{x}^k being moderately close to the path of analytic centers.

4.6. Ill-conditioning. The barrier method of the previous sections encounters ill-conditioned matrices (as μ tends to zero). We briefly discuss the two critical points in our computations.

1) First, as μ tends to zero, the matrix $A(\tilde{x})$ approaches the singular matrix $A(\tilde{x}^{\text{opt}})$, and is therefore ill conditioned. Simple considerations show that the minimum eigenvalue of $A(\tilde{x}(\mu))$ is of order $O(\mu)$. It is our experience that for the small examples below with $\mu \geq 10^{-10}$ the inversion of the matrix $A(\tilde{x})$ can be carried out to sufficient accuracy (Matlab is using double precision arithmetic), provided that the

maximum eigenvalue of $A(\tilde{x}^{\text{opt}})$ is $O(1)$. For many practical applications, it suffices to approximate the optimal solution up to low accuracy only (e.g., $\mu \geq 10^{-6}$), and, in these cases, we expect the barrier method to work well even for larger problems. We do not examine any methods for stabilizing the computation of $A(\tilde{x})^{-1}$ in the case that a very high accuracy of the optimal solution is desired, and we suspect that further difficulties may arise.

However, interior-point methods that use a centering procedure at each iteration have an “implicit stability” that can be explained as follows: From the proof of Lemma 1 (Appendix A), it is obvious that the evaluation of the Hessian yields a positive (semi)definite matrix H , regardless of how inaccurate the computation of the matrix $B = A(\tilde{x})^{-1}$ is. In our algorithm, we use a uniformly positive definite approximation \hat{H} of the Hessian H that is obtained from a simple “stabilization procedure,” described below. Since inexact Newton’s method with a line-search converges for *any* uniformly positive definite approximation \hat{H} of the Hessian, the center will be found eventually, even if H is a random positive definite matrix. Similarly, the extrapolation is a descent direction for the objective value λ for *any* positive definite approximation of H (see step 1) of §4.4). This property suffices to prove that a method as outlined above always converges to an optimal solution \tilde{x}^{opt} , even if the computation of the Hessian is inaccurate. We note that such a statement is not true for methods that do not use a centering procedure. If the Hessian is computed inaccurately, such a method may converge to a nonoptimal point. Furthermore, in general, the Hessians that are evaluated at points on the central path are less ill conditioned than the Hessians that are evaluated at points far away from the central path. (For barrier functions of linear programs with a unique optimal solution, we can prove, for example, that the condition number of the Hessians near the central path is globally bounded independent of μ , while, in general, the condition number of the Hessian becomes unbounded as the argument approaches the boundary of the feasible set.) These facts may also explain our observation in §5.3.

2) Second, as μ tends to zero, the Hessian $H(\tilde{x}(\mu)) = D^2\varphi(\tilde{x}(\mu), \mu)$ becomes ill conditioned. This type of ill conditioning also occurs when solving (degenerate) linear programs by interior-point methods. Lustig, Marsten, and Shanno [18], Gill et al. [7], and others present solutions for such instabilities (via iterative refinement) and show with a large number of numerical experiments that their strategies are effective. In our program, we use the following simple strategy: Given the Hessian $H = H(\tilde{x})$ at some point \tilde{x} , set $\hat{H} := H + \epsilon \|H\|_{\infty} I$ (with $\epsilon = 10^{-10}$) and denote the Newton step by $\Delta\tilde{x} = H^{-1}g$ and the “stabilized Newton step” by $\Delta\hat{x} = \hat{H}^{-1}g$. As motivated in definition (9), the canonical norm associated with this method at the point \tilde{x} is the norm $\|h\|_H = (h^T H h)^{1/2}$. It is straightforward to verify (e.g., Stewart and Sun, [36, Thm. 2.11, p. 124]) that

$$\frac{\|\Delta\hat{x} - \Delta\tilde{x}\|_H}{\|\Delta\tilde{x}\|_H} \leq \epsilon \frac{\text{lub}_{\infty}(H)}{\text{lub}_2(H^{-1})} \leq \sqrt{n} \epsilon \text{cond}_2(H).$$

Since $\Delta\hat{x}$ is just an iterative direction for a line-search during Newton’s method, this error is not crucial. For very ill-conditioned H , though, this stabilization does increase the number of Newton steps.

5. Some numerical results. The method outlined in §4 has been implemented in Matlab [20]. We present a few preliminary examples for which the method shows the same convergence behavior as interior-point methods applied to linear programs. This—along with the work of Alizadeh (see Appendix B of this paper)—strongly sug-

TABLE 1

n	m	$s_{m,n}$	Iterations	Hessians	Inexact Newton steps	Multiplicity
5	10	500	7.8/9	9.5/14	23.7/37	3.0

gests that the method may be very efficient for solving minimax eigenvalue problems and for more general convex programming problems (see [12]).

5.1. Random examples. In Table 1, we give results for minimizing the largest eigenvalue of affine combinations of m random symmetric matrices of size n for different values of m and n . Our stopping criterion is $n\mu/\rho \leq 10^{-4}$. In each iteration, we performed one extrapolation and a small number of Newton and “inexact Newton” steps with a line search. We list m , n , and the sample size $s_{m,n}$ of how many random problems were tested for each pair m, n . We further list the average and the maximum number of iterations needed and the average and maximum number of evaluations of the Hessian and total (inexact) Newton steps. Finally, we record the average multiplicity of the maximum eigenvalue in the optimum. For $n = 5$, only about 20% of all problems had a finite λ^{opt} . For the unbounded problems, a negative definite combination was found in the first iteration³, so that we only list the statistics for the bounded problems. For $n = 10$, four problems were unbounded; for $n > 10$, none.

This table does not allow any conclusions regarding the effect of the condition numbers of the linear systems on algorithm stability for large problems. We believe, however, that it gives some impression about how the number of iterations depends on the size of the problem. We can observe the same slow growth of the number of iterations with the dimensions m and n as has been observed throughout for interior-point methods for linear programs; see, e.g., [18], [7]. This makes interior-point methods particularly suitable for parallel computation, since the sequential part of the algorithm (the number of iterations) is small compared to the parallelizable part of solving a (large) system of linear equations at each iteration.

5.2. Boyd and Yang’s example. Here we use our method to solve two examples given in [3, Chap. 8]. Boyd and Yang modelled a simple two-input two-output control system and reduced the question of whether there exists a quadratic Lyapunov function that establishes stability of this control system to a problem of the form (1), involving 22 matrices $A^{(i)}$ of size 40×40 . In these examples, $A^{(0)} = 0$, and the problem was to find whether there exists a definite linear combination of the $A^{(i)}$, $i \geq 1$. For problem (1), there does, but problem (2) is bounded, i.e., $\lambda^{\text{opt}} = 0$ for $x = 0$. When solving these problems with our implementation, it takes one iteration, three evaluations of the Hessian, and twelve steps of (inexact) Newton’s method to find a negative definite combination for problem (1), and six iterations, nine Hessians, and 24 inexact Newton steps for problem (2) to discover that the optimal solution for problem (2) is within 10^{-4} of $5.7 \cdot 10^{-5}$. (It is exactly zero.) We emphasize that, also for problem (2), we can stop after *one* iteration, since, by Lemma 3, the existence of the first analytic center already implies boundedness of (1). A more careful imple-

³ This holds, with two exceptions where it was found in the second iteration. For the first iteration, we added the extra bound $\|x\| \leq 1000$ to avoid divergence for the unbounded problems.

mentation that determines only whether the first center exists or not will suffice for this type of problem and will be more efficient. (The case that there exists a nonzero positive semidefinite but not a positive definite combination will be hard to detect, however.) Boyd and Yang [3] solve a variation of problem (1)

$$\min_{|x_i| \leq 1} \lambda_{\max} \left(\sum_{i=1}^n x_i A^{(i)} \right).$$

This problem has a nonempty and finite set of optimal solutions for any set of symmetric $A^{(i)}$, while problem (1) does not. However, it is not well-posed in the sense that a definite combination of the two matrices $A^{(1)} := \text{diag}(1, -1, -1)$ and $A^{(2)} := \text{diag}(-1 + \epsilon, 1 + \epsilon, 1)$ might not be detected for very small $\epsilon > 0$. Boyd and Yang solve the problem by the cutting plane algorithm and by the subgradient method. In Tables 2 and 3, we list their results and those that we obtain from an interior-point method by imposing the same bounds on the problem as they. It is straightforward (but not efficient!) to modify the interior-point algorithm to this situation. The tables show the number of iterations necessary to determine that there is a negative combination or to find the optimal value up to an accuracy of 10^{-4} and of 10^{-6} . It should be noted that each iteration of the subgradient method involves an eigenvalue computation of a 40×40 matrix (this consists of five 8×8 blocks in this example, and is thus relatively cheap). In addition, the i th iteration of the cutting plane algorithm involves the solution of a linear program with $m + 1$ unknowns and $2m + i$ constraints. It is difficult to compare the computational effort of all three of these methods under consideration of the sparsity pattern of the matrices $A^{(i)}$, but, for $m < n$ and n sparse, as is the case here, we believe that an efficient implementation of the interior-point method may be very fast.

For problem (2), Boyd and Yang only determine that the problem has a largest eigenvalue that is larger than $-\epsilon$. We list the results for two different values of ϵ . Since the subgradient method does not provide a lower bound on the optimal solution, it fails for this example.

5.3. Overton's example. This is an example taken from Overton [25]. The problem is to find the diagonal of a 10×10 matrix M to minimize its maximum eigenvalue in absolute value. The off-diagonal elements of M are given. There are obvious modifications of the algorithm in this paper that do not increase the size of the problem and that take the "extreme sparsity" of the matrices $A^{(i)}$ —one nonzero

TABLE 4

element on the diagonal for $1 \leq i \leq 10$ —into account. Here, however, we simply apply our algorithm with the matrices

$$\hat{A}^{(i)} := \begin{pmatrix} A^{(i)} & 0 \\ 0 & -A^{(i)} \end{pmatrix}, \quad 0 \leq i \leq 10,$$

thus doubling the size of the problem and working with 11 matrices of size 20. To test the limitations of our algorithm, we first deliberately set the stopping criterion to $1.0 \cdot 10^{-20}$. The optimal value λ^{opt} that our program computes for this problem is 22.36612164584166. This result is obtained in iteration 17 for $\mu = 1.14 \cdot 10^{-15}$ and $\rho = 1.18$, and it is accurate to at least 13 digits. The program stops in the next iteration with the Matlab message that the matrix $(A(\tilde{x}))$ to be inverted has a condition number of 10^{17} , and our algorithm then terminates with an error message. In Table 4, we run the problem with stopping criterion $n\mu/\rho \leq 10^{-4}$ and list the iteration number, λ_{\max} in that iteration, the value of μ , and the rates by which $\lambda_{\max} - \lambda^{\text{opt}}$ is reduced compared to the previous iteration. Note that the final accuracy is higher than the four digits guaranteed by Lemma 4. In these iterations, the Hessian is recomputed ten times, and a total of 25 (inexact) Newton steps are performed. Overton [25] presents an algorithm for solving this problem based on successive quadratic programming (QP). In each iteration, his algorithm solves a small number of quadratic programs with $m + 1$ unknowns and several equality constraints, the number depending on the estimated multiplicity of λ_{\max} at the solution. Overton also presents numerical experiments for the above problem and notes that “this problem is quite difficult to solve, since at the optimal solution the interior eigenvalues are nearly equal to λ_{\max} .” His program computes the optimal solution with ten digits of accuracy in 14 iterations solving a total of 26 QP’s. We test the interior-point method for different settings of the various parameter values, but we do not observe any irregular behaviour of the interior-point method. The observed robustness of the interior-point method coincides with the fact that the proof of convergence of the method is independent of the data and only depends on the dimensions m and n .

Overton [26] also suggests a successive linear programming algorithm for problem (1) that is better suited for large problems. Since our current implementation does not exploit sparsity, we cannot compare the two methods for large problems. (For small problems, Overton favours his SQP algorithm.) We note that both of Overton’s methods compute “dual matrix” information that is relevant for sensitivity analysis of the solution; see [26], as well as Appendix B and the proof of Lemma 4 in Appendix A.

We also apply the software package of Nesterov and Nemirovsky to solve this problem. Using the default option of short primal steps, their algorithm takes 23

iterations to obtain the solution 22.36614 (six digits of accuracy), and, using the option of large primal steps, the algorithm takes 15 iterations to find the solution 22.366124 (seven digits of accuracy). In both cases, the algorithm stops at this point with the error message “unable to compute the LU factorization.” We also test a number of test problems that are provided with the package. In all cases, the algorithm with large primal steps yield a slightly more accurate solution in less iterations, but, also, in all cases, the algorithm terminates with an error message after obtaining five to nine digits of accuracy. We believe that the linear algebra used by Matlab for our program is more stable than the one used by Nesterov and Nemirovsky, and this may be the most important reason for the observed difference in accuracy of the two programs. However, Nesterov and Nemirovsky do not use a centering step, and (as motivated in §4.6) this may be another reason for the higher accuracy of our algorithm⁴. For this problem, both programs (the one from Nesterov and Nemirovsky, as well as our Matlab version) are run with double precision on a 386 IBM PC.

It is hard to compare the computational effort of the algorithm of Nesterov and Nemirovsky with ours. For both algorithms, the computational effort in each iteration is dominated by the computation of the Hessian. Our algorithm uses a slightly smaller number of recomputations of the Hessian, but a larger number of additional operations per Hessian.

Appendix A. We briefly outline the proofs of Lemmas 1, 3, and 4.

Proof of Lemma 1. It is sufficient to prove that the function $\phi(x) := -\log \det_+(A(x))$ is strictly convex for all x for which $A(x)$ is positive definite. By the results of §4.3, the ij th entry of the Hessian of ϕ is given by

$$H_{ij} = BA^{(i)} \bullet A^{(j)}B.$$

Let $z \in \mathbb{R}^n$ be nonzero; then

$$z^T H z = B \left(\sum z_i A^{(i)} \right) \bullet \left(\sum z_j A^{(j)} \right) B = \left\| \left(\sum z_i A^{(i)} \right) B \right\|_F^2$$

is the square of the Frobenius norm of the nonzero matrix $(\sum z_i A^{(i)})B$ and thus positive. (The matrix is nonzero, since, by assumption, the $A^{(i)}$ are linearly independent and B is invertible.) \square

Proof of Lemma 3. 1) Suppose that λ^{opt} is finite, i.e., $\lambda^{\text{opt}} \geq 0$ by assumption on $A^{(0)}$. We show that the barrier function $\varphi(\cdot, \mu)$ has unique minimizers. By definition of \tilde{w} , the point \tilde{x}^0 is a unique minimum of $\varphi(\cdot, 1)$. (Its gradient is zero at \tilde{x}^0 , and, by Lemma 1, $\varphi(\cdot, 1)$ is strictly convex.) The existence of a unique minimum for the convex function $\varphi(\cdot, 1)$ implies that $\varphi(\tilde{x}, 1) \rightarrow \infty$ as $\tilde{x} \rightarrow \infty$. Now let $\mu \in (0, 1)$. Since $\lambda^{\text{opt}} \geq 0$, it follows that $\varphi(\tilde{x}, \mu) = \infty$ if $\lambda \leq 0$. For $\lambda > 0$, it follows trivially that $\varphi(\tilde{x}, \mu) > \varphi(\tilde{x}, 1)$; hence $\varphi(\tilde{x}, \mu) \rightarrow \infty$ as $\tilde{x} \rightarrow \infty$. Thus, the existence of a unique minimum for $\varphi(\cdot, \mu)$ follows again from strict convexity of $\varphi(\cdot, \mu)$.

2) Conversely, if $\lambda^{\text{opt}} = -\infty$ then there exists an $\bar{x} \in \mathbb{R}^m$ such that $\lambda_{\max}(\sum \bar{x}_i A^{(i)}) < -1$. For $\bar{x} := (\bar{x}, -1)^T$ and $\mu \in (0, 1)$ such that $\rho/\mu > \tilde{w}^T \bar{x}$, we find that $\varphi(t\bar{x}, \mu) \rightarrow -\infty$ as $t \rightarrow \infty$; i.e., a perturbed center does not exist for this μ .

3) Suppose that the analytic center exists for some $\mu > 0$. Then there is no $x \neq 0$ such that $\sum x_i A^{(i)} \leq 0$. (The $A^{(i)}$ are linearly independent, and $\varphi(\cdot, \mu)$ decreases

⁴ A modification of our algorithm that does without centering gave only five digits accuracy in 23 iterations.

along the ray given by $\tilde{x} = (x^T, 0)^T$ if $\sum x_i A^{(i)} \leq 0$.) Hence, there is an $\epsilon > 0$ such that $\lambda_{\max}(\sum x_i A^{(i)}) \geq \epsilon$ for all x with $\|x\| = 1$. Also, λ^{opt} is finite. For $\|x\| \geq 1 + \lambda^{\text{opt}}/\epsilon$, it follows that $\lambda_{\max}(A(x)) = \lambda_{\max}(A^{(0)} + \sum x_i A^{(i)}) \geq \lambda_{\min}(A^{(0)}) + \lambda_{\max}(\sum x_i A^{(i)}) \geq 0 + \epsilon(1 + \lambda^{\text{opt}}/\epsilon) = \lambda^{\text{opt}} + \epsilon$. Therefore, the compact domain $\|x\| \leq 1 + \lambda^{\text{opt}}/\epsilon$ contains all optimal solutions, and the set of optimal solutions is not empty.

4) Suppose that the set of optimal solutions is finite and nonempty. Let \bar{x} be an optimal solution. Then there exists a circle of radius r that contains the optimal set $S_{\text{opt}} \subset \bar{x} + K_r$ and $\lambda_{\max}(A(x)) \geq \lambda^{\text{opt}} + \epsilon$ for $x \in \partial(\bar{x} + K_r)$, the boundary of $\bar{x} + K_r$. Let $\|g\| = r$, then, by convexity, $\lambda_{\max}(A(\bar{x} + \theta g)) \geq \lambda^{\text{opt}} + \theta\epsilon$ for $\theta \geq 1$; hence, $\lambda > \lambda^{\text{opt}} + \theta\epsilon$ if $\lambda I - A(\bar{x} + \theta g) > 0$. Therefore, for any fixed $\mu > 0$, the quantity λ/μ grows at least linearly with θ , while $\log \det_+(A(\tilde{x}))$ is sublinear in θ , (the determinant is a multinomial in the matrix coefficients). For $\tilde{w} = 0$, this implies that $\varphi(\tilde{x}, \mu) \rightarrow \infty$ as $\tilde{x} \rightarrow \infty$, i.e., $\varphi(\cdot, \mu)$ has unique minimizers, i.e., the analytic centers exist for all $\mu > 0$. \square

Proof of Lemma 4. This lemma can either be shown directly using the results in [11] or more elegantly using the duality results of [1]. We show the second approach. By the results on Newton's method in §3.3, the assumption on \tilde{x} implies that the analytic center exists, and therefore, by Lemma 3, the set of optimal solutions of (1) is nonempty and bounded. First, suppose that \tilde{x} is on the central path, $\tilde{x} = \tilde{x}(\mu)$ for some $\mu > 0$ and $\tilde{w} = 0$. Then, by definition, the partial derivatives of φ are all zero, that is (by (17) and (18)),

$$(21) \quad \frac{\partial}{\partial \tilde{x}_i} \varphi(\tilde{x}, \mu) = A^{(i)} \bullet B(\tilde{x}) = 0 \quad \text{for } i = 1, \dots, m$$

and

$$(22) \quad \frac{\partial}{\partial \lambda} \varphi(\tilde{x}, \mu) = \frac{\rho}{\mu} - \text{trace} B(\tilde{x}) = 0.$$

Also from Appendix B, the dual problem as given in [1] is

$$\max_{Y \geq 0} \{A^{(0)} \bullet Y \mid \text{trace} Y = 1, A^{(i)} \bullet Y = 0\}.$$

Hence, the matrix $(\mu/\rho)B(\tilde{x})$ is dual feasible, and the “duality gap” can easily be computed as

$$\lambda - \frac{\mu}{\rho} B(\tilde{x}) \bullet A^{(0)} = -\frac{\mu}{\rho} \sum_{i=1}^{m+1} \tilde{x}_i (A^{(i)} \bullet B(\tilde{x})) - \frac{\mu}{\rho} B(\tilde{x}) \bullet A^{(0)}$$

(by substituting (21) and (22) and using $A^{(m+1)} = -I$)

$$= -\frac{\mu}{\rho} \left(A^{(0)} + \sum_{i=1}^{m+1} \tilde{x}_i A^{(i)} \right) \bullet B(\tilde{x}) = \frac{\mu}{\rho} A(\tilde{x}) \bullet B(\tilde{x}) = \frac{n\mu}{\rho},$$

and is an upper bound for $\lambda - \lambda^{\text{opt}}$. A similar criterion also holds for points \tilde{x} near the central path: Suppose that the Newton step $\Delta\tilde{x}$ starting at \tilde{x} for finding the analytic center $\tilde{x}(\mu)$ has H -norm less than $\sqrt{\alpha}/4$, $\|\Delta\tilde{x}\|_H \leq \sqrt{\alpha}/4$.

This assumption is equivalent to $\|\tilde{w} + g(\tilde{x}, \mu)\|_{H^{-1}} \leq \sqrt{\alpha}/4$, where $g(\tilde{x}, \mu)$ is the norm of the gradient of the perturbed barrier function defined in (18) for $\tilde{w} \neq 0$. Often (for example, if the optimal solution x^{opt} is unique), we can show that

$\lim_{\mu \rightarrow 0} \|\tilde{w}\|_{H(x(\mu))^{-1}} = 0$, so that the above-mentioned stopping criterion is also useful when following a path of perturbed centers.

By the inner ellipsoidal approximation of the feasible set in [23], [11], it follows in a straightforward manner that the above bound on $\lambda - \lambda^{\text{opt}}$ still holds in the weaker form stated in Lemma 4. \square

Proof of the remark in step 3) §4.4. We show that the last component of $D\varphi(\tilde{x} - \beta\tilde{x}', \mu)$ is a decreasing function of β for small $|\beta|$. Clearly,

$$\frac{d}{d\beta} D\varphi(\tilde{x} - \beta\tilde{x}', \mu)e_{m+1} = -\tilde{x}'^T H(\tilde{x} - \beta\tilde{x}')e_{m+1} = -e_{m+1}^T H^{-1}(\tilde{x})H(\tilde{x} - \beta\tilde{x}')e_{m+1}$$

is negative (and equal to -1) for $\beta = 0$. (Here, $H(\tilde{x}) = D^2\varphi(\tilde{x}, \mu)$ is independent of μ as noted in (19).) From the definition of self-concordance, we can show that this is also negative if $\|\beta\tilde{x}'\|_{H(\tilde{x})} \leq \sqrt{\alpha}/4$. \square

We note that (for the case of the barrier function of a linearly constrained problem) there are (very “artificial”) examples that $\hat{\mu}_{k+1} > \mu_k$ for large $\beta < \beta_{\max}$ even when the extrapolation started on the central path and $\hat{\mu}_{k+1} < \mu_k$ for smaller values of $\beta > 0$. In general, however, it is true that $\lim_{\beta \rightarrow \beta_{\max}} \hat{\mu}_{k+1} = 0$, and in our program the safeguard $\mu_{k+1} \leq \mu_k/2$ is never needed.

Appendix B. Duality. We briefly state a nice duality theorem for problem (5) presented by Alizadeh in [1].

A slightly more general form of problem (5), in that it allows a general linear objective function and does not fix $A^{(m+1)} = -I$, is the problem

$$\max_{x \in \mathbb{R}^{m+1}} \left\{ b^T x \mid C - \sum_i x_i A^{(i)} \geq 0 \right\}, \quad (\text{primal}),$$

where $C = A^{(0)}$. Alizadeh gives a short and self-contained proof that for this problem there is a dual problem

$$\min_{Y \geq 0} \{ C \bullet Y \mid A^{(i)} \bullet Y = b_i \}, \quad (\text{dual})$$

for which the following duality relations hold (the dual variable is a positive semidefinite matrix Y). Optimal solutions x^{opt} and Y^{opt} exist and the optimal values are the same if both problems have strictly feasible solutions. Furthermore, $b^T x \leq C \bullet Y$ for any primal and dual feasible variables x and Y . Alizadeh notes a surprising structural similarity of these problems to linear programming, develops a potential reduction method for the dual problem, and applies it to approximate the solution of combinatorial optimization problems.

The above duality result implies that the dual of problem (5) is given by

$$\max_{Y \geq 0} \{ A^{(0)} \bullet Y \mid Y \bullet I = 1, A^{(i)} \bullet Y = 0 \}.$$

Acknowledgments. The author thanks Prof. Michael Saunders for many helpful comments and for his warm hospitality at Stanford University. The author particularly thanks Prof. Stephen Boyd for bringing the problem and its applications to his attention and for many helpful discussions and suggestions, as well as for the data for the test problem in §5.2. Finally, the author thanks the referees for their constructive criticism.

CONDITIONS FOR OPTIMALITY OVER H^∞ *

J. WILLIAM HELTON[†] AND ORLANDO MERINO[‡]

Abstract. The fundamental optimization problem in worst-case frequency domain design where stability is the key constraint is

$$\begin{aligned} &\text{Given } \Gamma \text{ a map from } \mathbb{T} \times \mathbb{C}^N \text{ to } \mathbb{R}^+ \\ &\text{FIND } \gamma^* > 0 \text{ and } f^* \in A_N \text{ such that} \\ (\text{OPT}_{A_N}) \quad &\gamma^* = \inf_{f \in A_N} \sup_{\theta} \Gamma(e^{i\theta}, f(e^{i\theta})) = \sup_{\theta} \Gamma(e^{i\theta}, f^*(e^{i\theta})). \end{aligned}$$

Here A_N denotes the \mathbb{C}^N -valued functions on the unit circle \mathbb{T} with analytic continuation to the unit disk \mathbb{D} that are continuous on the closed unit disk. The special case where the sublevel sets of Γ in z are “disks” in \mathbb{C}^N is the main mathematical problem in the area called H^∞ -control (cf. [B. A. Francis, *Lecture Notes in Control and Information Sci.*, Vol. 88, Springer-Verlag, Berlin, New York, 1986]), which has been one of the main emphases of control since the early 1980s. This article gives necessary conditions for f^* in A_N to be a solution to such a problem. These conditions are practical for computer implementation and are sufficient as well as necessary when $N \leq 2$ or when Γ is convex in the second variable. In §3, for $N = 2$, it is proved that there are very nice Γ (strictly pseudoconvex) producing an OPT problem having nonunique solutions. In §4 it is shown that coordinate descent algorithms often suggested by engineers for $N > 1$ sometimes do not attain the optimum (in practice, almost never). Section 5 treats another type of problem. Here $\tilde{\Gamma} \geq 0$ maps $\mathbb{T} \times \mathbb{R}^K \times \mathbb{C}^N$ to \mathbb{R} , and it is the goal to solve

$$(\text{UNCOPT-S}) \quad \inf_{f \in A_N} \sup_{\theta} \sup_{\alpha \in \mathcal{R}_{e^{i\theta}}} \tilde{\Gamma}(e^{i\theta}, \alpha, f(e^{i\theta})).$$

Here $\mathcal{R}_{e^{i\theta}}$ is a given closed set in \mathbb{R}^K . This problem is basic to engineering situations where there is uncertainty in the accuracy of mathematical models.

1. Introduction. The fundamental optimization problem in worst-case frequency domain design where stability is the key constraint is

$$\begin{aligned} &\text{Given } \Gamma \text{ a map from } \mathbb{T} \times \mathbb{C}^N \text{ to } \mathbb{R}^+, \\ &\text{FIND } \gamma^* > 0 \text{ and } f^* \in A_N \text{ such that} \\ (\text{OPT}_{A_N}) \quad &\gamma^* = \inf_{f \in A_N} \sup_{\theta} \Gamma(e^{i\theta}, f(e^{i\theta})) = \sup_{\theta} \Gamma(e^{i\theta}, f^*(e^{i\theta})). \end{aligned}$$

Here A_N denotes the \mathbb{C}^N -valued functions on the unit circle \mathbb{T} with analytic continuation to the unit disk \mathbb{D} , which are continuous on the closed unit disk. (See [Fr], [H1], and [H2].) The special case where the sublevel sets

$$S_\theta(c) = \{z \in \mathbb{C}^N : \Gamma(e^{i\theta}, z) \leq c\}$$

of Γ in z are “disks” in \mathbb{C}^N is the main mathematical problem in the area called H^∞ -control (cf. [Fr]), which has been one of the main emphases of control since the early 1980s. This article gives necessary conditions for f^* in A_N to be a solution to such a problem. These conditions are practical for computer implementation and are sufficient as well as necessary when $N \leq 2$ or when Γ is convex in the second variable. In §3 we prove that for $N = 2$ there are very nice Γ (strictly pseudoconvex) producing an OPT problem having nonunique

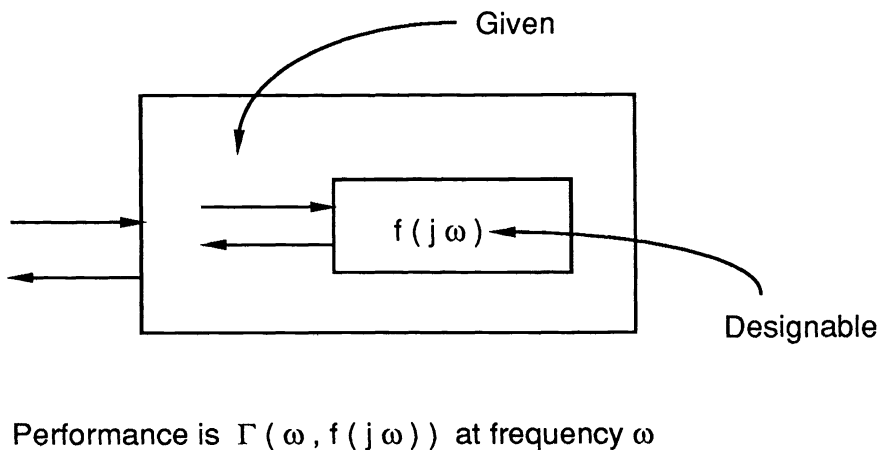

FIG. 1.1

solutions. In §4 we show that coordinate descent algorithms often suggested by engineers for $N > 1$ sometimes do not attain the optimum (in practice, almost never). Section 5 treats another type of problem. Here $\tilde{\Gamma} \geq 0$ maps $\mathbb{T} \times \mathbb{R}^K \times \mathbb{C}^N$ to \mathbb{R} , and we wish to solve

$$(\text{UNCOPT-S}) \quad \inf_{f \in A_N} \sup_{\theta} \sup_{\alpha \in \mathcal{R}_{e^{i\theta}}} \tilde{\Gamma}(e^{i\theta}, \alpha, f(e^{i\theta})).$$

Here $\mathcal{R}_{e^{i\theta}}$ is a given closed set in \mathbb{R}^K . This problem is basic to engineering situations where there is uncertainty in the accuracy of mathematical models, for example, in the area of robust control [Dor], [Doy], [H1].

The problem UNCOPT is strictly more complicated than OPT and indeed has OPT as one “pure component” of it. To see this, for given $\tilde{\Gamma}$, define Γ by “solving”

$$(\text{UNC}) \quad \Gamma(e^{i\theta}, z) \triangleq \sup_{\alpha \in \mathcal{R}_{e^{i\theta}}} \tilde{\Gamma}(e^{i\theta}, \alpha, z).$$

Then, solving UNCOPT is equivalent to solving UNC and OPT for Γ . (Refer to our computer program for solving OPT. The results of §2 are used to compute diagnostics printed out at each iteration.)

1.1. Motivation. The OPT problem is central to the design of a system where specifications are given in the frequency domain and stability is a key issue. Suppose that our objective is to design a system, part of which we are forced to use (in control, it is called the plant) and part of which is designable; see Fig. 1.1. The objective of the design is to find the admissible f that gives the best performance. If we denominate performance Γ as a “cost,” then the big Γ is bad, and the “worst case” is the frequency ω at which

$$\sup_{\omega} \Gamma(\omega, f(j\omega))$$

occurs. We seek to minimize this over all admissible f . The stipulation that the designable part of the circuit be stable amounts to requiring that f has no poles in the right half plane (R.H.P.). In other words, $f \in A_N$ (R.H.P.). This is exactly the R.H.P.-version OPT problem. Even when parts of the system other than the designable part are in H^∞ , we can frequently reparametrize to get OPT. Consequently, OPT arises in a large class of problems.

Indeed, the OPT problem is so basic it might be called *the fundamental H^∞ problem of control*. This sits in distinction to the fundamental problem of H^∞ control, and there are varying opinions as to what that is.

Graphic interpretations of OPT are informative and useful. A sublevel set $\mathcal{L}_\omega(c) = \{z \in \mathbb{C}^N : \Gamma(\omega, z) < c\}$ of Γ is just the set of designable parameters z that give performance better than c . The objective is to find a function f with no poles in the R.H.P. so that each $f(j\omega)$ belongs to $\mathcal{L}_\omega(c)$. Any such f makes the performance of the overall system at least as good as c for all ω . Thus OPT corresponds to find such f for the smallest value of c for which f can be found. One example is the Horowitz templates of control; thus this article gives an optimality theory for a significant portion of Horowitz control.

Related frequency domain design theories are those originated by Mayne and Polak and more recently pursued by their students (e.g., Tits and Fan). In a sense, the problem they study is more general than OPT; though, technically speaking, it is not (since it is finite-dimensional). They optimize performance over classes of rational functions (which, of course, are highly nonconvex). We optimize over the class of all analytic functions on the R.H.P. and exploit their special structure to obtain the elegant and sharp optimality conditions found in this paper. Ironically, infinite-dimensionality of A_N helps because it guarantees that, at optimum, “every constraint is active.” (This is condition (i) of Theorem 2.2.) In another direction, linear programming is a viable approach to OPT problems, provided that Γ has sublevel sets $\mathcal{L}_\theta(c)$ that are convex. Then, we can approximate the $\mathcal{L}^\theta(c)$ by a simplex and use standard packages. This has been explored extensively by Boyd in [BB], and crude numerical comparisons of linear programming to other H^∞ methods were done in [BHM], [HS]. The theorems given have required that Γ be a smooth function; they do not apply as stated to a simplex in \mathbb{C}^N , since a simplex has corners. They would apply to a smooth approximation of the simplex, and so they might well be adaptable for use in linear-programming-based codes. Also, for $N = 1$, a general version of Theorem 2.1 appears in [HM] that applies to $\mathcal{L}_\theta(c)$, which are simplicies.

When each $\mathcal{L}_\omega(c)$ is a “disk” such as

$$S_\omega(c) = \left\{ (z_1, z_2, \dots, z_N) \in \mathbb{C}^N : \sum_{i=1}^N p_i(j\omega) |K_i(j\omega) - z|^2 \leq c \right\}$$

for some complex-valued functions K_i and positive-valued functions p_i in \mathbb{C}^N , the problem has an *explicit solution*. Other solvable OPT problems are easy to recognize, since so few of them exist. Crudely speaking, OPT_E with $E = H_n^\infty$ (see §1.2), is completely solved below:

- (i) when each $\mathcal{L}_\omega(c)$ is a disk on \mathbb{C}^N ,
- (ii) when each $\mathcal{L}_\omega(c)$ is a matrix ball,
- (iii) when each $\mathcal{L}_\omega(c)$ is a ball of symmetric matrices,
- (iv) when each $\mathcal{L}_\omega(c)$ is a ball of antisymmetric matrices.

A function Γ each of whose sublevel sets $\mathcal{L}_\omega(c)$ are disks in this sense will be called *quasi-circular*. (There is much literature on solutions to quasi-circular problems. See [BGR], [Dym], [FF], [Fr], [GM], [H4], and [Yng].)

Example 1. The famous “mixed sensitivity” performance measure of control is

$$(1.1) \quad \tilde{\Gamma}(\omega, T) \triangleq W_1(j\omega)|T - 1|^2 + W_2(j\omega)|T|^2,$$

where W_1 weights low frequencies and W_2 weights high frequencies. Interpolation constraints are easy to put in and convert $\tilde{\Gamma}$ to a Γ of a similar form. These problems are quasi-circular, as are the famous 1, 2, and 4 block problems of H^∞ control.

Example 2 (power mismatch and amplifier design). Classical control is very close to the work of Bode on amplifier design. Likewise, H^∞ -control is mathematically the same (actually a little easier) than the subject of gain equalization (or even noise suppression) in amplifiers. Historically, Youla and Saito [YS], gave a theory of single-input, single-output (SISO) gain equalization, and Helton gave a theory of multiple-input, multiple-output (MIMO) design (surveyed in [H5]), which preceded H^∞ -control and which contributed to its inception. These paradigm problems are quasi-circular.

Example 3. Two competing constraints typically yield \mathcal{L}_θ , which are intersections of two disks, and so forth.

Example 4. Bercovici, Foias, and Tannenbaum have recent results on Γ 's that are based on the spectral radius of a matrix. These are highly nonsmooth Γ 's and demonstrate interesting properties. This arises in a class of control problems with plant uncertainty.

Uncertainty in the mathematical model for a physical system, which, in control, is called plant uncertainty, naturally leads to OPT problems with very complicated Γ . Our formulation is to start with a performance measure $\tilde{\Gamma}$ that depends on what we believe the plant P to be at frequency ω and the choice T of the designable parameter at ω . The basic design optimization problem is

$$(\text{UNCOPT-S}_{\text{RHP}}) \quad \inf_{T \in A_N^\infty} \sup_{\omega} \sup_{p \in R_\omega} \tilde{\Gamma}(\omega, p, T(j\omega)).$$

Here R_ω denotes the range of values p at frequency ω that we believe the plant $P(j\omega)$ might actually take. This, of course, is the R.H.P. version of (UNCOPT-S). For this problem, “tightening the specs” amounts to calculating the “tightened” performance measure

$$(\text{UNC}_{\text{RHP}}) \quad \Gamma(\omega, T) = \sup_{p \in R_\omega} \tilde{\Gamma}(\omega, p, T).$$

After this is done, solving the full UNCOPT-S_{RHP} problem is equivalent to an OPT on the R.H.P. Thus OPT is the pure H^∞ part of UNCOPT (which is another good reason for calling OPT the fundamental H^∞ problem of control).

Plant uncertainty when treated in this way simply amounts to a mathematization of the age old engineering adage: “In the presence of uncertainty, tighten the specs.”

The maximization in UNC is time consuming and is a subject unto itself (the structured singular value (s.s.v.) and environs). Consequently, we certainly expect that the most effective numerical algorithms at the $(k + 1)$ th iteration will update current guess f^k and $P^k(j\omega)$ by doing a UNC step to increase $\tilde{\Gamma}(\omega, P, f^k(j\omega))$ for each ω , then an f step to decrease $\|\Gamma\|_\infty$, then another P step, then another f step, and so forth.

Doyle's μ -synthesis (after substantial reparameterization and a compromise) is such an algorithm. It is very natural, since the function $\Gamma(\omega, p, z)$ of UNCOPT is in many control applications for fixed p quasi-circular. Thus coordinate optimization produces a sequence $P^k \in L^\infty$ and $f^k \in H^\infty$, where the update for f^k comes by solving a quasi-circular OPT problem. We could imagine an infinite variety of choices between spending a long time on each P maximization step before going to an f step, or vice versa. Consequently, it is clear that, to begin a systematic study of the H^∞ plant uncertainty problem UNCOPT',

we should analyze two extreme situations. The *first* is where we do the p maximization completely; this is UNC. It is in principle studied by the s.s.v. school. The *second* is OPT for the “tightened” performance measure Γ . (For numerous articles on uncertainty and robustness, see [Dor].)

1.2. Notation. For convenience, we refer to OPT_E as the problem OPT, where the minimization is over the set $E \subset H_N^\infty$, and f^* is in E . By L_N^∞ , we represent the set of all \mathbb{C}^N -valued, essentially bounded measurable functions on \mathbb{T} , and H_N^∞ consists of those elements of L_N^∞ that extend to bounded analytic functions on \mathbb{D} . The space H_N^1 is defined similarly as consisting of \mathbb{C}^N -valued measurable functions F on \mathbb{T} that extend analytically to \mathbb{D} and have finite L^1 -norm, $\|F\|_{L^1} = \int_0^{2\pi} \|F(e^{i\theta})\|_{\mathbb{C}^N} (d\theta/2\pi) < \infty$. If $E \subset H_N^\infty$, set

$$(1.1) \quad RE \triangleq \{f \in E : \overline{f(e^{-i\theta})} = f(e^{i\theta}) \text{ a.e. on } \mathbb{T}\}.$$

Another way of defining RE is as the set of elements of E with real Fourier coefficients. Frequency response functions in engineering are all real on the real axis. Thus spaces such as RH_N^∞ , RA_N , and the corresponding OPT problems are the only ones that occur in engineering applications.

We investigate local conditions for solutions to OPT. For this, we use the terms *optimizer* and *directional optimizer*, which we now define below.

DEFINITION 1.1. Let $E \subset H_N^\infty$ and $f^* \in E$. The function f^* is a *local optimizer* for OPT_E if there exists an open set $V \subset E$ such that $f^* \in V$ and

$$(1.2) \quad \sup_{\theta} \Gamma(e^{i\theta}, f^*(e^{i\theta})) \leq \sup_{\theta} \Gamma(e^{i\theta}, f(e^{i\theta})) \quad \forall f \in V.$$

The function f^* is a *directional optimizer* for OPT_E if, for each $h \in E$, there exists $t_h > 0$ such that

$$(1.3) \quad \sup \Gamma(e^{i\theta}, f^*(e^{i\theta})) \leq \sup \Gamma(e^{i\theta}, f^*(e^{i\theta}) + t h(e^{i\theta})) \quad \forall t \in (0, t_h).$$

The terms *strict local optimizer* and *strict local directional optimizer* are defined similarly, with strict inequality in (1.2) and (1.3), respectively.

Of course, if E is finite-dimensional, the concepts local optimizer and directional optimizer coincide. This is a simple consequence of the compactness of the unit ball in E . In the infinite-dimensional case, a strict directional optimizer may not be a strict local optimizer.

Now we establish some notation needed throughout the paper. Elements $z \in \mathbb{C}^N$ are represented as column vectors. By z^\dagger , we denote the transpose of z , so that $\bar{z}^\dagger z = \|z\|_{\mathbb{C}^N}^2$, and, if z has entries $z_l, l = 1, \dots, N$, then $\text{Re } z$ represents the column vector with entries $\text{Re } z_l, l = 1, \dots, N$. Let $G : \mathbb{C}^N \rightarrow \mathbb{R}$ be a class C^3 function. Then the order 2 expansion of G about z_0 is

$$(1.4) \quad \begin{aligned} G(z_0 + w) = & G(z_0) + 2 \text{Re } \frac{\partial G}{\partial z}(z_0)^\dagger w \\ & + \frac{1}{2} \left\{ 2\bar{w}^\dagger \frac{\partial^2 G}{\partial \bar{z} \partial z}(z_0) w + 2 \text{Re } \left(w^\dagger \frac{\partial^2 G}{\partial z^2}(z_0) w \right) \right\} \\ & + \mathcal{O}(\|w\|_{\mathbb{C}^N}^3), \end{aligned}$$

where $\partial G / \partial z(z_0)$ is a column vector on entries $\partial G / \partial z_l(z_0), l = 1, \dots, N$ and $\partial^2 G / \partial \bar{z} \partial z(z_0)$ (respectively, $\partial^2 G / \partial z^2(z_0)$) is an $N \times N$ matrix, with entries $\partial^2 G / \partial \bar{z}_l \partial z_j(z_0)$ (respectively, $\partial^2 G / \partial z_l \partial z_j(z_0)$), $j, l = 1, \dots, N$.

2. Necessary conditions and sufficient conditions for solutions to OPT. The following theorem of Helton in [H3] gives a clean-cut characterization of functions $f \in A_1$ that solve the problem OPT.

THEOREM 2.1 ($N = 1$). *Let $\Gamma : \mathbb{T} \times \mathbb{C} \rightarrow \mathbb{R}^+$ be of class C^2 . A continuous function $f^* \in A_1$ for which $a(e^{i\theta}) = (\partial\Gamma/\partial z)(e^{i\theta}, f^*(e^{i\theta}))$ is never zero is a strict local directional optimizer if and only if (i) $\Gamma(e^{i\theta}, f^*(e^{i\theta}))$ is constant in θ , and (ii) the winding number of a about 0 is positive. \square*

See [A] for a definition of winding number of a curve. It is also known that, for $N = 1$, under fairly general hypotheses, the solution exists, is unique, and has certain degree of smoothness (see [HM]). Thus Theorem 2.1 gives a practical test when $N = 1$ for determining if a given function $f^* \in A_1$ solves OPT.

We see that the situation for the case where $N > 1$ is quite different. Uniqueness no longer holds—this is the subject of §3.

Also, conditions (i) and (ii) can be generalized to the case where $N > 1$, but they are not sufficient to guarantee that a particular function $f^* \in A_N$ is a solution to OPT_{A_N} .

2.1. Direction optima. We start the study of the general case ($N \geq 1$) by presenting a generalization of (i) and (ii) of Theorem 2.1. For a given function $a : \mathbb{T} \rightarrow \mathbb{C}^N$, we write

$$N(a) = \{h \in H_N^\infty : a^t(e^{i\theta})h(e^{i\theta}) = 0, \text{ a.e. on } \mathbb{T}\}.$$

THEOREM 2.2. *Let Γ be of class C^3 and left $f^* \in A_N$ be such that $(\partial\Gamma/\partial z)(e^{i\theta}, f^*(e^{i\theta}))$ never equals 0 on \mathbb{T} . If $f^* \in A$ is a local directional optimizer, then*

(I) *The function $\Gamma(\cdot, f^*(\cdot))$ is constant on \mathbb{T} ,*

(II) *There exist functions $F \in H_N^1$ and $\lambda : \mathbb{T} \rightarrow \mathbb{R}^+$ measurable and positive almost everywhere on \mathbb{T} such that*

$$\frac{\partial\Gamma}{\partial z}(e^{i\theta}, f^*(e^{i\theta})) = \lambda(e^{i\theta})\chi(e^{i\theta})F(e^{i\theta}) \quad \text{a.e. on } \mathbb{T}.$$

Here χ is the function $\chi(e^{i\theta}) = e^{i\theta}$;

(III) *For every $h \in N((\partial\Gamma/\partial z)(\cdot, f^*(\cdot))) \cap A_N$, $h \neq 0$,*

$$\sup_{\theta} \left\{ \overline{h(e^{i\theta})}^\dagger \frac{\partial^2\Gamma}{\partial z \partial \bar{z}}(e^{i\theta}, f^*(e^{i\theta}))h(e^{i\theta}) + \text{Re} \left(h(e^{i\theta})^\dagger \frac{\partial^2\Gamma}{\partial z^2}(e^{i\theta}, f^*(e^{i\theta}))h(e^{i\theta}) \right) \right\} \geq 0.$$

Conversely, conditions (I)–(III) with strict inequality imply that f^* is a strict local directional optimizer.

To see that Theorem 2.2 generalizes Theorem 2.1, we obtain the latter from the former, by directly comparing (i), (ii) of Theorem 2.1 with (I)–(III) of Theorem 2.2. This we do below.

Since (i) and (I) are identical, we now look at (ii) versus (II). If (ii) is assumed, then we can write $a(e^{i\theta}) = (e^{i\theta})^n a_1(e^{i\theta})$, where n is the winding number of a about 0. In particular, $\text{wind}(a_1; 0) = 0$, so we can write $a_1(e^{i\theta}) = |a(e^{i\theta})|e^{u(e^{i\theta})i}$, where u is continuous and real-valued. If u^* is the harmonic conjugate of u , then

$$a_1 = \lambda(e^{i\theta})e^{i\theta}F(e^{i\theta}),$$

where $F(e^{i\theta}) = (e^{i\theta})^{n-1}e^{-u^*+iu}$ is in H_1^1 and $\lambda(e^{i\theta}) = |a(e^{i\theta})| \cdot e^{u^*(e^{i\theta})}$ is positive measurable. Thus (II) holds. This can be reversed to show that (II) implies (ii).

We now claim that (III) is trivially satisfied when $N = 1$ and (II) holds. Indeed, if $h \in H_1^\infty$ satisfies $(\partial\Gamma/\partial z)(e^{i\theta}, f^*(e^{i\theta})) \cdot h(e^{i\theta}) = 0$ almost everywhere on \mathbb{T} , we must have $h = 0$, since F is not the function zero. Thus $N((\partial\Gamma/\partial z)(\cdot, f^*(\cdot))) = \{0\}$.

If the function Γ is *real symmetric*, i.e.,

$$(2.1) \quad \Gamma(e^{i\theta}, z) = \Gamma(e^{-i\theta}, \bar{z}) \quad \forall e^{i\theta} \in \Pi, \forall z \in \mathbb{C}^N,$$

then we can consider the problem OPT_{RA_N} and try to obtain a version of Theorem 2.2 specialized to this situation. We have the following (partial) result.

THEOREM 2.2'. *In addition to the hypotheses to Theorem 2.2, assume that $f \in RA_N$ and that Γ satisfies (2.1). Modify conditions (II) and (III) of Theorem 2.2 by requiring that $F \in RH_N^1$ in statement (II), and that $h \in RN$ $\partial\Gamma/\partial z(\cdot, f^*(\cdot))$.*

Then (I)–(III) are necessary for $f^ \in RA_N$ to be a local directional optimizer for OPT_{RA_N} .*

Given Γ and f^* as in Theorem 2.2, we see that we can associate to the function

$$(2.2) \quad a(\cdot) = \frac{\partial\Gamma}{\partial z}(\cdot, f^*(\cdot))$$

defined on \mathbb{T} and valued in \mathbb{C}^N , a unique positive integer $w(a)$ (see Theorem 2.5). When $N = 1$, the integer $w(a)$ is precisely the winding number about zero of the function a .

DEFINITION 2.3. Let $b \in L_N^\infty$. A function $F \in H_N^1$ is an *analytic direction* for b if $\|F\|_{H_N^1} = 1$ and if there exists a measurable function $\lambda: \mathbb{T} \rightarrow \mathbb{R}^+$ such that

$$b(e^{i\theta}) = \lambda(e^{i\theta})F(e^{i\theta}) \quad \text{a.e. on } \mathbb{T}.$$

Hence (II) of Theorem 2.2 is equivalent to stating that $\chi^{-1}(\cdot)(\partial\Gamma/\partial z)(\cdot, f^*(\cdot))$ has an analytic direction.

DEFINITION 2.4. Let $b \in L_N^\infty$, set $\omega(b) \triangleq \sup\{m \in \mathbb{Z} : \chi^{-m}b \text{ has an analytic direction}\}$.

THEOREM 2.5. *Let Γ be as in the hypotheses to Theorem 2.2. If $f^* \in A_N$ is an optimizer for OPT_E and if $a(\cdot) = \partial\Gamma/\partial z(\cdot, f^*(\cdot))$, then*

- (1) $1 \leq \omega(a) < \infty$,
- (2) $\chi^{-\omega(a)} a$ has a unique analytic direction F_0 . Moreover, F_0 is a strong outer-function,¹
- (3) Let $F \in H_N^1$ be such that $\|F\|_{L^1} = 1$. Then F is an analytic direction for a if and only if there exist a constant $\mu > 0$ and elements $z_1, \dots, z_{\omega(a)}$ in the closed unit disk in \mathbb{C} such that

$$(2.3) \quad F(e^{i\theta}) = \prod_{l=1}^{\omega(a)} (e^{i\theta} - z_l)(1 - \bar{z}_l e^{i\theta}) F_0(e^{i\theta}) \quad \text{a.e. on } \mathbb{T},$$

- (4) If $f \in RA_N$ and Γ satisfies (2.1), then the function F_0 in 2 is in RH_N^1 , and the zeros z_l in (2.3) come in conjugate pairs.

See Theorem A.3 in Appendix A.

It is shown in [H3] that, when a has rational entries $a_j, j = 1, \dots, N$, we can compute an integer L out of the zeros and poles of the a_j 's, so that a necessary condition for optimality is $L > 0$. The number L proves to be precisely $\omega(a)$. Hence, in this case, (II) amounts to saying $\omega(a) \geq 1$.

THEOREM 2.6. *Assume the hypotheses of Theorem 2.2 (or Theorem 2.8). Let Γ and f^* be as in Theorem 2.2 (or Theorem 2.8). We have that*

¹ F_0 is strong outer if F_0 is an outer function such that $(\chi - e^{i\varphi})^{-2}F_0 \notin H_N^1$, for every $e^{i\varphi} \in \mathbb{T}$.

(1) If the function a can be extended meromorphically to a neighborhood of \mathbb{D}^- , then $\omega(a) = z(a) - p(a)$, where by definition $z(a) =$ number of zeros in \mathbb{D} plus number of double zeros on $\partial\mathbb{D}$, common to all the a_j 's, counting multiplicities,

$p(a) =$ total number of poles in \mathbb{D} plus total number of double poles on $\partial\mathbb{D}$, of the a_j 's;

(2) If, for some j_0 , the coordinate function a_{j_0} is never 0 on \mathbb{T} and has winding number $\omega(a_{j_0})$ about 0, then $1 \leq \omega(a) \leq \omega(a_{j_0})$. If also $\omega(a_{j_0}) = 1$, then $a_j/a_{j_0} \in H_1^\infty$, for $j = 1, \dots, N$.

The necessity of (I) and $\omega(a) > 0$ was first demonstrated for $N \geq 1$ in [H3] under stronger hypotheses than in Theorem 2.2.

We have found that Theorem 2.6 is particularly valuable in practice. We have a code for solving iteratively OPT, and, after each iterate f^k is produced, tests corresponding to (I) and (II) are performed. When $N = 1$, numerical experiments (to be reported elsewhere) show that

$$e^k = \left(\sup_{\theta} \Gamma(e^{i\theta}, f^k(e^{i\theta})) - \inf_{\theta} \Gamma(e^{i\theta}, f^k(e^{i\theta})) \right) / \sup_{\theta} \left\| \frac{\partial \Gamma}{\partial z}(e^{i\theta}, f^k(e^{i\theta})) \right\|_{\mathbb{C}^N}$$

is a good predictor of the true error $\|f^k - f^*\|_\infty$, while the winding number $\omega(a^k)$, where $\omega(a^k) = \omega(\partial\Gamma/\partial z(\cdot, f^k))$, very quickly stabilizes and proves to be unimportant. However, when $N > 1$, the situation is quite different: e^k tends to zero at superlinear rate, but $\|f^k - f^*\|_\infty$ decreases at a much slower rate. Since we do not have a good estimate of $\|f^k - f^*\|_\infty$, we employ (2) of Theorem 2.6 to produce a diagnostic that works well in combination with e^k . It consists in first locating $a_{j_0}^k = \partial\Gamma/\partial z(\cdot, f^*)$, which is never zero on \mathbb{T} and has $w(a_{j_0}^k) = 1$. Then we compute that

$$r^k = \sum_{j=1}^N \|P_{H_1^{2\perp}}(a_j^k/a_{j_0}^k)\|_{L^2},$$

where $P_{H_1^{2\perp}}$ denotes the orthogonal projection onto $H^{2\perp}$. Note that $r^k = 0$ implies that (II) holds,² so, as $f^k \rightarrow f^*$ in a computer run, we observe that $f^k \rightarrow 0$.

Until this point, we have given versions of (I) and (II) that are useful for computation. Unfortunately, (III) remains unwieldy, since we must check a certain condition for all analytic functions. How to overcome this remains the main open question in this area of necessary and sufficient conditions for optimality. However, when $N = 2$, we obtain an elegant and practical theorem.

THEOREM 2.7. *Set $N = 2$ in Theorem 2.2 and let $a(\cdot) = \partial\Gamma/\partial z(\cdot, f^*(\cdot))$ and $b(\cdot) = (-\partial\Gamma/\partial z_2(\cdot, f^*(\cdot)), \partial\Gamma/\partial z_1(\cdot, f^*(\cdot)))^\dagger$. Furthermore, suppose that the function $\chi^{-\omega(a)}$. a has an analytic direction F_0 that is continuous and nonzero on \mathbb{T} . Then (III) is equivalent to the statement below.*

At least one of the following statements is true:

(i) *There exists $e^{i\theta} \in \mathbb{T}$ such that*

$$b^\dagger(e^{i\theta})A(e^{i\theta})b(e^{i\theta}) \geq |b^\dagger(e^{i\theta})B(e^{i\theta})b(e^{i\theta})|;$$

(ii) *$b^\dagger Bb$ is never zero on \mathbb{T} , and either*

(a) *$\omega(b^\dagger Bb) > 2\omega(a)$, or*

² Of course, such an $a_{j_0}^k$ (with no zeros on \mathbb{T} and winding number about 0 equal to 1) does not always occur. However, for generic Γ , [M1] very strongly suggests $a_{j_0}^k$ as above do occur, at least for f^k close to f^* .

(b) $\omega(b^\dagger Bb) < 2\omega(a)$, and $\omega(b^\dagger Bb)$ is odd.

We illustrate use of the theorems above with an example.

Example 1. For $N = 2$ and $\varepsilon > 0$, let

$$\Gamma_\varepsilon(e^{i\theta}, z_1, z_2) = |100 + z_1 e^{i\theta} + 0.1(z_1 z_2 + z_1 + z_2)|^2 \\ + |100 + z_2 e^{i\theta} + 0.1(z_1 z_2 + z_1 + z_2)|^2 + \varepsilon |z_1|^2 + \varepsilon |z_2|^2.$$

We have that

$$\frac{\partial \Gamma_\varepsilon}{\partial z_1}(e^{i\theta}, z_1, z_2) = \overline{(100 + z_1 e^{i\theta} + 0.1(z_1 z_2 + z_1 + z_2))} \cdot (e^{i\theta} + 0.1 + 0.1 z_2) \\ + \overline{(100 + z_2 e^{i\theta} + 0.1(z_1 z_2 + z_1 + z_2))} \cdot (0.1 + 0.1 z_2) + \varepsilon \overline{z_1}$$

and

$$\frac{\partial \Gamma_\varepsilon}{\partial z_2}(e^{i\theta}, z_1, z_2) = \overline{(100 + z_1 0.1(z_1 z_2 + z_1 + z_2))} (0.1 + 0.1 z_1) \\ + \overline{(100 + z_2 e^{i\theta} + 0.1(z_1 z_2 + z_1 + z_2))} (e^{i\theta} + 0.1 + 0.1 z_1) + \varepsilon \overline{z_2}.$$

We now show that the constant function $f(e^{i\theta}) = (0, 0)$ satisfies (I) and (II), but is not an optimizer for Γ_ε , if $\varepsilon < 19$.

Now (I) holds for

$$\Gamma_\varepsilon(e^{i\theta}, 0, 0) = 20,000 \quad \forall e^{i\theta} \in \mathbb{T}.$$

To check (II), evaluate the partial derivatives of Γ_ε to obtain

$$\left(\frac{\partial \Gamma_\varepsilon}{\partial z_1}(e^{i\theta}, 0, 0), \frac{\partial \Gamma_\varepsilon}{\partial z_2}(e^{i\theta}, 0, 0) \right) = (100e^{i\theta} + 20, 100e^{i\theta} + 20).$$

Note that $100e^{i\theta} + 20 = 100|e^{i\theta} + 0.2|^2(e^{i\theta}/(1 + 0.2e^{i\theta}))$, so that (II) holds.

We claim that $f^*(0, 0)$ does not solve OPT when $\varepsilon < 19$. Begin by computing $b^\dagger Ab$ and $b^\dagger Bb$ at $(0, 0)$, as follows:

$$\overline{b}^\dagger Ab|_{z_1=0, z_2=0} \\ = \begin{pmatrix} -100e^{i\theta} - 20 \\ 100e^{i\theta} + 20 \end{pmatrix}^\dagger \begin{pmatrix} 1.02 + 0.1e^{i\theta} + 0.1e^{-i\theta} + \varepsilon & 0.02 + 0.1e^{i\theta} + 0.1e^{-i\theta} \\ 0.02 + 0.1e^{i\theta} + 0.1e^{-i\theta} & 1.02 + 0.1e^{i\theta} + 0.1e^{-i\theta} + \varepsilon \end{pmatrix} \\ \cdot \begin{pmatrix} -100e^{i\theta} - 20 \\ 100e^{i\theta} + 20 \end{pmatrix} \\ = 2(1 + \varepsilon)(100e^{i\theta} + 20)^2$$

and

$$b^\dagger Bb|_{z_1=0, z_2=0} = (-100e^{i\theta} - 20, 100e^{i\theta} + 20) \begin{pmatrix} 0 & 20 \\ 20 & 0 \end{pmatrix} \begin{pmatrix} -100e^{i\theta} - 20 \\ 100e^{i\theta} + 20 \end{pmatrix} \\ = -40(100e^{i\theta} + 20)^2.$$

Now $\varepsilon < 19$ implies that

$$(\bar{b}^\dagger Ab)(e^{i\theta}) < |(b^\dagger Bb)(e^{i\theta})| \quad \forall e^{i\theta} \in \mathbb{T},$$

so that (1) of Theorem 2.7 does not hold. We also have that

$$\omega(bBb^t) = 2 = 2\omega(a),$$

and (2) of Theorem 2.7 also fails. Then Theorems 2.7 and 2.2 imply that f^* is not a local directional optimizer.

Now we turn to proofs.

The following is a more general version of Theorem 2.2 in that the differentiability of $\Gamma(e^{i\theta}, z)$ at $z = f^*(e^{i\theta})$ is required only almost everywhere on \mathbb{T} . This weaker hypothesis and even weaker hypotheses are physically desirable for treating problems that arose in §5.

THEOREM 2.8. *Suppose that E is either H_N^∞ or A_N . Let $\Gamma : \mathbb{T} \times \mathbb{C}_N \rightarrow \mathbb{R}^+$ and $f^* \in E$ be given, such that*

- (1) *The function $g(\cdot) \triangleq \Gamma(\cdot, f^*(\cdot))$ is continuous on \mathbb{T} ;*
- (2) *$\Gamma(e^{i\theta}, z)$ is of class C^2 at $z = f^*(e^{i\theta})$ for almost all $e^{i\theta} \in \mathbb{T}$. Moreover, for such $e^{i\theta} \in \mathbb{T}$, the remainders $R_l(e^{i\theta}, z)$, $l = 1, 2$ of the order l Taylor expansion of $\Gamma(e^{i\theta}, f^*(e^{i\theta}) + z)$ about $z_0 = 0$ satisfy*

$$(2.4) \quad \sup_{\theta} |R_l(e^{i\theta}, z)/\|z\|_{\mathbb{C}_N}^l \rightarrow 0 \quad \text{as } z \rightarrow 0, l = 1, 2;$$

- (3) *The function $a(\cdot) = \partial\Gamma/\partial z(\cdot, f^*(\cdot))$ is bounded and bounded away from 0. If $E = A_N$, assume further that the set $\{e^{i\theta} \in \mathbb{T} : a \text{ is not continuous at } e^{i\theta}\}^-$ has linear Lebesgue measure 0;*

- (4) *There exists a continuous function $g_0 : \mathbb{T} \rightarrow \mathbb{C}^N$ such that*

$$\sup_{\theta} \left\| \frac{1}{\|a(\cdot)\|_{\mathbb{C}^N}} \cdot \bar{a}(\cdot) + g_0(\cdot) \right\|_{\mathbb{C}_N} < 1.$$

Then necessary conditions for f^ to be a directional optimizer for OPT_E are*

- (I) *g is constant;*
- (II) *$\chi^{-1} a$ has an analytic direction F ;*
- (III)

$$\sup_{\theta} \left\{ \overline{h(e^{i\theta})}^\dagger \frac{\partial^2 T}{\partial \bar{z} \partial z}(P(e^{i\theta})) h(e^{i\theta}) + \operatorname{Re} h(e^{i\theta})^\dagger \frac{\partial^2 \Gamma}{\partial z^2}(P(e^{i\theta})) h(e^{i\theta}) \right\} \geq 0$$

$$\forall h \in N(a) \cap E.$$

These conditions are also sufficient for f^ to be a strict directional optimizer if (III) is modified as to have strict inequality.*

Proof. Consider the function Γ_1 on $\mathbb{T} \times \mathbb{C}_N$ defined by

$$\begin{aligned} \Gamma_1(e^{i\theta}, z) &= g(e^{i\theta}) + 2 \operatorname{Re} \frac{\sqrt{g(e^{i\theta})}}{|a(e^{i\theta})|} a(e^{i\theta})^\dagger z + \|z\|_{\mathbb{C}_N}^2 \\ &= \left\| \frac{\sqrt{g(e^{i\theta})}}{\|a(e^{i\theta})\|_{\mathbb{C}^N}} \bar{a}(e^{i\theta}) + z \right\|_{\mathbb{C}_N}^2. \end{aligned}$$

If at least one of the hypotheses (I), (II) is not satisfied, then the function $0 \in A_N$ is not a solution to OPT_E for Γ_1 (Theorem A1 in Appendix A). Therefore, by Theorem A1 or Theorem A2, there exists a function $f' \in E$ such that

$$(2.5) \quad \sup_{\theta} \Gamma_1(e^{i\theta}, f'(e^{i\theta})) < \gamma^* \triangleq \sup_{\theta} \Gamma_1(e^{i\theta}, 0).$$

We claim that there exists an open set F that contains the set $P = \{e^{i\theta} \in \mathbb{T} : g(e^{i\theta}) = \gamma^*\}$ and a constant $\delta_0 \geq 0$, such that

$$(2.6) \quad \sup_{e^{i\theta} \in F} \operatorname{Re} a(e^{i\theta})^\dagger f'(e^{i\theta}) < -\delta_0.$$

To prove the claim, consider any decreasing sequence $\{F_n\}$ of open sets in \mathbb{T} such that $\cap F_n = P$. If the claim is false, then

$$(2.7) \quad m \left\{ e^{i\theta} \in F_n : \operatorname{Re} \frac{\sqrt{g(e^{i\theta})}}{|a(e^{i\theta})|} \cdot a(e^{i\theta})^\dagger f'(e^{i\theta}) > \frac{-1}{n} \right\} > 0 \quad \forall n \in \mathbb{N}.$$

Here mC is the Lebesgue measure of C . Choose $\delta > 0$ arbitrary and pick $N_\delta \in \mathbb{N}$ such that

$$(2.8) \quad g(e^{i\theta}) > \gamma^* - \delta \quad \forall e^{i\theta} \in F_n, n \geq N_\delta.$$

Then, from (2.7) and (2.8),

$$(2.9) \quad m \left\{ e^{i\theta} \in F_n : g + 2 \operatorname{Re} \frac{\sqrt{g(e^{i\theta})}}{|a(e^{i\theta})|} a(e^{i\theta})^\dagger f'(e^{i\theta}) + |f'(e^{i\theta})|^2 > \gamma^* - \delta - \frac{2}{n} \right\} > 0$$

$\forall n \geq N_\delta,$

i.e.,

$$(2.10) \quad \sup_{\theta} \Gamma_1(e^{i\theta}, f'(e^{i\theta})) \geq \gamma^* - \delta.$$

Since δ is arbitrary, it follows from (2.10) that

$$(2.11) \quad \sup_{\theta} \Gamma_1(e^{i\theta}, f'(e^{i\theta})) \geq \gamma^*,$$

which is impossible, by (2.5). This proves the claim.

Consider the following expansion, valid almost everywhere on \mathbb{T} :

$$(2.12) \quad \begin{aligned} \Gamma(e^{i\theta}, f^*(e^{i\theta}) + t(f'(e^{i\theta}) - f^*(e^{i\theta}))) &= \Gamma(e^{i\theta}, f^*(e^{i\theta})) \\ &+ 2t \operatorname{Re} a(e^{i\theta})^\dagger (h(e^{i\theta}) - f^*(e^{i\theta})) \\ &+ R_1(e^{i\theta}, t(f'(e^{i\theta}) - f^*(e^{i\theta}))). \end{aligned}$$

By (2.6) and hypothesis (2), there exist $t_0 > 0$ such that

$$(2.13) \quad \sup_{e^{i\theta} \in F} \Gamma(e^{i\theta}, f^*(e^{i\theta}) + t(f'(e^{i\theta}) - f^*(e^{i\theta}))) \leq \gamma^* - t\delta_0 \quad \forall t \in (0, t_0).$$

Also, since the open set F contains P and since $\Gamma(e^{i\theta}, f^*(e^{i\theta}))$ is continuous, there exists $t_1 \geq 0$ such that

$$(2.14) \quad \sup_{e^{i\theta} \in \mathbb{T}/F} \Gamma(e^{i\theta}, f^*(e^{i\theta}) + t(f'(e^{i\theta}) - f^*(e^{i\theta}))) < \gamma^* \quad \forall t \in (0, t_1).$$

Combining (2.13) and (2.14), we obtain that f^* is not a local directional optimizer, and this shows that (I) and (II) are necessary.

Let $h \in N(a)$. An order 2 expansion of $\Gamma(e^{i\theta} z)$ about $z = f^*(e^{i\theta})$ gives

$$\begin{aligned} 0 &\leq \sup_{\theta} \frac{1}{t^2} \{ \Gamma(e^{i\theta}, f^*(e^{i\theta}) + th(e^{i\theta})) - \gamma^* \} \\ (2.15) &\leq \sup_{\theta} 2 \left\{ \overline{h(e^{i\theta})}^{\dagger} \frac{\partial^2 \Gamma}{\partial \bar{z} \partial z}(e^{i\theta}, f^*(e^{i\theta})) h(e^{i\theta}) + \operatorname{Re} h(e^{i\theta})^{\dagger} \frac{\partial^2 \Gamma}{\partial z^2}(e^{i\theta}, f^*(e^{i\theta})) h(e^{i\theta}) \right\} \\ &\quad + \sup_{\theta} \frac{1}{t^2} R_2(e^{i\theta}, th(e^{i\theta})) \end{aligned}$$

Let $t \rightarrow 0$ in (2.15) and use (2.4) to obtain (III).

For sufficiency, assume (I)–(III) and that $f^* \in E$ is not a directional optimizer; i.e., there exists $h \in H_N^{\infty}$ and $t_0 > 0$ such that

$$\sup_{\theta} \Gamma(e^{i\theta}, f^*(e^{i\theta}) + th(e^{i\theta})) < \gamma^* \quad \forall t \in (0, t_0).$$

We first analyze the case where $h \notin N(a)$.

LEMMA 2.9. *If $h \notin N(a)$, then $\sup_{\theta} \operatorname{Re} a(e^{i\theta})^{\dagger} h(e^{i\theta}) > 0$.*

Proof. If $\sup_{\theta} \operatorname{Re} a(e^{i\theta})^{\dagger} h(e^{i\theta}) \leq 0$, then, since (II) holds, for some $\lambda > 0$ and $F \in H_N^1$, $a = \lambda \chi F$. Therefore

$$(2.16) \quad \sup_{\theta} \operatorname{Re} \chi(e^{i\theta}) F(e^{i\theta})^{\dagger} h(e^{i\theta}) \leq 0,$$

and Corollary 4.8 in [G] implies that $\chi F^{\dagger} h$ is either an outer function or the function zero. Since $\chi F^{\dagger} h$ has nontrivial inner part, we must have that $F^{\dagger} h = 0$, i.e., $h \in N(a)$. \square

Set

$$(2.17) \quad s \triangleq \sup_{\theta} \operatorname{Re} a^{\dagger} h$$

and pick $t_0 > 0$ small enough so that the function R_1 in (2.12) satisfies

$$(2.18) \quad \sup_{\theta} \|R_1(e^{i\theta}, th(e^{i\theta}))\| < \frac{s}{2} t \quad \forall t \in (0, t_0).$$

Then, an order 1 expansion of $\Gamma(e^{i\theta}, z)$ about $z = f^*(e^{i\theta})$ and (2.18) imply that

$$(2.19) \quad \sup_{\theta} \Gamma(e^{i\theta}, f^*(e^{i\theta}) + th(e^{i\theta})) \geq \gamma^* + st - \frac{s}{2} t > \gamma^* \quad \forall t \in (0, t_0).$$

Hence $h \in N(a)$ implies that h is not a descent direction. If how $h \in N(a)$, then strict inequality in (III) for the function h , an order 2 expansion of $\Gamma(e^{i\theta}, z)$ about $z = f^*(e^{i\theta})$, and hypothesis (2), imply that, for some $t_1 > 0$,

$$\sup_{\theta} \Gamma(e^{i\theta}, f^*(e^{i\theta}) + th(e^{i\theta})) > \gamma^* \quad \forall t \in (0, t_1).$$

This proves sufficiency.

THEOREM 2.8'. *In addition to the hypotheses to Theorem 2.8, suppose that Γ is real symmetric, i.e., (2.1) holds, and that $f^* \in RH_N^{\infty}$. Modify condition (II) by requiring that $F \in RH_N^1$, and modify condition (III) so that $h \in N(\partial\Gamma/\partial z(\cdot, f^*(\cdot))) \cap RE$. Then (I)–(III) are necessary for f^* to be a local optimizer to OPT_{RE} .*

Proof of Theorem 2.6. For each $j = 1, \dots, N$, let P_j, Q_j be polynomials containing the zeros poles of a_j in \mathbb{D} , and the double zeros and double poles of P_j and Q_j on \mathbb{T} . Let P be the greatest common divisor of all the P_j 's and let Q be the least common multiple of the Q_j 's. Then we have that

$$(2.20) \quad a = \frac{P}{Q} b,$$

where b extends analytically to a neighborhood of \mathbb{D}^- and has no zeros in \mathbb{D}^- .

Now use the formula

$$(e^{i\theta} - z_0)(1 - \bar{z}_0 e^{i\theta}) = e^{i\theta} |e^{i\theta} - z_0|^2 \quad \text{if } z_0 \in \mathbb{D}$$

and

$$(e^{i\theta} - z_0)^2 = -e^{i\theta} |e^{i\theta} - z_0|^2 \quad \text{if } z_0 \in \mathbb{T}$$

to obtain a measurable function $\lambda : \mathbb{T} \rightarrow \mathbb{R}^+$ such that

$$(2.21) \quad \frac{P}{Q} = \lambda \chi^{w(P)-w(Q)} R,$$

where R is a rational function with no zeros on poles on the closed unit disk \mathbb{D}^- . Note that $w(P) = z(a)$, $w(Q) = p(a)$. Hence (2.20) and (2.21) imply that

$$(2.22) \quad w(P) - w(Q) \leq w(a).$$

Equality in (2.22) follows from representation (2.3) in Theorem 2.5.

To prove (2), let $h \in A_1$ be defined by $h = e^{-u^*+ui}$, where u is a C^1 -function such that

$$(2.23) \quad a_{j_0} = \chi^{\omega(a_{j_0})} e^{v+ui}$$

and u^* is the harmonic conjugate of u . Since $u \in C^1$, we have $h \in A_1$. Moreover, the extension of h to the closed unit disk has no zeros there. From (2.23) and (II), we have that

$$(2.24) \quad \lambda \chi^{\omega(a)} F_{j_0} = \chi^{\omega(a_{j_0})} h e^{v+u^*},$$

and, since $1/h \in A_1$, we conclude that $F_{j_0}/h \in H_1^1$. Now $\omega(a_{j_0}) < \omega(a)$ is impossible, since otherwise the function $\chi^{\omega(a)-\omega(a_{j_0})} F_{j_0}/h$ is in H_1^1 , but (2.23) says that this function is positive almost everywhere on \mathbb{T} .

Finally, if $\omega(a_{j_0}) = 1$, then $\omega(a) = 1$, and from (II) we have that $F_{j_0}^{-1} \in A_1$ and

$$\frac{a_j}{a_{j_0}} = \frac{\lambda \chi F_j}{\lambda \chi F_{j_0}} = F_j / F_{j_0},$$

i.e., $a_j/a_{j_0} \in A_1$. \square

The following result establishes smoothness of λ and F of (II) in Theorem 2.2, given a smooth $(\partial\Gamma/\partial z)(\cdot, f^*(\cdot))$.

PROPOSITION 2.10. *Assume the hypotheses of Theorem 2.2. If $\partial\Gamma/\partial z(\cdot, f^*(\cdot)) \in C^\infty$, then the function λ, F in (II) are, respectively, in C_1^∞ and C_N^∞ . Moreover, the function λ is never zero on \mathbb{T} if $\omega(a) = 1$.*

Proof. By the proof of Theorem 2.8, the function $h = 0$ is the best H_N^∞ -approximation to the continuous function $(1/\|a(\cdot)\|_{\mathbb{C}^N}) \cdot \bar{a}(\cdot)$; therefore $F_1 = \chi F$ is a singular vector for the Hankel operator of symbol $\bar{a}/\|a\|_{\mathbb{C}^N}$. By [HS], F is in $C_N^\infty(\mathbb{T})$. Moreover, the same proof shows that $a/\|a\| = F/\|F\|_{\mathbb{C}^N}$; i.e., the function $f_1\|F_1\|$ is in $C_N^\infty(\mathbb{T})$. Hence $\|F\|$ is also in C_1^∞ , and this implies that the zeros of F on \mathbb{T} , if any, have even order. Now each double zero of F on \mathbb{T} contributes 1 to $\omega(a)$, as we can see from

$$\frac{(e^{i\theta} - e^{i\theta_0})^2}{|e^{i\theta} - e^{i\theta_0}|^2} = -e^{i\theta}.$$

On the other hand, if $w(a) = 1$, then $w(F) = 0$, so that $\|F\|$ is in C_i^∞ . \square

Clearly, one requirement to simplify (III) is to know something about the structure of $N(\partial\Gamma/\partial z(\cdot, f^*(\cdot)))$. Our next lemma gives a parameterization of this set.

LEMMA 2.11. *Let $a \in C_N^1(\mathbb{T})$, $F \in H_N^1 \cap C_N^1(\mathbb{T})$ such that $a(e^{i\theta}) \neq 0$ for every θ and*

$$\frac{1}{\|a(e^{i\theta})\|_N} \cdot a(e^{i\theta}) = \frac{1}{\|F(e^{i\theta})\|} \cdot F(e^{i\theta}).$$

Then there exist functions $\{k_j\}_{j=1}^{N-1}$ in A_N such that

$$(2.25) \quad N(a) \cap A_N = A_1 k_1 + \cdots + A_1 k_{N-1}.$$

Also, for almost all $e^{i\theta} \in \mathbb{T}$, the set

$$\{k_1(e^{i\theta}), \dots, k_{N-1}(e^{i\theta})\}$$

spans in \mathbb{C}^N a linear subspace of (complex) dimension $N - 1$.

Proof. The first step is to find a matrix-valued function M in $H_{N \times L}^\infty$, $L \geq 1$, with C^1 entries whose boundary values $M(e^{i\theta})$ are rank $N - 1$ matrices and which satisfies $F^\dagger M = 0$. One such matrix M is

$$M = [M_1, M_2, \dots, M_N]$$

where

$$M_j = \begin{pmatrix} -F_1 & -F_2 & \cdots & -\hat{F}_j & \cdots & -F_N \\ F_j & 0 & \cdots & & & 0 \\ 0 & F_j & & \ddots & & \\ & 0 & & & & 0 \\ 0 & 0 & & 0 & & F_j \end{pmatrix}, \quad j = 1, \dots, N$$

and “ $\hat{}$ ” indicates that the corresponding column is suppressed. Clearly, the rank of M is at least $N - 1$, almost everywhere on \mathbb{T} since, for almost all $e^{i\theta} \in \mathbb{T}$, one of the F_j ’s is nonzero at $e^{i\theta}$. That the rank is not N follows from the fact that F is in the null space of M^\dagger . To remedy this, we take the inner-outer factorization $M^\dagger = \Theta Q$ of M with $\Theta \in H_{L \times N-1}^\infty$ and $Q \in H_{N-1 \times N}^\infty$ (cf. [RR1], [RR2], [Go]). Q is continuous because M is once differentiable. Now $\text{Range } Q(e^{i\theta}) = \text{Range } M(e^{i\theta})$, since $\Theta(e^{i\theta})$ is unitary, so $F^\dagger Q^\dagger = 0$, and this shows that $Q^\dagger A_{N-1} \subset N(a)$. Also, $\dim \text{Range } Q(e^{i\theta}) = N - 1$ for all θ , so, if $f \in N(a)$, then the function $h = (QQ^\dagger)^{-1}Qf$ is in A_{N-1} , and it satisfies $f = Q^\dagger h$. Therefore $N(a) \cap A_N = Q^\dagger A_{N-1}$. \square

Before proving Theorem 2.7, we restate (III) of Theorem 2.2.

LEMMA 2.12. Let Γ be of class C^2 and let $f^* \in A$ be a directional optimizer, such that an analytic direction F for χ^{-1} satisfies $F \in C^1$. Then (III) is equivalent to

$$(2.26) \quad \sup_{\theta} \{ \bar{f}^\dagger \tilde{A} f + \operatorname{Re} f^\dagger \tilde{B} f \} \geq 0 \quad \forall f \in A_{N-1}.$$

Here

$$\begin{aligned} \tilde{A} &\triangleq \left(\bar{k}_i^\dagger \frac{\partial^2 \Gamma}{\partial \bar{z} \partial z}(\cdot, f^*) k_j \right)_{i,j=1}^{N-1}, \\ \tilde{B} &\triangleq \left(k_i^\dagger \frac{\partial^2 \Gamma}{\partial z^2}(\cdot, f^*) k_j \right)_{i,j=1}^{N-1}, \end{aligned}$$

and $\{k_i\}_{i=1}^{N-1}$ are functions in A_N parameterizing $N(a) \cap A_N$ as in Lemma 2.11.

Proof. By Lemma 2.11, every $h \in N(a)$ has the form $h = \sum_{l=1}^{N-1} f_l k_l$ for some scalar valued functions $\{f_l\}_{l=1}^{N-1}$ in A_1 . Hence, for every θ , we have

$$\begin{aligned} & \overline{\left(\sum_{l=1}^{N-1} f_l(e^{i\theta}) k_l(e^{i\theta}) \right)}^\dagger A(e^{i\theta}) \left(\sum_{j=1}^{N-1} f_j(e^{i\theta}) k_j(e^{i\theta}) \right) \\ & + \operatorname{Re} \left\{ \left(\sum_{l=1}^{N-1} f_l(e^{i\theta}) k_l(e^{i\theta}) \right)^\dagger B(e^{i\theta}) \left(\sum_{j=1}^{N-1} f_j(e^{i\theta}) k_j(e^{i\theta}) \right)^\dagger \right\} \\ & = \sum_{l,j=1}^{N-1} \overline{f_l(e^{i\theta})} f_j(e^{i\theta}) \overline{k_l(e^{i\theta})}^\dagger A(e^{i\theta}) k_j(e^{i\theta}) + \operatorname{Re} \sum_{l,j=1}^{N-1} f_l(e^{i\theta}) f_j(e^{i\theta}) k_l(e^{i\theta})^\dagger B(e^{i\theta}) k_j(e^{i\theta}) \\ & = \overline{f(e^{i\theta})}^\dagger \tilde{A}(e^{i\theta}) f(e^{i\theta}) + \operatorname{Re} f(e^{i\theta})^\dagger \tilde{B}(e^{i\theta}) f(e^{i\theta}), \end{aligned}$$

and now the equivalence of (III) and (2.26) is clear. \square

Proof of Theorem 2.7. First, we claim that, if $F \triangleq (-f_2, f_1)^\dagger$, where $F_0 = (f_1, f_2)^\dagger$ is the analytic direction of $\chi^{-\omega(a)}a$, then

$$N(a) = \{\varphi F : \varphi \in H_1^\infty\}.$$

One inclusion is clear. The other inclusion we prove as follows: Since F is nonzero on \mathbb{D}^- by hypothesis, the Corona theorem asserts the existence of functions g_1, g_2 in H_1^∞ such that

$$(2.27) \quad f_1 g_1 + f_2 g_2 = 1,$$

where $F_0^\dagger = (f_1, f_2)$. Now pick $h \in N(a)$, so that

$$(2.28) \quad f_1 h_1 + f_2 h_2 = 0$$

and use (2.27) to obtain

$$h_1 = f_2 g_2 - g_1 f_2 h_2;$$

i.e., we have that, for $\varphi \triangleq g_1 h_2 - g_2 h_1$,

$$(2.29) \quad h_1 = -f_2 \varphi.$$

By substituting (2.29) into (2.28), we have $h_2 = f_1\varphi$. This proves the claim. Note that $b = \chi^{-\omega(a)}F$.

Now from the definition of b and from (2.1), we have

$$(2.30) \quad \begin{aligned} \tilde{A} &= \frac{1}{\lambda^2} \bar{b}^\dagger Ab, \\ \tilde{B} &= \frac{1}{\lambda^2 \chi^{2w(a)}} \cdot b^\dagger Bb \end{aligned}$$

and we can rewrite inequality (2.26) as

$$(2.31) \quad \sup_{\theta} \left\{ bAb^* |f|^2 + \operatorname{Re} \frac{f^2 bBb^t}{\chi^{2w(a)}} \right\} \geq 0.$$

Then the sufficiency of (i) and part (a) of (ii) of Theorem 2.7 is clear. Suppose that bBb^t is never zero and that $\omega(bBb^t)$ is odd, and pick $f \in A$ arbitrary. If f has a zero on \mathbb{T} , then (2.31) follows, while, if it does not have a zero, the winding number of $f^2 bBb^t / \chi^{2w(a)}$ about zero is a well-defined odd number. In this case, $\operatorname{Re} f^2 bBb^t / \chi^{2w(a)}$ is positive for some $e^{i\theta} \in \mathbb{T}$, and this shows that part (b) of (ii) of Theorem 2.7 is sufficient.

To prove necessity, assume that neither one of (i) and (ii) of Theorem 2.7 hold, i.e.,

$$(2.32) \quad b(e^{i\theta})A(e^{i\theta})b^*(e^{i\theta}) < |b(e^{i\theta})B(e^{i\theta})b^t(e^{i\theta})| \quad \forall e^{i\theta} \in \mathbb{T}$$

and that $w(bBb^t)$ is even and no greater than $2w(a)$. Then there exists $g_0 \in A_1$ with no zeros on \mathbb{T} so that

$$\frac{-\overline{(bBb^t)}}{|bBb^t|} \chi^{2w(a)} = \frac{g_0^2}{|g_0|^2}.$$

Hence

$$(2.33) \quad (bAb^*)|g_0|^2 + \operatorname{Re} \left\{ \frac{g_0^2(bBb^t)}{\chi^{2w(a)}} \right\} = (bAb^*)|g_0|^2 - |bBb^t| |g_0|^2,$$

and combining (2.32) and (2.33), we see that (III) fails. \square

2.2. A sufficient condition for true optima. The previous section treated local *directional* optima. Here we find conditions sufficient to guarantee that f^* is a local optimizer for OPT.

The question to be answered is whether (I)–(III) with strict inequality are enough to force f^* to be an optimizer (see Definition 1.1).

A strict local optimizer f^* has the property that sequences $\{f^k\}$ in A_N converging to f^* satisfy

$$(2.34) \quad \sup_{\theta} \Gamma(\cdot, f^k) > \sup_{\theta} \Gamma(\cdot, f^*) \quad \text{for } k \text{ large enough.}$$

This does not necessarily have to happen if f^* is merely a strict local directional optimizer, or if (almost equivalently) the hypotheses of Theorem 2.11 hold. In Theorem 2.13, we replace (III) by a stronger condition, which is sufficient to guarantee (2.34).

THEOREM 2.13. *Let Γ and f^* be as in the hypothesis of Theorem 2.2. For f^* to be a strict local optimizer, it is sufficient that, in addition to (I) and (II), the following condition holds:*

$$(2.35) \quad \text{For each } \theta \in [0, 2\pi) \text{ and every nonzero } z = (z_1, \dots, z_N) \in \mathbb{C}^N \text{ such that } a(e^{i\theta})^\dagger z = 0, \text{ the Hessian } H_\theta \text{ of } \Gamma(e^{i\theta}, \cdot) \text{ at } f^*(e^{i\theta}) \text{ satisfies } H_\theta[z, z] > 0.$$

Proof. Suppose that $f^* \in A_N$ satisfies (I), (II), and (2.35) and let $\{f^k\}$ be a sequence in $A_N \setminus \{0\}$ such that $h^k \triangleq f^k - f^* \rightarrow 0$ as $k \rightarrow \infty$; we see that (2.34) holds.

If $\{h^k\}$ is a subsequence such that $h^{k_j} \in N(a)$ for all j , then the Taylor expansion of $\Gamma(e^{i\theta}, \cdot)$ about $f^*(e^{i\theta})$ gives

$$(2.36) \quad \Gamma(e^{i\theta}, f^*(e^{i\theta}) + h^{k_j}(e^{i\theta})) = S^* + H_0[h^{k_j}(e^{i\theta}), h^{k_j}(e^{i\theta})] + E_2(e^{i\theta}, h^{k_j}(e^{i\theta})),$$

where $\sup_\theta |E_2(e^{i\theta}, h^{k_j}(e^{i\theta}))| \rightarrow 0$ as $j \rightarrow \infty$. Note that by (2.35), for each θ , there exists $\varepsilon(\theta) > 0$ such that $H_\theta[z, z] > \varepsilon(\theta)\|z\|_N^2$, if $a(e^{i\theta})z = 0$. If $\varepsilon \triangleq \inf_\theta \varepsilon(\theta)$, then $\varepsilon > 0$ by continuity of H_θ in θ . Hence the inequality

$$(2.37) \quad \Gamma(e^{i\theta}, f^*(e^{i\theta}) + h^k(e^{i\theta})) > s^* + \varepsilon\|h^k(e^{i\theta})\|_N^2 + E_2(e^{i\theta}, h^k(e^{i\theta}))$$

implies that $s^{k_j} > s^*$ for j large enough.

Now we can assume, without loss of generality, that, for every k , we have $h^k \notin N(a)$. By Lemma 2.14, which follows, for each θ there exists $\delta(e^{i\theta}) \in \mathbb{R}$ such that, for all $z \in \mathbb{C}^N$ with $a(e^{i\theta})z^\dagger \neq 0$,

$$(2.38) \quad H_\theta[z, z] > \delta(e^{i\theta})|a(e^{i\theta})^\dagger z|^2.$$

Note that negative $\delta(e^{i\theta})$'s are not excluded.

Pick δ_0 such that, for all θ , $\delta(e^{i\theta}) > \delta_0$. This is always possible if the numbers $\delta(e^{i\theta})$ are chosen in an optimal way, by continuity of H_θ in θ . Then, for each θ and all $z \neq 0$, $H_\theta[z, z] + |\delta_0||a(e^{i\theta})^\dagger z|^2$ is positive and, furthermore, is continuous in θ . Hence there exists $\varepsilon_0 > 0$ such that

$$(2.39) \quad H_\theta[z, z] + |\delta_0||a(e^{i\theta})^\dagger \cdot z|^2 > \varepsilon\|z\|^2 \quad \forall e^{i\theta} \in \mathbb{T}, z \in \mathbb{C}^N.$$

By Lemma 2.9, there exist elements $\theta_k, k \in \mathbb{N}$ such that

$$(2.40) \quad \operatorname{Re} a(e^{i\theta_k})^\dagger h^k(e^{i\theta_k}) = a(e^{i\theta_k})^\dagger h^k(e^{i\theta_k}) > 0.$$

Since $\|h^k\|_\infty \rightarrow 0$ as $k \rightarrow \infty$, there exists $k_1 \in \mathbb{N}$ such that

$$(2.41) \quad 2 > |\delta_0|a(e^{i\theta_k})^\dagger h^k(e^{i\theta_k}), \quad k \geq k_0.$$

Now consider for each k the Taylor expansion

$$(2.42) \quad \begin{aligned} \Gamma(e^{i\theta_k}, f^k(e^{i\theta_k})) &= \Gamma(e^{i\theta_k}, f^*(e^{i\theta_k})) + 2 \operatorname{Re} a(e^{i\theta_k})^\dagger h^k(e^{i\theta_k}) \\ &\quad + H_\theta[h^k(e^{i\theta_k}), h^k(e^{i\theta_k})] + E_2(e^{i\theta_k}, h^k(e^{i\theta_k})), \end{aligned}$$

where $\sup_\theta |E_2(e^{i\theta_k}, h^k(e^{i\theta_k}))|/\|h^k(e^{i\theta_k})\|_{\mathbb{C}^N}^2 \rightarrow 0$ as $k \rightarrow \infty$. Thus, from (2.39)–(2.41), we obtain

$$(2.43) \quad \begin{aligned} \Gamma(e^{i\theta_k}, f^k(e^{i\theta_k})) - s^* &\geq 2a(e^{i\theta_k})h^k(e^{i\theta_k}) + \varepsilon\|h^k(e^{i\theta_k})\|_N^2 \\ &\quad - |\delta_0| |a(e^{i\theta_k})h^k(e^{i\theta_k})|^2 + E_2(e^{i\theta_k}, h^k(e^{i\theta_k})) \\ &\geq \varepsilon\|h^k(e^{i\theta_k})\|_N^2 + E_2(e^{i\theta_k}, h^k(e^{i\theta_k})), \end{aligned}$$

and the conclusion of the theorem follows by taking k large enough in (2.43). \square

LEMMA 2.14. Let $b \in \mathbb{C}^N \setminus \{0\}$ and $Q[\cdot, \cdot]$ be a real-valued form on \mathbb{C}^1 that is real linear in each coordinate separately. If $Q[z, z] > 0$ for every $z \in \mathbb{C}^N A, z \neq 0$ such that $b^\dagger z = 0$, then there exists a real constant δ_0 such that

$$(2.44) \quad Q[z, z] > \delta_0 |b^\dagger z|^2 \quad \forall z \in \{z \in \mathbb{C}^N : b^\dagger z \neq 0\}.$$

The proof of Lemma 2.11 simply explains the fact that general real-valued quadratic form on \mathbb{C}^N satisfies an equality

$$Q[z, z] = \bar{z}^\dagger A z + \operatorname{Re}(z^\dagger B z) \quad \forall z \in \mathbb{C}^N,$$

where A is an $N \times N$ selfadjoint matrix and B is an $N \times N$ complex symmetric.

Proof of Lemma 2.14. Make a change of coordinates to assume without loss of generality that $b^\dagger = (b_1, 0, \dots, 0)$, so that, for any $z \in \mathbb{C}^N, z^\dagger \cdot b = 0$ if and only if $z^\dagger = (z_1, z_2, \dots, z_N)$ with $z_1 = 0$. By hypothesis, there exists $\delta > 0$ such that

$$(2.45) \quad Q[0, z_2, \dots, z_N], (0, z_2, \dots, z_N)] > 3\delta^2(|z_2|^2 + \dots + |z_N|^2)$$

with equality only if $z_i = 0$ for all i . From (2.45), we obtain that

$$(2.46) \quad Q[0, z_2, \dots, z_N], (0, z_2, \dots, z_N)] > 2 \sum_{i=2}^N \delta_i^2 |z_i|^2 + \operatorname{Re} \left(\sum_{i=2}^N \delta_i^2 z_i^2 \right).$$

If

$$(2.47) \quad Q[z, z] = \sum_{i=1}^N A_{ii} |z_i|^2 + \sum_{1 \leq i < j \leq N} \operatorname{Re} A_{ij} z_i \bar{z}_j + \sum_{1 \leq i \leq j \leq N} \operatorname{Re} B_{ij} z_i z_j,$$

where $a_{ii} > 0, A_{ij} = \overline{a_{ji}}$. Then by (2.46) we have

$$(2.48) \quad \begin{aligned} Q[z, z] &\geq A_{11} |z_1|^2 + \sum_{2 \leq j \leq N} \operatorname{Re} A_{1j} z_1 \bar{z}_j + \sum_{2 \leq j \leq N} \operatorname{Re} (B_{1j} z_1 z_j) \\ &\quad + 2 \sum_{j=2}^N \delta_j^2 |z_j|^2 + \operatorname{Re} \left(\sum_{j=2}^N \delta_j^2 z_j^2 \right) \\ &= A_{11} |z_1|^2 + \operatorname{Re} B_{11} z_1^2 + \sum_{j=2}^N S_j, \end{aligned}$$

where by definition

$$(2.49) \quad S_j \triangleq \operatorname{Re} A_{1j} z_1 \bar{z}_j + 2\delta_j^2 |z_j|^2 + \operatorname{Re} (B_{1j} z_1 z_j + \delta_j^2 z_j^2).$$

Hence, for each $j, 2 \leq j \leq N$, we have that

$$\begin{aligned} S_j &= \operatorname{Re} (A_{1j} - B_{1j}) z_1 \bar{z}_j + \delta_j^2 |z_j|^2 + \left| \frac{B_{1j} z_1}{2\delta} + \delta z_j \right|^2 \\ &\quad + \operatorname{Re} \left(\frac{B_{1j} z_1}{2\delta} + \delta z_j \right)^2 - \left| \frac{B_{1j}}{2\delta} \right|^2 |z_1|^2 - \operatorname{Re} \left(\frac{B_{1j}}{2\delta} \right)^2 z_1^2 \\ &= \left(- \left| \frac{B_{1j}}{2\delta} \right|^2 - \left| \frac{a_{1j} - B_{1j}}{2\delta} \right|^2 \right) |z_1|^2 - \operatorname{Re} \left(\frac{B_{1j}}{2\delta} \right)^2 z_1^2 + \left| \frac{A_{1j} - b_{1j}}{2\delta} z_1 + \delta z_j \right|^2 \\ &\quad + \left| \frac{B_{1j} z_1}{2\delta} + \delta z_j \right|^2 + \operatorname{Re} \left(\frac{B_{1j} z_1}{2\delta} + \delta z_j \right)^2, \end{aligned}$$

and we obtain the inequality

$$(2.50) \quad S_j \geq \left(-2 \left| \frac{B_{1j}}{2\delta} \right|^2 - \left| \frac{A_{1j} - B_{1j}}{2\delta} \right|^2 \right) |z_1|^2, \quad 2 \leq j \leq N.$$

Finally, (2.48) and (2.50) imply that

$$Q[z, z] \geq \left(a_{11} + |B_{11}| + \sum_{j=2}^N \left(-2 \left| \frac{B_{1j}}{2\delta} \right|^2 - \left| \frac{A_{1j} - B_{1j}}{2\delta} \right|^2 \right) \right) |z_1|^2. \quad \square$$

We close §2 with an example.

Example 2. Our objective is to make use of Theorem 2.7 and show that $f^* = (0, 0)$ is a strict local optimizer for the functions Γ_ε defined in Example 1, when $\varepsilon > 19$. It was shown in Example 1 that (I) and (II) hold for all $\varepsilon > 0$, and now let us fix θ . The Hessian of $\Gamma(e^{i\theta}, \cdot)$ at $f^*(e^{i\theta})$ and direction z is

$$(2.51) \quad \begin{aligned} H_\theta[z, z] = & 2(|e^{i\theta} + 0.1|^2 + 0.01 + \varepsilon)|z_1|^2 + 4(0.2 \cos \theta + 0.2) \operatorname{Re} z_1 \bar{z}_2 \\ & + 2(|e^{i\theta} + 0.1|^2 + 0.01 + \varepsilon)|z_2|^2 + 80 \operatorname{Re} z_1 z_2. \end{aligned}$$

The equation $a(e^{i\theta})^\dagger z = 0$ implies that, for some $z_1 \in \mathbb{C}$,

$$(2.52) \quad z = (z_1, -z_1).$$

Combine (2.51) and (2.52) to obtain

$$H_\theta[z, z] = 4(1 + \varepsilon)|z_1|^2 + 80 \operatorname{Re} z_1^2.$$

Since we assume $\varepsilon > 19$, it follows that $H_\theta[z, z] > 0$, for all $z \in \mathbb{C}^N$ such that $a(e^{i\theta})^\dagger z = 0$; i.e., (2.35) holds.

3. Nonuniqueness of solutions. One of the main open questions in the study of OPT is that of uniqueness of solutions for $N > 1$. In the case where $N = 1$, it is known.³

THEOREM 3.1 (see [HM]). *Let Γ be the class C^1 and let $\gamma^* > 0$ be a local optimum for OPT (3), such that the gradient $\partial\Gamma/\partial z(e^{i\theta}, z)$ never vanishes when $\Gamma(e^{i\theta}, z) = s^*$, the sets $S_\theta(s^*)$ are uniformly bounded in θ and, for all θ , diffeomorphic to the unit disk in C^1 . If a solution $f^* \in A_1$ to OPT for Γ exists, then it is unique (in A_1).*

For $N > 1$, it is known that there are functions Γ whose sets $S_\theta(s^*)$ are convex (but not strictly convex) where solutions to OPT are not unique. For example, $\Gamma(e^{i\theta}, z) = \max(|e^{i\theta} - z_1|, |z_2|)$ produces an OPT problem for which any

$$f_1(e^{i\theta}) = 0 \quad \text{and} \quad f_2 \in A_1, \quad |f_2(e^{i\theta})| \leq 1, \quad \forall e^{i\theta} \in \mathbb{T}$$

is a solution. This Γ is not smooth; however, smoothing it slightly still produces the same qualitative behavior in OPT.

THEOREM 3.2 (see [HH]). *If $N \geq 1$, Γ of class C^1 in z and both $\Gamma, \partial\Gamma/\partial z$ continuous in θ , and the sets $S_\theta(s^*)$ are strictly convex (uniformly in θ) and nondegenerate, then an H_N^∞ solution f^* to OPT for Γ exists and is unique.*

Since uniqueness is very desirable for computational success, it is worth considerable effort to find simple conditions on Γ that a priori guarantee uniqueness for OPT. One

³ The original version of Theorem 3.1 has stronger hypotheses. However, examination of its proof yields the formulation we give here.

appealing possibility that is consistent with all the evidence listed is that smooth Γ that are strictly plurisubharmonic⁴ in z yield a uniqueness for OPT. This is appealing because most Γ produced in engineering are at least approximable by such functions. Unfortunately, this pleasant prospect is not to be. This section is devoted to presenting a very well-behaved Γ when $N = 2$ for which OPT has two solutions.

Example 1. Our examples lie in a one parameter ($\varepsilon \geq 0$) family Γ_ε of objective functions defined in Example 1 of §2.

We prove the following proposition.

PROPOSITION 3.3. *The functions Γ_ε for $\varepsilon > 0$ are strictly plurisubharmonic for all $e^{i\theta} \in \mathbb{T}$ and*

(a) *For each ε , $0 < \varepsilon < 19$, the problem OPT has a strict local optimum s_ε^* at each of the constant functions*

$$f_\varepsilon^1 = (c_\varepsilon, -c_\varepsilon), \quad f_\varepsilon^2 = (-c_\varepsilon, c_\varepsilon),$$

where $c_\varepsilon = 5\sqrt{2(19 - \varepsilon)}$;

(b) *The functions $f_\varepsilon^1, f_\varepsilon^2$ belong to the same connected component of $S_\theta(s_\varepsilon^*)$ for all $\varepsilon < 19$ that are sufficiently close to 19.*

Proof. For all $\varepsilon > 0$ and each $(e^{i\theta}, z) \in \mathbb{T} \times \mathbb{C}^N$, the matrix

$$\begin{aligned} & \left(\left(\frac{\partial^2 \Gamma_\varepsilon(e^{i\theta}, z_1, z_2)}{\partial \bar{z}_i \partial z_j} \right) \frac{\partial^2 \Gamma}{\partial z} \right) \\ &= \begin{pmatrix} |e^{i\theta} + 0.1 + 0.1z_2|^2 + |0.1z_2 + 0.1|^2 + \varepsilon & (0.1\bar{z}_1 + 0.1)(e^{i\theta} + 0.1 + 0.1z_2) \\ (0.1\bar{z}_2 + 0.1)(e^{i\theta} + 0.1 + 0.1z_1) & + (e^{-i\theta} + 0.1\bar{z}_1 + 0.1)(0.1 + 0.1z_2) \\ + (e^{-i\theta} + 0.1\bar{z}^2 + 0.1)(0.1 + 0.1z_1) & |e^{i\theta} + 0.1 + 0.1z_2|^2 + |0.1z_2 + 0.1|^2 + \varepsilon \end{pmatrix} \end{aligned}$$

is strictly positive definite, which shows that $\Gamma(e^{i\theta}, \cdot)$ is strictly plurisubharmonic.

(a) We have that, for every θ ,

$$\begin{aligned} (3.1) \quad \Gamma_\varepsilon(e^{i\theta}, f_\varepsilon^1(e^{i\theta})) &= |100 - 0.1c_\varepsilon^2 + e^{i\theta}c_\varepsilon|^2 + |100 - 0.1c_\varepsilon^2 - e^{i\theta}c_\varepsilon|^2 + 2\varepsilon c_\varepsilon^2 \\ &= 2(100 - 0.1c_\varepsilon^2)^2 + 2c_\varepsilon^2(\varepsilon + 1). \end{aligned}$$

Hence (I) holds for f_ε^1 . We also have that, for all θ ,

$$\begin{aligned} (3.2) \quad \frac{\partial \Gamma_\varepsilon}{\partial z_1}(e^{i\theta}, f_\varepsilon^1(e^{i\theta})) &= (1 + \varepsilon)(5e^{i\theta} + 1), \\ \frac{\partial \Gamma_\varepsilon}{\partial z_2}(e^{i\theta}, f_\varepsilon^1(e^{i\theta})) &= (1 + \varepsilon)(5e^{i\theta} + 1). \end{aligned}$$

As it was done in Example 1, we find an analytic function $g \in A_1$ and a continuous $\lambda > 0$ such that

$$(3.3) \quad (1 + \varepsilon)(5e^{i\theta} + 1) = \lambda(e^{i\theta})\chi(e^{i\theta}) \cdot g(e^{i\theta}) \quad \forall e^{i\theta} \in \mathbb{T};$$

i.e., (II) holds for all $\varepsilon > 0$. To check (III), note first that, if $a_\varepsilon \triangleq (\partial \Gamma / \partial z)(\cdot, f_\varepsilon^1)$, then

$$A_2 \cap N(a_\varepsilon) = \{(h_1, h_2) \in A_2 : h_1 = -h_2\}$$

⁴ The function Γ is strictly plurisubharmonic in z means that

$$\bar{w}^\dagger \frac{\partial^2 \Gamma}{\partial \bar{z} \partial z}(e^{i\theta}, z)w > 0 \quad \forall w \in \mathbb{C}^N \setminus \{0\} \text{ such that } \frac{\partial \Gamma}{\partial z}(e^{i\theta}, z)^\dagger w = 0.$$

and that the Hessian of Γ_ε in z at f_ε^1 satisfies

$$\begin{aligned} H_\theta^\varepsilon[(z_1, z_2), (z_1, z_2)] &= 2(|e^{i\theta} + 0.1 - 0.1c_\varepsilon|^2 + |0.1 - 0.1c_\varepsilon|^2 + \varepsilon)|z_1|^2 \\ &\quad + 4 \operatorname{Re}((0.1c_\varepsilon + 0.1)(e^{i\theta} + 0.1 - 0.1c_\varepsilon) \\ &\quad + (e^{-i\theta} + 0.1 - 0.1c_\varepsilon))z_1\bar{z}_2 \\ &\quad + 2(|e^{i\theta} + 0.1 + 0.1c_\varepsilon|^2 + |0.1 + 0.1c_\varepsilon|^2 + \varepsilon)|z_2|^2 \\ &\quad + 4(\varepsilon + 1) \operatorname{Re} z_1 z_2. \end{aligned}$$

Hence, for $z_2 = -z_1$, we obtain, after some algebra,

$$H_\theta^\varepsilon[(z_1, -z_1), (z_1, -z_1)] = 4(19 - \varepsilon)|z_1|^2 + 4(\varepsilon + 1)(|z_1|^2 - \operatorname{Re} z_1^2),$$

so it is clear that (III) holds. Moreover, Theorem 2.2 applies, and OPT has a strict local solution at f_ε^1 for $\varepsilon < 19$. Note that, by symmetry, the same can be said of f_ε^2 .

(b) We have from (2.11) that

$$\left(\frac{\partial \Gamma_{\varepsilon_0}}{\partial z_1}(e^{i\theta}, 0), \frac{\partial \Gamma_{\varepsilon_0}}{\partial z_2}(e^{i\theta}, 0) \right) \neq 0 \quad \forall e^{i\theta} \in \mathbb{T}, \varepsilon \in [0, 19].$$

Then, by Lemma B1 of Appendix B, there exists in \mathbb{C}^N an open neighborhood V of 0 such that, for all θ and all $\varepsilon \in [0, 19]$, the sets

$$W(\theta, s) = \{z \in V : \Gamma_\varepsilon(e^{i\theta}, z) = s\}$$

are connected.

Now pick $\varepsilon < 19$ so close to 19 that both $f_\varepsilon^1(e^{i\theta})$ and $f_\varepsilon^2(e^{i\theta})$ lie in V for all θ . If we denote with s_ε the optimal value

$$s_\varepsilon = \sup_\theta \Gamma(e^{i\theta}, (c(\varepsilon), -c(\varepsilon))),$$

we have that

$$f_\varepsilon^i(e^{i\theta}) \in W(\theta, s_\varepsilon) \quad \forall e^{i\theta} \in \mathbb{T}, \quad i = 1, 2,$$

and this proves (b). \square

There are various applications of OPT in addition to the engineering ones that we emphasize in this paper. One application is in a branch of several complex variables; computing what is called a Kobayashi extremal for a particular domain \mathcal{D} in \mathbb{C}^n is a special case of OPT. (See [H2].) In particular, the problems produced by “strictly pseudoconvex” \mathcal{D} gives Γ that are strictly plurisubharmonic. Thus a Kobayashi extremal problem for such a \mathcal{D} with nonunique solution also is an example of the type given here. (L. Lempert (in a private communication) found such an example, but it is unpublished.)

4. Coordinate descent approaches to OPT. In standard \mathbb{R}^n optimization of nonlinear functions, it is a natural idea and fairly common in folklore to reduce the original problem to a sequence of one-dimensional problems through the technique of coordinate descent. As we see, the analogue of such a technique is seriously flawed in our setting. The explanation is based upon the difference in (II) of Theorem 2.2 between the cases where $N = 1$ and $N > 1$.

This section presents a simple (practical) test, Theorem 4.1, to determine when the natural coordinate descent algorithm for “solving” OPT stops. Fortunately, this stopping criterion compares directly to Theorem 2.2, which tells us when we are at a true optimum to OPT. As we see, the conditions of Theorem 4.1 are so much weaker than those of Theorem 4.1 that we propose the following conjecture.

CONJECTURE. *For generic Γ , coordinate descent does not obtain the true optimum. In other words, with probability one, coordinate descent gives the wrong answer.*

Now the coordinate descent CD algorithm is presented. Given $\Gamma : \partial\mathbb{D} \times \mathbb{C}^N \rightarrow \mathbb{R}^+$ and $f^0 = (A_1^0, f_2^0, \dots) \in A_N$, an update $f_1 \in A_N$ is obtained in the following way:

$$(CD1) \quad \text{Find } h_1 = h_1^* \in A_1 \text{ that minimizes } \sup_{\theta} \Gamma(\cdot, f_1^0 h_1, f_2^0, \dots, f_N^0);$$

$$(CD2) \quad \text{Find } h_2 = h_2^* \in A_2 \text{ that minimizes } \sup_{\theta} \Gamma(\cdot, f_1^0 + h_1^*, f_2^0 + h_2, f_3^0, \dots, f_N^0);$$

\vdots

$$(CDN) \quad \begin{array}{l} \text{Find } h_N = h_N^* \in A_N \text{ that minimizes} \\ \sup_{\theta} \Gamma(\cdot, f_1^0 + h_1^*, \dots, f_{N-1}^0 + h_{N-1}^*, f_N^0 + h_N). \end{array}$$

Then set $f^1 = f^0 + (h_1^*, \dots, h_N^*)$.

To analyze the CD algorithm, we write the mathematical statement of what it means for the algorithm to stop. We call $(f_1^*, f_2^*, \dots, f_N^*) = f^* \in A_N$ a *coordinate descent solution* to OPT, provided that

$$(CDS) \quad \begin{array}{l} \inf_{f_1} \sup_{\theta} \Gamma(e^{i\theta}, f_1, f_2^*, \dots, f_N^*) = \|\Gamma(\cdot, f^*\|_{\infty}, \\ \inf_{f_2} \sup_{\theta} \Gamma(e^{i\theta}, f_1^*, f_2, f_3^*, \dots, f_N^*) = \|\Gamma(\cdot, \dots, f^*)\|_{\infty}, \end{array}$$

and so forth.

THEOREM 4.1. *If $f^* \in A_N$ is such that $\partial\Gamma/\partial z_j(\cdot, f^*(\cdot))$ never equals zero on \mathbb{T} , for $j = 1, \dots, N$, then f^* is a CDS if and only if*

- (i) $\Gamma(\cdot, f^*(\cdot))$ is constant on \mathbb{T} ,
- (ii) (a) $\omega(\partial\Gamma/\partial z_j(\cdot, f^*(\cdot))) > 0, j = 1, \dots, N$, or, equivalently,
 (b) $\partial\Gamma/\partial z_j(\cdot, f^*(\cdot)) = \lambda_j(\cdot)\chi(\cdot)F_j(\cdot)$, where $\lambda_j : \mathbb{T} \rightarrow \mathbb{R}^+, j = 1, \dots, N$, are measurable functions and $F_j \in H_1^1$, for $j = 1, \dots, N$.

Proof. The proof follows from Theorem 2.1.

The key issue is the following: Does CD give solutions to OPT? To answer this, we compare this to conditions (I) and (II) of Theorem 2.1, which characterizes solutions to OPT. First, note that Theorem 4.1(i) and Theorem 2.2(I) are the same.

Now turn to condition (II). Here there is a big discrepancy. First, note that Theorem 4.1(ii) is exactly (II) of Theorem 2.2 with the (string) added condition that $\lambda_1 = \lambda_2 = \dots = \lambda_N$. Consequently, CD stops without even addressing the key optimality condition II in Theorem 2.2.

To get another perspective, suppose that the a_j have meromorphic continuations to a neighborhood of \mathbb{D} and consider the winding number conditions. Theorem 4.1 says that, inside \mathbb{D} ,

$$(\#\text{zeros} - \#\text{poles})(a_j) > 0, \quad j = 1, \dots, N.$$

Typically (see [M1]), we have

$$(4.1) \quad (\#\text{zeros} - \#\text{poles})(a_j) = 1, \quad j = 1, \dots, N,$$

while, for true optimum,

$$(4.2) \quad (\#\text{common zeros} - \text{total } \#\text{poles}(a_j)) > 0.$$

If we combine (4.2) with (4.3), we obtain that *all* zeros of the a_j are common (see §2).

Further evidence that condition (II) of Theorem 1 and Theorem 2.1 are worlds apart is supplied by simple computer experiments. The first case we tried is reported below.

Example 1. Let

$$\begin{aligned} \Gamma(e^{i\theta}, z_1, z_2) = & \left(\operatorname{re} \left(\frac{1}{e^{i\theta}} - z_1 \right) \right)^2 + 4 \left(\operatorname{im} \left(\frac{1}{e^{i\theta}} - z_1 \right) \right)^2 \\ & + \left(\operatorname{re} \left(\frac{1}{e^{i\theta}} - z_2 \right) \right)^2 + 0.25 \left(\operatorname{im} \left(\frac{1}{e^{i\theta}} - z_2 \right) \right)^2. \end{aligned}$$

Coordinate descent, initialized at $f^0(e^{i\theta}) = (0, 0)$, yields for this function optimal values $s_c^* \cong 2.54423$, attained at $f_c(e^{i\theta}) = (((-10 + \sqrt{73})/6)e^{i\theta}, 0)$. These values occur at step (CD1). On the other hand, Theorems 2.2 and 2.6 can be used to prove that f_c is not a local optimizer for OPT. In fact, $s^* \cong 2.09101$ is the (unique) optimal value, attained at

$$f^*(e^{i\theta}) \cong (-0.421325e^{i\theta}, 0.733838e^{i\theta}).$$

Example 2. Set

$$\begin{aligned} \Gamma(e^{i\theta}, z_z, z_2) = & (2 + 0.1 \cos \theta) \left(\operatorname{re} \left(\frac{1}{e^{i\theta} - 0.2} - z_1 \right) \right)^2 + 9 \left(\operatorname{im} \left(\frac{1}{e^{i\theta} - 0.2} - z_1 \right) \right)^2 \\ & + (4 - 0.2 \cos \theta) \left(\operatorname{re} \left(\frac{1}{e^{i\theta}} - z_2 \right) \right)^2 + \left(\operatorname{im} \left(\frac{1}{e^{i\theta}} - z_2 \right) \right)^2. \end{aligned}$$

The optimal value in OPT is $s^* \cong 5.28606$, while coordinate descent, initialized at $f^0 = (0, 0)$, completes (CD1) to finally get to a complete halt right at (CD2), giving $s_c^* \cong 7.14102$. Thus, in this example, there is approximately a 35% error in the answer.

5. The UNCOPT problem. In §2 we treated the problem OPT. As it was mentioned there, OPT is central to the problem of system design in the frequency domain. To formulate OPT in this context, complete knowledge of the part of the system that is given is required, to be able to determine what value the performance function Γ takes at specified values $e^{i\theta} \in \mathbb{T}$ and $z \in \mathbb{C}^N$. This is an idealized situation: typically, the engineer is confronted with the problem of design under the presence of unknown values for some of the parameters α that enter the model. However, he or she may know ranges through which α can vary. The standard jargon in control calls the parameter α the plant uncertainty.

In this situation, a performance function $\tilde{\Gamma}(e^{i\theta}, \alpha, z)$ is available, where α lives in a set $\mathcal{R}(e^{i\theta}) \subset \mathbb{R}^K$. Since the exact values of α are not known, a true worst-case analysis uses the function UNC in §1, $\Gamma(e^{i\theta}, z) \triangleq \sup_{\alpha \in \mathcal{R}(e^{i\theta})} \tilde{\Gamma}(e^{i\theta}, \alpha, z)$.

It is the purpose of this section to study this and other similar problems. More precisely, we state conditions for (local) optimality, when the function Γ is smooth, which involve in

their formulation only the function $\tilde{\Gamma}$ (and not Γ). For more details about the engineering application, we refer to [Doy], [H4], [HMer].

Let $\tilde{\Gamma}$ be a positive-valued function of $(e^{i\theta}, \alpha, z) \in \mathbb{T} \times \mathbb{R}^k \times \mathbb{C}_N$, such that all derivatives in α and z of order up to 3 exist everywhere and are continuous in $e^{i\theta}$. Let $g : \mathbb{T} \times \mathbb{R}^K \rightarrow \mathbb{R}$ be a C^2 -function, such that the sets

$$(5.1) \quad \mathcal{R}(e^{i\theta}) \triangleq \{\alpha \in \mathbb{R}^k / g(e^{i\theta}, \alpha) \leq 0\}$$

have nonempty interior and satisfy

$$(5.2) \quad \alpha \in \partial \mathcal{R}(e^{i\theta}) \Rightarrow \frac{\partial g}{\partial \alpha}(e^{i\theta}, \alpha) \neq 0.$$

By UNCOPT, we denote the problem of finding solutions to either one of the statements UNCOPT-I and UNCOPT-S':

$$(UNCOPT-S') \quad \inf_{f \in A_N} \sup_{\theta} \sup_{\substack{\alpha \in \mathbb{R}^k \\ g(e^{i\theta}, \alpha) \leq 0}} \tilde{\Gamma}(e^{i\theta}, \alpha, f(e^{i\theta})),$$

$$(UNCOPT-I) \quad \inf_{f \in A_N} \sup_{\theta} \inf_{\substack{\alpha \in \mathbb{R}^k \\ g(e^{i\theta}, \alpha) \leq 0}} \tilde{\Gamma}(e^{i\theta}, \alpha, f(e^{i\theta})).$$

These problems split naturally and cleanly into two separate problems:

$$(5.3a) \quad \Gamma(e^{i\theta}, z) = \sup_{\alpha \in \mathcal{R}(e^{i\theta})} \tilde{\Gamma}(e^{i\theta}, \alpha, z)$$

for UNCOPT-S', or

$$(5.3b) \quad \Gamma(e^{i\theta}, z) = \inf_{\alpha \in \mathcal{R}(e^{i\theta})} \tilde{\Gamma}(e^{i\theta}, \alpha, z)$$

for UNCOPT-I. Then UNCOPT-S' and UNCOPT both become OPT for Γ . Indeed, it is convenient to define what we mean by solution to UNCOPT and UNCOPT-I directly in terms of OPT. We now formalize this.

DEFINITION 5.1. Let $\alpha^* : \mathbb{T} \rightarrow \mathbb{R}^k$ measurable and $f^* \in A_N$ and suppose that $\alpha^*(e^{i\theta}) \in \mathcal{R}(e^{i\theta})$, for all $e^{i\theta} \in \mathbb{T}$. Then we call (f^*, α^*) a feasible pair.

DEFINITION 5.2. Let (f^*, α^*) be a feasible pair. Then (f^*, α^*) is a local solution to UNCOPT-S' (respectively, UNCOPT-I), if

(1) f^* is a strict (local) directional minimizer to OPT for the function Γ in (5.3a) (respectively, (5.3b));

(2) for almost all $e^{i\theta} \in \mathbb{T}$, $\alpha^*(e^{i\theta})$ is an optimizer for $\tilde{\Gamma}(e^{i\theta}, \alpha, f^*(e^{i\theta}))$; i.e.,

$$(5.4) \quad \Gamma(e^{i\theta}, f^*(e^{i\theta})) = \tilde{\Gamma}(e^{i\theta}, \alpha^*(e^{i\theta}), f^*(e^{i\theta})).$$

Thus we obtain essentially by definition our first and most basic recipe for characterizing solutions.

RECIPE. To check if the feasible pair (f^*, α^*) solves UNCOPT locally,

(1) use the classical Kuhn-Tucker conditions (see [GMW]) to check if α^* optimizes $\Gamma(e^{i\theta}, \cdot, f^*(e^{i\theta}))$;

(2) use §2 to check that f^* is a solution to OPT for Γ given by (5.3). This is one of the main motivations for §2.

One important shortcoming of the recipe is that an explicit formula for Γ is not normally available. Therefore the results of §2 cannot be applied directly. We would like a test of optimality expressed directly in terms of $\tilde{\Gamma}$ rather than the secondary function Γ . Under what basically are smoothness assumptions for Γ , this can be carried out. That is the main objective of this section.

The smoothness hypothesis on Γ is not a trivial one. It is easy to find examples where this is violated (see comments following Theorem 5.7).

We caution the reader that local optima are not adequate to ensure robustness in engineering designs. Consequently, we must compute enough local optima to be sure of finding a global one.

Our goal is to characterize optima α^*, f^* directly in terms of $\tilde{\Gamma}$. A most naive approach would be to set

$$\Gamma_1(e^{i\theta}, z) = \tilde{\Gamma}(e^{i\theta}, \alpha^*(e^{i\theta}), z),$$

assume the same function f^* as solution, and then proceed. Unfortunately, the assumption is false, the conclusion it gives for condition III is wrong, and so the issue is much more difficult. We must consider that a solution α^* to (5.3) depends on both θ and z . Indeed, it is by applying this that we get our main results, below. First, we provide some notation.

Let (f^*, α^*) be an admissible pair. The following statements (I') and (II') are essential to the characterization of solutions to UNCOPT:

(I') $\tilde{\Gamma}(\cdot, \alpha^*(\cdot), f^*(\cdot))$ is constant on \mathbb{T} ;

(II') $\chi^{-1}(\cdot) \partial \tilde{\Gamma} / \partial z(\cdot, \alpha^*(\cdot), f^*(\cdot))$ has an analytic direction.

Statements (I') and (II') duplicate in an obvious way statements (I) and (II) of §2. There is also, under appropriate hypotheses, another statement involving second-order derivatives of $\tilde{\Gamma}$ (see III' in Theorem 5.7), which is more difficult to check than (I') and (II'). This we introduce later.

Note that (II') makes perfect sense for cases in which $\partial \tilde{\Gamma} / \partial z(\cdot, \alpha^*(\cdot), f^*(\cdot))$ is not continuous. In fact, we believe that (I') and (II') are necessary for optimality in many cases that are not covered by the theorems proved in this section. We analyze this in a later paper. We certainly recommend in practical situations considering both (I') and (II') as necessary, even if the hypotheses of theorems do not guarantee necessity for optimality.

DEFINITION 5.3. A feasible pair (f^*, α^*) is an *interior pair* (respectively, *boundary pair*), provided that there exists $\delta > 0$ such that $g(e^{i\theta}, \alpha^*(e^{i\theta}), f^*(e^{i\theta})) \leq \delta < 0$ almost everywhere on \mathbb{T} (respectively, $g(e^{i\theta}, \alpha^*(e^{i\theta}), f^*(e^{i\theta})) = 0$ almost everywhere on \mathbb{T}).

DEFINITION 5.4. An interior pair (f^*, α^*) is called *regular* if $\partial^2 g / \partial \alpha^2(e^{i\theta}, \alpha^*(e^{i\theta}))$ is invertible almost everywhere on \mathbb{T} , with inverse essentially bounded in norm on \mathbb{T} . A boundary pair is *regular* if the Hessian $(\partial^2 g / \partial u^2)(e^{i\theta}, \alpha^*(e^{i\theta}))$ when compressed to the tangent plane to $\partial \mathcal{R}(e^{i\theta})$ at $\alpha^*(e^{i\theta})$ is invertible (with inverse bounded uniformly in θ).

In other words, $D(e^{i\theta})^\dagger \partial^2 g / \partial \alpha^2(e^{i\theta}, \alpha^*(e^{i\theta})) D(e^{i\theta})$ is invertible almost everywhere on \mathbb{T} , with inverse essentially bounded in norm on \mathbb{T} . Here D is any $k \times k-1$ matrix-valued measurable function, such that $D(e^{i\theta})$ has as column vectors that form an orthonormal basis for the space $\{\beta \in \mathbb{R}^k : (\partial \tilde{\Gamma} / \partial \alpha)(P(e^{i\theta}))^\dagger \cdot \beta = 0\}$.

THEOREM 5.5. Let (f^*, α^*) be a regular interior or boundary pair such that α^* is continuous on \mathbb{T} and $(\partial \tilde{\Gamma} / \partial z)(\cdot, \alpha^*(\cdot), f^*(\cdot))$ never equals zero on \mathbb{T} . If (f^*, α^*) is a solution to UNCOPT, then (I) and (II) hold.

Conversely, if (I) and (II) hold for the regular interior pair (f^*, α^*) and if $\tilde{\Gamma}(e^{i\theta}, \alpha^*(e^{i\theta}), \cdot)$ is locally strictly convex at $z = f^*(e^{i\theta_0})$ for some $e^{i\theta_0} \in \mathbb{T}$, then (f^*, α^*) solves UNCOPT-S'.

One basic observation is that a given boundary pair that solves UNCOPT is also a solution to the problem obtained by constraining α to satisfy $g(e^{i\theta}, \alpha) = 0$. Since the analysis is always local, many results that apply to solutions that are interior pairs, after reparametrization, could be stated for the boundary case. This is the case in the next theorem. If (f^*, α^*) is a fixed feasible pair, we use the notation $P(e^{i\theta}) = (e^{i\theta}, \alpha^*(e^{i\theta}), f^*(e^{i\theta}))$. Also, by $\partial^2 \tilde{\Gamma} / \partial z \partial \alpha (P(e^{i\theta}))$, we denote the $N \times K$ matrix, with (l, j) entry $(\partial^2 \tilde{\Gamma} / \partial z_l \partial \alpha_j)(P(e^{i\theta}))$.

THEOREM 5.6. *Suppose that Γ, g , and (f^*, α^*) satisfy the hypotheses of Theorem 5.5 with the possible exception of convexity. Assume further that (f^*, α^*) is an interior pair. Then necessary conditions for (f^*, α^*) to solve UNCOPT are (I') and (II') as in Theorem 5.5, and for every $h \in N(\partial \tilde{\Gamma} / \partial z(\cdot, \alpha^*(\cdot), f^*(\cdot))) \cap A_N$,*

$$\begin{aligned} \sup_{\theta} \left\{ \overline{h(e^{i\theta})}^\dagger \left(\frac{-\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha} (P(e^{i\theta})) \frac{\partial^2 \tilde{\Gamma}}{\partial \alpha^2} (P(e^{i\theta}))^{-1} \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha} (P(e^{i\theta}))^\dagger + \frac{\partial^2 \tilde{\Gamma}}{\partial \bar{z} \partial z} (P(e^{i\theta})) \right) h(e^{i\theta}) \right. \\ \left. + \operatorname{Re} h(e^{i\theta})^\dagger \left(\frac{-\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha} (P(e^{i\theta})) \frac{\partial^2 \tilde{\Gamma}}{\partial \alpha^2} (P(e^{i\theta}))^{-1} \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha} (P(e^{i\theta}))^\dagger \right. \right. \\ \left. \left. + \frac{\partial^2 \tilde{\Gamma}}{\partial \bar{z} \partial z} (P(e^{i\theta})) \right) h(e^{i\theta}) \right\} \\ \geq 0. \end{aligned} \quad (5.5)$$

If strict inequality is placed in (5.5), then these conditions are also sufficient.

Suppose that (f^*, α^*) is a boundary pair with α^* continuous on \mathbb{T} and that $\tilde{\Gamma}$ has been reparameterized as

$$\tilde{\Gamma}(e^{i\theta}, \beta, z) = \tilde{\Gamma}(e^{i\theta}, w(e^{i\theta}, \beta), z),$$

where

$$w(e^{i\theta}, \cdot) : \mathbb{R}^{k-1} \rightarrow \partial \mathcal{R}(e^{i\theta}) \subset \mathbb{R}^k$$

is a smooth (on $\mathbb{T} \times \mathbb{R}^{k-1}$) parameterization of $\partial \mathcal{R}(e^{i\theta})$ valid near $\alpha^*(e^{i\theta})$. Then replace $\tilde{\Gamma}$ by $\tilde{\Gamma}$ and $\partial / \partial \alpha$ by $\partial / \partial \beta$ in (5.5) to obtain (5.5'). Thus the interior case theorem, above, holds for the boundary case, provided that (5.5') replaces (5.5).

Theorem 5.6 in the case where $N = 2$ can be reduced to a practical test, in identical manner to what was done in §2, Theorem 2.7.

We now present what is the most general result of this section. Assumptions require a fairly detailed knowledge of the function Γ arising from $\tilde{\Gamma}$ as in (5.3). This is hypothesis (iv) in the following theorem. Recall that, if v is in \mathbb{C}^N , then $\operatorname{Re} v$ is the column vector with entries $\operatorname{Re} v_l, l = 1, \dots, N$. Also, if α is an \mathbb{R}^k -valued function on \mathbb{C}^N , then, by $\partial \alpha / \partial z(\cdot)$, we denote a $K \times N$ matrix with (j, l) entry given by $\partial \alpha_j / \partial z_l(\cdot)$.

THEOREM 5.7. *Let (f^*, α^*) be a pair of admissible functions, such that $\partial \tilde{\Gamma} / \partial z(\cdot, \alpha^*(\cdot), f^*(\cdot))$ never equals zero on \mathbb{T} . Suppose that there exists an open set $V \subset \mathbb{C}^N$ and a function $\alpha : \mathbb{T} \times V \rightarrow \mathbb{R}^k$ such that*

- (i) $g(e^{i\theta}, \alpha(e^{i\theta}, z)) \leq 0, \forall z \in V, e^{i\theta} \in \mathbb{T}$;
- (ii) *For each $e^{i\theta} \in \mathbb{T}$, the function $\alpha(e^{i\theta}, \cdot)$ is C^2 on V . Also, $\alpha(e^{i\theta}, \cdot)$ and its derivatives in z are continuous in $e^{i\theta} \in \mathbb{T}$;*
- (iii) $\alpha(e^{i\theta}, 0) = \alpha^*(e^{i\theta}), \forall e^{i\theta} \in \mathbb{T}$;
- (iv) $\tilde{\Gamma}(e^{i\theta}, \alpha(e^{i\theta}, z), f^*(e^{i\theta}) + z) = \Gamma(e^{i\theta}, f^*(e^{i\theta}) + z), \forall e^{i\theta} \in \mathbb{T}, z \in V$.

For each $e^{i\theta} \in \mathbb{T}$, let $\eta = \eta(e^{i\theta}, 0)$ be the unique solution to

$$\frac{\partial \tilde{\Gamma}}{\partial \alpha} (P(e^{i\theta})) - \eta \frac{\partial g}{\partial \alpha} (e^{i\theta}, \alpha^*(e^{i\theta})) = 0.$$

FIG. 5.1

Typically, η is referred to as a Lagrange multiplier. Then conditions (I'), (II'), and condition (III'), below, are necessary for (f^*, α^*) to be a solution to UNCOPT.

(III') For every $h \in N((\partial \tilde{\Gamma} / \partial z)(\cdot, \alpha^*(\cdot), f^*(\cdot)))$,

$$\sup_{\theta} \left\{ 4 \operatorname{Re} \left(h(e^{i\theta})^\dagger \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta})) \right) 2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger h(e^{i\theta}) \right. \\ + \left(2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger h(e^{i\theta}) \right)^\dagger \left(\frac{\partial^2 \tilde{\Gamma}}{\partial \alpha^2}(P(e^{i\theta})) - \eta(e^{i\theta}, 0) \frac{\partial g}{\partial \alpha^2}(e^{i\theta}, \alpha^*(e^{i\theta}, \cdot)) \right) \\ \cdot \left(2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger h(e^{i\theta}) \right) \\ \left. + 2 \overline{h(e^{i\theta})} \frac{\partial^2 \tilde{\Gamma}}{\partial \bar{z} \partial z}(P(e^{i\theta})) h(e^{i\theta}) + 2 \operatorname{Re} h(e^{i\theta})^\dagger \frac{\partial^2 \tilde{\Gamma}}{\partial z^2}(P(e^{i\theta})) h(e^{i\theta}) \right\} \geq 0.$$

If strict inequality is considered in (III'), then the three conditions above are also sufficient.

A fragile hypothesis in this theorem is the assumption that $\alpha(\cdot)$ is a differentiable function. While it often might hold for interior or boundary pairs (f^*, α^*) , it seems unlikely to survive a case where α moves from the interior to the boundary. Even interior pairs (f^*, α^*) may occur with discontinuous α^* . We illustrate this with a pictorial example, in which the function Γ arising from (5.3) is continuous but not differentiable.

The plot of a function $\tilde{\Gamma}(e^{i\theta}, \alpha, z)$ with z and $e^{i\theta}$ fixed is shown in Figure 5.1. We assume that for this function $\tilde{\Gamma}$ the picture in the left half plane in Figure 5.1 does not change with z , while the peak in the right half plane has height given by $|z|^{2+1}$.

Hence, for this function $\tilde{\Gamma}$, we have that

$$\Gamma(e^{i\theta}, z) = \sup_{\alpha} \tilde{\Gamma}(e^{i\theta}, \alpha, z) = \begin{cases} 2 & \text{if } |z| \leq 1, \\ |z|^2 + 1 & \text{if } |z| > 1, \end{cases}$$

and it is clear that Γ is not differentiable in z , if $|z| = 1$.

A practical inconvenience with the previous result is that it requires us to know not only $\alpha(e^{i\theta}, f^*(e^{i\theta}))$, but also $\partial\alpha/\partial z(e^{i\theta}, 0)$. Fortunately, Theorem 5.6 has no dependence on $\partial\alpha/\partial z(e^{i\theta}, 0)$, so this is one advantage of it.

Basic for proving Theorem 5.7 is the following expansion:

$$\begin{aligned} \tilde{\Gamma}(e^{i\theta}, \alpha, f^*(e^{i\theta}) + tz) &= \tilde{\Gamma}(P(e^{i\theta})) + 2 \operatorname{Re} \frac{\partial \tilde{\Gamma}}{\partial z}(P(e^{i\theta}))^\dagger(tz) \\ &\quad + \frac{\partial \tilde{\Gamma}}{\partial \alpha}(P(e^{i\theta}))^\dagger(\alpha - \alpha^*(e^{i\theta})) \\ &\quad + \frac{1}{2} \left\{ 2 \operatorname{Re} tz^t \frac{\partial^2 \tilde{\Gamma}}{\partial \alpha \partial z}(P(e^{i\theta}))tz \right. \\ &\quad + (\alpha - \alpha^*(e^{i\theta}))^\dagger \frac{\partial^2 \tilde{\Gamma}}{\partial \alpha^2}(P(e^{i\theta}))(\alpha - \alpha^*(e^{i\theta})) \\ &\quad + 2t^2 \bar{z}^\dagger \frac{\partial^2 \tilde{\Gamma}}{\partial \bar{z} \partial z}(P(e^{i\theta}))z + 2t^2 \operatorname{Re} \frac{\partial^2 \tilde{\Gamma}}{\partial z^2}(P(e^{i\theta}))z \Big\} \\ &\quad + E_2(e^{i\theta}, \alpha, tz) \quad \forall e^{i\theta} \in \mathbb{T}, z \in V, t \in (0, 1), \end{aligned} \tag{5.6}$$

where the function E_2 is continuous on $\mathbb{T} \times V$ and

$$\sup_{\theta} \frac{1}{t^2}, E_2(e^{i\theta}, \alpha(e^{i\theta}, tz), tz) \rightarrow 0 \quad \text{as } t \rightarrow 0. \tag{5.7}$$

LEMMA 5.8. *Under the hypotheses of Theorem 5.7,*

$$\frac{\partial \tilde{\Gamma}}{\partial \alpha}(P(e^{i\theta}))^\dagger \cdot \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger = 0 \quad \forall (e^{i\theta}) \in \mathbb{T}.$$

Proof. Fix $e^{i\theta} \in \mathbb{T}$. Then hypothesis (iv) implies that

$$\frac{d}{dt} \tilde{\Gamma}(e^{i\theta}, \alpha(e^{i\theta}, tw), f^*(e^{i\theta}))|_{t=0} = 0 \quad \forall w \in V,$$

i.e.,

$$\begin{aligned} \frac{\partial \tilde{\Gamma}}{\partial \alpha}(P(e^{i\theta}))^\dagger \cdot 2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger w \\ = 2 \operatorname{Re} \frac{\partial \tilde{\Gamma}}{\partial \alpha}(P(e^{i\theta}))^\dagger \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger w = 0 \quad \forall w \in \mathbb{C}^N, e^{i\theta} \in \mathbb{T}. \end{aligned} \tag{5.8}$$

Set $w = \overline{(\partial\alpha/\partial z)(e^{i\theta}, 0)(\partial\tilde{\Gamma}/\partial\alpha)(P(e^{i\theta}))}$ in (5.8) to obtain

$$\left\| \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0) \frac{\partial \tilde{\Gamma}}{\partial \alpha}(P(e^{i\theta})) \right\|_{\mathbb{C}_N} = 0 \quad \forall e^{i\theta} \in \mathbb{T}. \quad \square$$

LEMMA 5.9. *Assume the hypotheses of Theorem 5.7 and let $(f^* \alpha^*)$ be a solution to UNCOPT. Then $h^* = 0$ is a directional minimizer for $\sup_{\theta} \Gamma_1(e^{i\theta}, h(e^{i\theta}))$ over A_N , where Γ_1 is defined as*

$$\Gamma_1(e^{i\theta}, z) \triangleq \tilde{\Gamma}(P(e^{i\theta})) + 2 \operatorname{Re} \frac{\partial \tilde{\Gamma}}{\partial \alpha}(P(e^{i\theta}))^\dagger z + \|z\|_{\mathbb{C}^N}^2. \tag{5.9}$$

Proof. Combine expansion (5.6) with Lemma 5.8 to obtain a function $G_1 : \mathbb{T} \times \mathbb{R}^k \times \mathbb{C}^N \rightarrow \mathbb{R}$ such that

$$(5.10) \quad \frac{1}{t} \sup_{\theta} |G_1(e^{i\theta}, \alpha(e^{i\theta}, tz), tz)| \rightarrow 0 \quad \text{as } t \rightarrow 0 \quad \forall z \in \mathbb{C}^N$$

and

$$(5.11) \quad \begin{aligned} & \tilde{\Gamma}(e^{i\theta}, \alpha(e^{i\theta}, tz), f^*(e^{i\theta}) + tz) \\ &= \tilde{\Gamma}(P(e^{i\theta})) + 2t \operatorname{Re} \frac{\partial \tilde{\Gamma}}{\partial \alpha}(P(e^{i\theta}))^\dagger z + G_1(e^{i\theta}, \alpha(e^{i\theta}, tz), tz). \end{aligned}$$

The remainder of the proof is similar to the first part of the proof of Theorem 2.8. \square

The necessity of (I') and (II') follows immediately from the proof of Theorem 2.8 and from Lemma 5.9. Now we move to (III'). We need the following lemma.

LEMMA 5.10. *Under the hypotheses of Theorem 5.7, if the pair (f^*, α^*) is a solution to UNCOPT, then there exists $t_1 > 0$ and a continuous function $h_0 : \mathbb{T} \times t_1 V \rightarrow \mathbb{R}$ such that*

$$(5.12) \quad \begin{aligned} & \frac{\partial \tilde{\Gamma}}{\partial \alpha}(P(e^{i\theta}))^\dagger (\alpha(e^{i\theta}, tz) - \alpha^*(e^{i\theta})) \\ &= -\eta(e^{i\theta}, z) \left(2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger z \right)^\dagger \frac{\partial^2 g}{\partial \alpha^2}(e^{i\theta}, \alpha^*(e^{i\theta})) \\ & \quad \cdot \left(2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger z \right) t^2 \\ & \quad + R_0(e^{i\theta}, tz) \quad \forall t \in (0, t_1), z \in V, e^{i\theta} \in \mathbb{T} \end{aligned}$$

and

$$\sup_{\theta} \frac{R_0(e^{i\theta}, tz)}{t \|z\|_{\mathbb{C}^N}} \rightarrow 0 \quad \text{as } t \rightarrow 0.$$

Proof. If (f^*, α^*) is a regular interior point, then $(\partial \tilde{\Gamma} / \partial \alpha)(P(e^{i\theta})) = 0$ for all $e^{i\theta} \in \mathbb{T}$. Set $R_2 = 0$ and $t = 1$ to obtain the conclusion of the theorem.

Now assume that (f^*, α^*) is a regular boundary point. We have, from the expansion of $\alpha(e^{i\theta}, tz)$ about $t = 0$, the definition of $\eta(\cdot, 0)$, and from Lemma 5.8 that, for some $t' > 0$,

$$(5.13) \quad \begin{aligned} & \frac{\partial \tilde{\Gamma}}{\partial \alpha}(P(e^{i\theta}))^\dagger (\alpha(e^{i\theta}, tz) - \alpha^*(e^{i\theta})) \\ &= -\eta(e^{i\theta}, 0) \frac{\partial g}{\partial \alpha}(e^{i\theta}, \alpha^*(e^{i\theta}))^\dagger \left(\frac{d}{dt^2} \alpha(e^{i\theta}, tz) \Big|_{t=0} \right) \frac{t^2}{2} + R_2(e^{i\theta}, tz) \\ & \quad \forall z \in V, \quad t \in (0, t'), \quad e^{i\theta} \in \mathbb{T}, \end{aligned}$$

where R_2 is a continuous function satisfying $\sup_{\theta} (1/t \|z\|_{\mathbb{C}^N}) \cdot R_2(e^{i\theta}, tz) \rightarrow 0$ as $t \rightarrow 0$. Since for all $e^{i\theta} \in \mathbb{T}$, $\partial \tilde{\Gamma} / \partial w(P(e^{i\theta})) \neq 0$, then there exists $t_1 > 0$ such that

$$(5.14) \quad g(e^{i\theta}, \alpha(e^{i\theta}, tz)) = 0 \quad \forall t \in (0, t_1), \quad z \in V.$$

Note that, by compactness of \mathbb{T} , t_1 can be chosen to be independent of $e^{i\theta}$. Differentiating in (5.14) with respect to t , we have

$$(5.15) \quad \frac{\partial g}{\partial \alpha}(e^{i\theta}, \alpha(e^{i\theta}, tz))^\dagger 2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, tz)^\dagger z = 0 \quad \forall t \in (0, t_1), \quad z \in V.$$

Differentiating again, we obtain from (5.15)

$$(5.16) \quad \left(2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger z \right)^\dagger \frac{\partial^2 g}{\partial \alpha^2}(e^{i\theta}, \alpha^*(e^{i\theta})) \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger z \\ + \frac{\partial g}{\partial \alpha}(e^{i\theta}, \alpha^*(e^{i\theta}))^\dagger \left(\frac{d}{dt^2} \alpha(e^{i\theta}, tz) \Big|_{t_0=0} \right) = 0.$$

We combine (5.16) and (5.13) and set $R_0 = R_2$ to finish the proof of the lemma. \square
Combine (5.8) with Lemma 5.10 to obtain the expansion

$$(5.17) \quad \tilde{\Gamma}(e^{i\theta}, \alpha(e^{i\theta}, tz), f^*(e^{i\theta}) + tz) \\ = \tilde{\Gamma}(P(e^{i\theta})) + 2t \operatorname{Re} \frac{\partial \tilde{\Gamma}}{\partial \alpha}(P(e^{i\theta}))^\dagger z \\ + \frac{t^2}{2} \left\{ 4 \operatorname{Re} z^t \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta})) 2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger z \right. \\ + \left(2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger z \right)^\dagger \left(\frac{\partial \tilde{\Gamma}}{\partial \alpha^2}(P(e^{i\theta})) - \eta(e^{i\theta}, 0) \frac{\partial g}{\partial \alpha^2}(e^{i\theta}, \alpha^*(e^{i\theta})) \right) \\ \cdot \left(2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger z \right) \\ \left. + \bar{z}^\dagger \frac{\partial^2 \Gamma}{\partial \bar{z} \partial z}(P(e^{i\theta})) z + 2 \operatorname{Re} z^\dagger \frac{\partial^2 \tilde{\Gamma}}{\partial z^2}(P(e^{i\theta})) z \right\} \\ + R_3(e^{i\theta}, tz) \quad \forall z \in V, t \in (0, t_1), e^{i\theta} \in \mathbb{T},$$

where the function R_3 is continuous on $\mathbb{T} \times t_1 V$ and

$$(5.18) \quad \sup_{e^{i\theta} \in \mathbb{T}} \frac{R_3(e^{i\theta}, tz)}{t^2 \|z\|_{\mathbb{C}^N}} \rightarrow 0 \quad \text{as } t \rightarrow 0.$$

Pick $h \in N(\partial \tilde{\Gamma} / \partial z)(P(\cdot)) \cap A_N$.

Since (f^*, α^*) solves UNCOPT, then there exists $t_1 > 0$ such that

$$(5.19) \quad \sup_{\theta} \Gamma(e^{i\theta}, f^*(e^{i\theta}) + th(e^{i\theta})) \\ = \sup_{\theta} \tilde{\Gamma}(e^{i\theta}, \alpha(e^{i\theta}, th(e^{i\theta})), f^*(e^{i\theta}) + th(e^{i\theta})) > \gamma^* \\ \triangleq \sup_{\theta} \Gamma(e^{i\theta}, f^*(e^{i\theta})) \quad \forall t \in (0, t_1).$$

Combine (5.19), (I'), and expansion (5.17) to obtain that

$$(5.20) \quad \sup_{\theta} \left\{ 4 \operatorname{Re} z^t \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta})) 2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger z + \left(2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger z \right)^\dagger \right. \\ \cdot \left(\frac{\partial \tilde{\Gamma}}{\partial \alpha^2}(P(e^{i\theta})) - \eta(e^{i\theta}, 0) \frac{\partial g}{\partial \alpha^2}(e^{i\theta}, \alpha^*(e^{i\theta})) \right) \left(2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger z \right) \\ \left. + \bar{z}^\dagger \frac{\partial^2 \Gamma}{\partial \bar{z} \partial z}(P(e^{i\theta})) z + 2 \operatorname{Re} z^\dagger \frac{\partial^2 \tilde{\Gamma}}{\partial z^2}(P(e^{i\theta})) z \right\} \\ + \frac{R_2(e^{i\theta}, th(e^{i\theta}))}{t^2} > 0 \quad \forall t \in (0, t_1).$$

The necessity of (III') follows from letting $t \rightarrow 0$ in (5.20).

We now prove sufficiency of (I')–(III') with strict inequality. For this, assume that there exist $h \in A_N$ and a sequence $\{t_n\}$ of positive real numbers such that for all $n \in \mathbb{N}$

$$(5.21) \quad \sup_{\theta} \sup_{\alpha \in \mathcal{R}(e^{i\theta})} \tilde{\Gamma}(e^{i\theta}, \alpha, f^*(e^{i\theta}) + t_n h(e^{i\theta})) \leq \gamma^*.$$

From (5.21), we obtain

$$(5.22) \quad \tilde{\Gamma}(e^{i\theta}, \alpha(e^{i\theta}, t_n h(e^{i\theta})), f^*(e^{i\theta}) + t_n h(e^{i\theta})) < \gamma^* \quad \forall e^{i\theta} \in \mathbb{T}.$$

Now inequality (5.22) and expansion (5.17) imply that

$$(5.23) \quad 2 \operatorname{Re} \frac{\partial \tilde{\Gamma}}{\partial z}(P(e^{i\theta}))^\dagger h(e^{i\theta}) + o(t_n) < 0, \quad e^{i\theta} \in \mathbb{T}.$$

Letting $n \rightarrow \infty$ in (5.23), we obtain that

$$(5.24) \quad 2 \operatorname{Re} \frac{\partial \tilde{\Gamma}}{\partial z}(P(e^{i\theta}))^\dagger h(e^{i\theta}) \leq 0 \quad \forall e^{i\theta} \in \mathbb{T},$$

and Lemma 2.9 now implies that $h \in N(\partial \tilde{\Gamma} / \partial z(P(\cdot)))$. Combining again expansion (5.17) with inequality (5.22), we obtain

$$(5.25) \quad \begin{aligned} & 4 \operatorname{Re} h(e^{i\theta})^\dagger \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha} \cdot \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0) h(e^{i\theta}) + \left(2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0) z \right)^\dagger \\ & \cdot \left(\frac{\partial \tilde{\Gamma}}{\partial \alpha^2}(P(e^{i\theta})) - \eta(e^{i\theta}, 0) \frac{\partial g}{\partial \alpha^2}(e^{i\theta}, \alpha^*(e^{i\theta})) \right) \left(2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0) h(e^{i\theta}) \right)^\dagger \\ & + 2 \overline{h(e^{i\theta})}^\dagger \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \bar{z}}(P(e^{i\theta})) h(e^{i\theta}) + 2 \operatorname{Re} h(e^{i\theta})^\dagger \frac{\partial^2 \tilde{\Gamma}}{\partial z^2}(P(e^{i\theta})) h(e^{i\theta}) \\ & + t_n R_3(e^{i\theta}, t_n h(e^{i\theta})) \leq 0 \quad \forall e^{i\theta} \in \mathbb{T}. \end{aligned}$$

Letting $n \rightarrow \infty$ in (5.25), we see that strict inequality in (III') cannot hold. This proves the theorem. \square

Proof of Theorem 5.6. We only need to prove (5.5). Note that there exists $t_1 > 0$ such that

$$(5.26) \quad \frac{\partial \tilde{\Gamma}}{\partial \alpha}(e^{i\theta}, \alpha(e^{i\theta}, tz), f^*(e^{i\theta}) + tz) = 0 \quad \forall t \in (0, t_1), \quad e^{i\theta} \in \mathbb{T}.$$

Differentiating in (5.26) with respect to t we obtain

$$(5.27) \quad \begin{aligned} & \frac{\partial^2 \tilde{\Gamma}}{\partial \alpha^2}(e^{i\theta}, \alpha(e^{i\theta}, tz), f^*(e^{i\theta}) + tz)^\dagger \cdot 2 \operatorname{Re} \left(\frac{\partial \alpha}{\partial z}(e^{i\theta}, tz)^\dagger z \right) \\ & + 2 \operatorname{Re} \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(e^{i\theta}, \alpha(e^{i\theta}, tz), f^*(e^{i\theta}) + tz)^\dagger z = 0 \\ & \quad \forall t \in (0, t_1), \quad e^{i\theta} \in \mathbb{T}, \quad z \in V. \end{aligned}$$

Set $t = 0$ in (5.27) to obtain

$$\begin{aligned} & \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta})) \cdot 2 \operatorname{Re} \left(\frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger z \right) + 2 \operatorname{Re} \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta}))^\dagger z = 0 \\ & \quad \forall z \in V, \quad e^{i\theta} \in \mathbb{T}, \end{aligned}$$

i.e.,

$$(5.28) \quad 2 \operatorname{Re} \left(\frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger z \right) = -\frac{\partial^2 \tilde{\Gamma}}{\partial \alpha^2}(P(e^{i\theta}))^{-1} 2 \operatorname{Re} \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta}))^\dagger z$$

$\forall z \in V, \quad e^{i\theta} \in \mathbb{T}.$

Therefore we obtain from (5.28)

$$(5.29) \quad \begin{aligned} & \left(2 \operatorname{Re} z^\dagger \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta})) \right) ((\alpha(e^{i\theta}), tz) - \alpha^*(e^{i\theta})) \\ &= -2 \operatorname{Re} z^\dagger \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta})) \cdot \frac{\partial^2 \tilde{\Gamma}}{\alpha^2}(P(e^{i\theta}))^{-1} 2 \operatorname{Re} \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta}))^\dagger z + R_3(e^{i\theta}, z) \\ &= -2 \bar{z}^\dagger \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta})) \frac{\partial^2 \tilde{\Gamma}}{\partial \alpha^2}(P(e^{i\theta}))^{-1} \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta}))^\dagger z \\ & \quad - 2 \operatorname{Re} \left(z^\dagger \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta})) \frac{\partial^2 \tilde{\Gamma}}{\partial \alpha^2}(P(e^{i\theta})) \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta}))^\dagger z \right) + R_3(e^{i\theta}, z), \end{aligned}$$

where the error R_3 satisfies

$$(5.30) \quad \sup_{\theta} \frac{R_3(e^{i\theta}, z)}{\|z\|^2} \rightarrow 0 \quad \text{as } z \rightarrow 0.$$

Finally, the equality $\partial \tilde{\Gamma} / \partial \alpha(P(\cdot)) = 0$ and (5.29) and (5.6) imply that there exists $\eta > 0$ such that, if $\|h\|_\infty < \eta$, then

$$(5.31) \quad \begin{aligned} & \tilde{\Gamma}(e^{i\theta}, \alpha(e^{i\theta}, th(e^{i\theta})), f^*(e^{i\theta}) + th(e^{i\theta})) \\ &= \tilde{\Gamma}(P(e^{i\theta})) + \frac{t^2}{2} \left\{ \overline{h(e^{i\theta})}^\dagger \left(-\frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta})) \frac{\partial^2 \tilde{\Gamma}}{\partial \alpha^2}(P(e^{i\theta}))^{-1} \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta})) \right. \right. \\ & \quad \left. \left. + \frac{\partial^2 \tilde{\Gamma}}{\partial \bar{z} \partial z}(P(e^{i\theta})) \right) h(e^{i\theta}) \right. \\ & \quad \left. + \operatorname{Re} h(e^{i\theta})^\dagger \left(-\frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta})) \frac{\partial^2 \tilde{\Gamma}}{\partial \alpha^2}(P(e^{i\theta}))^{-1} \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta})) \right. \right. \\ & \quad \left. \left. + \frac{\partial^2 \tilde{\Gamma}}{\partial \bar{z} \partial \alpha}(P(e^{i\theta})) h(e^{i\theta}) \right) \right\} \\ & \quad + s(e^{i\theta}, th(e^{i\theta})) \quad \forall t \in (0, t), \quad e^{i\theta} \in \mathbb{T}, \end{aligned}$$

where $\sup_{\theta} (s(e^{i\theta}, th(e^{i\theta}))/t^2 \|h(e^{i\theta})\|_{\mathbb{C}^N}^2) \rightarrow 0$ as $t \rightarrow 0$ whenever $h(e^{i\theta}) \neq 0$. At this point, we proceed as in the proof of Theorem 5.7 to obtain the conclusion of the theorem.

Proof of Theorem 5.5. The first half of this theorem is already proved (Proof of Theorem 5.7). Assume that (I') and (II') hold. The fact that $\tilde{\Gamma}(e^{i\theta_0}, \alpha^*(e^{i\theta_0}), \cdot)$ is strictly convex near $z = f^*(e^{i\theta_0})$ merely says that

$$(5.32) \quad \bar{z} \frac{\partial^2 \tilde{\Gamma}}{\partial \bar{z} \partial z}(P(e^{i\theta_0}))z + \operatorname{Re} z^\dagger \frac{\partial^2 \tilde{\Gamma}}{\partial z^2}(P(e^{i\theta_0}))z > 0 \quad \forall z \in \mathbb{C}^N \setminus \{0\}.$$

On the other hand, since (t^*, α^*) is a regular interior point and the problem considered is UNCOPT-S, $(\partial^2 \tilde{\Gamma} / \partial \alpha^2)(P(e^{i\theta}))$ takes values that are nonpositive definite matrices; hence

$$(5.33) \quad -2 \operatorname{Re} z^\dagger \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta}))^\dagger \frac{\partial^2 \tilde{\Gamma}}{\partial \alpha^2}(P(e^{i\theta})) 2 \operatorname{Re} \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta}))z \geq 0$$

$\forall z \in \mathbb{C}^N, \quad e^{i\theta} \in \mathbb{T}.$

The combination of (5.32) and (5.33) shows that (5.5) holds with strict inequality if $h(e^{i\theta_0}) \neq 0$.

Note that (5.32) holds for all $e^{i\theta} \in \mathbb{T}$ that are close enough to $e^{i\theta_0}$. If $h(e^{i\theta_0}) = 0$, then we can pick $e^{i\theta_1}$ near $e^{i\theta_0}$ such that $h(e^{i\theta_1}) \neq 0$. Using (5.32) for $e^{i\theta} = e^{i\theta_1}$, we obtain (5.5) with strict inequality. \square

Our next task is to simplify (III'). The simplification is that the test is written in terms of η and $\partial\eta/\partial z$ rather than in terms of $\alpha(e^{i\theta}, z)$ and $\partial\alpha/\partial z(e^{i\theta}, z)$. The advantage is that η is a real-valued scalar function, while α is a \mathbb{C}^N -valued function. Thus the corollary gives a substantial reduction in dimension of the computation.

COROLLARY 5.11. *If, in addition to the hypotheses of Theorem 5.7, we have that, for each $e^{i\theta} \in \mathbb{T}$, the matrix*

$$(5.34) \quad \frac{\partial^2 \tilde{\Gamma}}{\partial \alpha^2}(P(e^{i\theta})) - \eta(e^{i\theta}, 0) \frac{\partial^2 g}{\partial \alpha^2}(e^{i\theta}, \alpha^*(e^{i\theta}))$$

is invertible, then condition (III'), below, is equivalent to condition (III''):

$$(III'') \quad \sup_{\theta} \{ \overline{h(e^{i\theta})}^\dagger A_1(e^{i\theta}) h(e^{i\theta}) + \operatorname{Re} h(e^{i\theta})^\dagger B_1(e^{i\theta}) h(e^{i\theta}) \} \geq 0,$$

where the $N \times N$ matrix-valued functions $A_1(\cdot)$ and $B_1(\cdot)$ are defined by

$$\begin{aligned} A_1(\cdot) &\triangleq \left(\frac{\partial g}{\partial \alpha}(\cdot, \alpha^*(\cdot)) \frac{\partial \eta}{\partial z}(\cdot, 0) \right)^\dagger \left(\frac{\partial^2 \tilde{\Gamma}}{\partial \alpha^2}(P(\cdot)) - \eta(\cdot, 0) \frac{\partial^2 g}{\partial \alpha^2}(\cdot, \alpha^*(\cdot)) \right)^{-1} \\ &\quad \cdot \left(\frac{\partial g}{\partial \alpha}(\cdot, \alpha^*(\cdot)) \frac{\partial \eta}{\partial z}(\cdot, 0) \right) - \left(\frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(\cdot)) \right) \\ &\quad \cdot \left(\frac{\partial^2 \tilde{\Gamma}}{\partial \alpha^2}(P(\cdot)) - \eta(\cdot, 0) \frac{\partial^2 g}{\partial \alpha^2}(\cdot, \alpha^*(\cdot)) \right)^{-1} \left(\frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(\cdot)) \right)^\dagger + \frac{\partial^2 \tilde{\Gamma}}{\partial \bar{z} \partial z}(P(\cdot)) \\ B_1(\cdot) &\triangleq \left(\frac{\partial g}{\partial \alpha}(\cdot, \alpha^*(\cdot)) \frac{\partial \eta}{\partial z}(\cdot, 0) \right)^\dagger \left(\frac{\partial^2 \tilde{\Gamma}}{\partial \alpha^2}(P(\cdot)) - \eta(\cdot, 0) \frac{\partial^2 g}{\partial \alpha^2}(\cdot, \alpha^*(\cdot)) \right)^{-1} \\ &\quad \cdot \left(\frac{\partial g}{\partial \alpha}(\cdot, \alpha^*(\cdot)) \frac{\partial \eta}{\partial z}(\cdot, 0) \right) - \left(\frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(\cdot, \cdot)) \right) \\ &\quad \cdot \left(\frac{\partial^2 \tilde{\Gamma}}{\partial \alpha^2}(P(\cdot)) - \eta(\cdot, 0) \frac{\partial^2 g}{\partial \alpha^2}(\cdot, \alpha^*(\cdot)) \right)^{-1} \left(\frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(\cdot)) \right)^\dagger + \frac{\partial^2 \tilde{\Gamma}}{\partial z^2}(P(\cdot)). \end{aligned}$$

Proof. We have the relation

$$(5.35) \quad \frac{\partial \tilde{\Gamma}}{\partial \alpha}(e^{i\theta}, \alpha(e^{i\theta}, tz), f^*(e^{i\theta}) + tz) - \eta(e^{i\theta}, tz) \frac{\partial g}{\partial \alpha}(e^{i\theta}, \alpha(e^{i\theta}, tz)) = 0,$$

valid in some neighborhood of $0 \in \mathbb{C}^N$.

Differentiating with respect to t in (5.35), we have

$$\begin{aligned}
 (5.36) \quad & \frac{\partial^2 \tilde{\Gamma}}{\partial \alpha^2}(e^{i\theta}, \alpha(e^{i\theta}, tz), f^*(e^{i\theta}) + tz) 2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, tz)^\dagger z \\
 & + 2 \operatorname{Re} \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(e^{i\theta}, \alpha(e^{i\theta}, tz), f^*(e^{i\theta}) + tz)^\dagger z \\
 & - \eta(e^{i\theta}, tz) \frac{\partial^2 g}{\partial \alpha^2}(e^{i\theta}, \alpha(e^{i\theta}, tz)) 2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, tz)^\dagger z \\
 & - \frac{\partial g}{\partial \alpha}(e^{i\theta}, \alpha(e^{i\theta}, tz)) \cdot 2 \operatorname{Re} \frac{\partial \eta}{\partial z}(e^{i\theta}, tz)^\dagger z = 0.
 \end{aligned}$$

Now take $t = 0$ in (5.36) to obtain

$$\begin{aligned}
 (5.37) \quad 2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger z &= \left(\frac{\partial^2 \tilde{\Gamma}}{\partial \alpha^2}(P(e^{i\theta})) - \eta(e^{i\theta}, 0) \frac{\partial^2 g}{\partial \alpha^2}(e^{i\theta}, \alpha^*(e^{i\theta})) \right)^{-1} \\
 &\cdot 2 \operatorname{Re} \left(\frac{\partial g}{\partial \alpha}(e^{i\theta}, \alpha^*(e^{i\theta})) \frac{\partial \eta}{\partial z}(e^{i\theta}, 0)^\dagger - \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta}))^\dagger \right) z.
 \end{aligned}$$

Let $L(e^{i\theta}, z)$ be defined by the equation

$$\begin{aligned}
 (5.38) \quad L(e^{i\theta}, z) &= 4 \operatorname{Re} z^\dagger \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta})) 2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger z + \left(2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger z \right)^\dagger \\
 &\cdot \left(\frac{\partial^2 \tilde{\Gamma}}{\partial \alpha^2}(P(e^{i\theta})) - \eta(e^{i\theta}, 0) \frac{\partial g}{\partial \alpha^2}(e^{i\theta}, \alpha^*(e^{i\theta})) \right) \left(2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger z \right).
 \end{aligned}$$

From (5.37) and (5.38), we have that

$$\begin{aligned}
 (5.39) \quad L(e^{i\theta}, z) &= 4 \operatorname{Re} z^\dagger \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta})) 2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger z \\
 &+ 2 \operatorname{Re} z^\dagger \left(\frac{\partial \eta}{\partial z}(e^{i\theta}, 0) \frac{\partial g}{\partial \alpha}(e^{i\theta}, \alpha^*(e^{i\theta}))^\dagger - \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta})) \right) \\
 &\cdot 2 \operatorname{Re} \frac{\partial \alpha}{\partial z}(e^{i\theta}, 0)^\dagger z.
 \end{aligned}$$

Equation (5.40) again implies that

$$\begin{aligned}
 (5.40) \quad L(e^{i\theta}, z) &= \left(2 \operatorname{Re} \frac{\partial \eta}{\partial z}(e^{i\theta}, 0) \frac{\partial g}{\partial \alpha}(e^{i\theta}, \alpha^*(e^{i\theta}))^\dagger + \frac{\partial^2 \tilde{\Gamma}}{\partial z \partial \alpha}(P(e^{i\theta})) \right) \\
 &\cdot \left(\frac{\partial \tilde{\Gamma}}{\partial \alpha^2}(P(e^{i\theta})) - \eta(e^{i\theta}, 0) \frac{\partial^2 g}{\partial \alpha^2}(e^{i\theta}, \alpha^*(e^{i\theta})) \right)^{-1} \\
 &\cdot 2 \operatorname{Re} \left(\frac{\partial g}{\partial \alpha}(e^{i\theta}, \alpha^*(e^{i\theta})) \frac{\partial \eta^\dagger}{\partial z}(e^{i\theta}, 0) - \frac{\partial^2 \Gamma}{\partial z \partial \alpha}(P(e^{i\theta}))^\dagger z \right).
 \end{aligned}$$

Now use the relation

$$(2 \operatorname{Re} z^\dagger b^\dagger) A (2 \operatorname{Re} bz) = 2 \bar{z}^\dagger \bar{b}^\dagger Abz + 2 \operatorname{Re} z^\dagger b^\dagger Abz,$$

in (5.40) to rewrite (III'). This gives the desired formulation of (III'). \square

All our theorems assume that there is a function $\alpha(e^{i\theta}, z)$ solving UNC and varying smoothly with parameters. It is important to have available conditions that automatically guarantee this. We give an example in the following proposition.

PROPOSITION 5.12. *Let (f^*, α^*) be a pair of admissible functions such that $\partial\Gamma/\partial z \times (\cdot, \alpha^*(\cdot), f^*(\cdot))$ never equals zero on \mathbb{T} . Suppose that, for each $e^{i\theta} \in \mathbb{T}$, $\alpha = \alpha^*(e^{i\theta})$ is the unique optimizer of $\tilde{\Gamma}(e^{i\theta}, \alpha, f^*(e^{i\theta}))$ over α satisfying $g(e^{i\theta}, \alpha) \leq 0$. Then either one of statements (a) and (b), below, is sufficient for the existence of a function $\alpha(\cdot, \cdot)$, which appears in Theorem 5.7:*

(a) *For each $e^{i\theta} \in \mathbb{T}$, $g(e^{i\theta}, \alpha^*(e^{i\theta})) < 0$, and the matrix $\partial^2\tilde{\Gamma}/\partial\alpha^2(e^{i\theta}, \alpha^*(e^{i\theta}), f^*(e^{i\theta}))$ is positive definite if the problem is UNCOPT-I, and negative definite if it is UNCOPT-S';*

(b) *For each $e^{i\theta} \in \mathbb{T}$, $g(e^{i\theta}, \alpha^*(e^{i\theta})) = 0$, there exists a real-valued function $\eta_1(e^{i\theta})$ such that $\partial\tilde{\Gamma}/\partial\alpha(\cdot, \alpha^*(\cdot), f^*(\cdot)) - \eta_1(\cdot)(\partial g/\partial\alpha)(\cdot, \alpha^*(\cdot)) = 0$. Let $M(e^{i\theta})$ be a real $K \times K$ matrix whose columns form a basis for the set of vectors in \mathbb{R}^k that are orthogonal to $\partial g/\partial\alpha(e^{i\theta}, \alpha^*(e^{i\theta}))$. Then*

$$M^\dagger(e^{i\theta}) \left(\frac{\partial^2\tilde{\Gamma}}{\partial\alpha^2}(e^{i\theta}, \alpha^*(e^{i\theta}), f^*(e^{i\theta})) - \eta_1(e^{i\theta}) \frac{\partial^2 g}{\partial\alpha^2}(e^{i\theta}, \alpha^*(e^{i\theta})) \right) M(e^{i\theta})$$

is positive definite if the problem is UNCOPT-I, and negative definite if it is UNCOPT-S'.

Proof. (a) The implicit function theorem applied to the function $(\partial\Gamma/\partial\alpha)(e^{i\theta}, \alpha, f^*(e^{i\theta}) + z)$ at $z = 0$ and $\alpha = \alpha^*(e^{i\theta})$ implies that there exists a neighborhood $V(e^{i\theta})$ of $\{e^{i\theta}\} \times \{0\}$ in $\mathbb{T} \times \mathbb{C}^N$ and a $C^{(1)}$ function $\alpha : V(e^{i\theta}) \rightarrow \mathbb{R}^k$ such that

$$(5.41) \quad \frac{\partial\tilde{\Gamma}}{\partial\alpha}(e^{i\theta}, \alpha(e^{i\theta}, z), f^*(e^{i\theta}) + z) = 0, \quad (e^{i\theta}, z) \in V(e^{i\theta}).$$

We can pick $V(e^{i\theta})$ so small that $\partial^2\tilde{\Gamma}/\partial\alpha^2(e^{i\theta}, \alpha(e^{i\theta}, z), f^*(e^{i\theta}) + z)$ does not change signature for $z \in V$, i.e., $\alpha = \alpha(e^{i\theta}, z)$ is unique among those satisfying $g(e^{i\theta}, \alpha) \leq 0$, for every $z \in V(e^{i\theta})$ ("Mountain Pass Theorem"). Clearly, (i), (iii), and (iv) in Theorem 5.7 hold, and (ii) does hold, at least in a neighborhood of each $e^{i\theta} \in \mathbb{T}$. By a compactness argument, we see that (ii) also holds. This proves (a). The proof of (b) is similar to that of (a). \square

Appendix A. We have the following theorem.

THEOREM A1. *Let $q \in L_N^\infty$ be such that $\|q(\cdot)\|_{\mathbb{C}^N}$ is bounded away from 0 on \mathbb{T} . Suppose that $q \neq H_N^\infty$ and*

$$\inf_{f \in H^\infty} \|q - f\|_\infty < \inf\{\|q - g\|_\infty : g \text{ is continuous on } \mathbb{T}\}.$$

Then

- (a) *the function 0 is a best approximation to q from H_N^∞ if and only if*
 - (1) $\|q(e^{i\theta})\|_{\mathbb{C}^N}$ *is constant almost everywhere,*
 - (2) *the function $\chi^{-1}\bar{q}$ has an analytic direction F ;*
- (b) *moreover, if $q \in RL_N^1$, $g_0 \in RL_N^1$, then 1 and 2 with $F \in RH_N^1$ are necessary and sufficient for 0 to be a best approximation to q from RH_N^∞ .*

THEOREM A2. *Under the hypotheses of Theorem A1, if the set $\{e^{i\theta} \in \mathbb{T} : q \text{ is not continuous at } \theta\}^-$ has (linear) Lebesgue measure zero, then*

$$\inf_{f \in H_N^\infty} \|q - f\|_\infty = \inf_{f \in A_N} \|q - f\|_\infty.$$

The conclusion also holds if H_N^∞ and A_N are replaced by RH_N^∞ and RA_N , and if $q \in RL_N^1$, $g_0 \in RL_N^1$.

THEOREM A3. *Under the hypotheses of Theorem A1, suppose that 0 is a best approximation to q . Then*

- (1) $1 \leq \omega(\bar{q}) < \infty$,
 (2) $\chi^{-\omega(\bar{q})}\bar{q}$ has a unique analytic direction F_0 ,
 (3) Let $F \in H_N^1$ be such that $\|F\|_{L_N^1} = 1$. Then F is an analytic direction for \bar{q} if and only if there exist elements $z_1, \dots, z_{\omega(\bar{q})}$ in \mathbb{D}^- such that

$$F(e^{i\theta}) = \gamma \left(\prod_{l=1}^{\omega(\bar{q})} (e^{i\theta} - z_l)(1 - \bar{z}_l e^{i\theta}) \right) F_0(e^{i\theta}).$$

Here γ is a normalizing factor.

The proof of Theorems A1–A3 can be found in [M2].

Appendix B. The following lemma proves facts used in §3.

LEMMA B1. Let $\psi : \mathbb{R}^n \times K \rightarrow \mathbb{R}$, be of class C^1 , K compact in \mathbb{R}^p , be a function such that

$$\left(\frac{\partial \psi}{\partial x_1}(0, \kappa), \dots, \frac{\partial \psi}{\partial x_n}(0, \kappa) \right) \neq 0 \in \mathbb{R}^n \quad \forall \kappa \in K.$$

Then there exists an open neighborhood V of 0 in \mathbb{R}^n , such that, for all $k \in K$ and all $s \in \mathbb{R}$, the set

$$W(k, s) = \{x \in V : \psi(x, k) = s\}$$

is connected.

Proof. Fix $k_0 \in K$ and assume that $(\partial \psi / \partial x_1)(0, k_0) \neq 0$. Define a function $\varphi : \mathbb{R}^n \times k \rightarrow \mathbb{R}^n \times K$ by $\varphi((x_1, \dots, x_n), k) = ((\psi((x_1, \dots, x_n), k), x_2, \dots, x_n), k)$; hence the Jacobian

$$D\varphi(0, k_0) = \begin{pmatrix} \frac{\partial \psi}{\partial x_1}(0, k_0) & \frac{\partial \psi}{\partial x_2}(0, k_0) & \cdots & \frac{\partial \psi}{\partial x_n}(0, k_0) & \frac{\partial \psi}{\partial k}(0, k_0) \\ 0 & 1 & & \cdot & \cdot \\ 0 & 0 & 1 & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ 0 & 0 & \cdots & 1 & \\ 0 & 0 & \cdots & & 1 \end{pmatrix}$$

is invertible, and therefore there exists neighborhoods V_{k_0} of 0 in \mathbb{R}^n , U_{k_0} of k_0 in K such that φ is a diffeomorphism on $V_{k_0} \times U_{k_0}$. Now, if $((x_1, \dots, x_n), k) = \varphi^{-1}((y_1, \dots, y_n), k)$, then

$$(B.1) \quad y_1 = \psi((x_1, \dots, x_n), k) = \psi \varphi^{-1}((y_1, \dots, y_n), k),$$

and this shows that, for each $k \in U_{k_0}$ and each $z \in \mathbb{R}$, the set

$$A_i(z) \triangleq \{((y_1, \dots, y_n), k) \in \varphi(V_{k_0} \times U_{k_0}) : \psi \varphi^{-1}((y_1, \dots, y_n), k) = z\}$$

is connected. Hence also connected is the set

$$\varphi^{-1}(A_k(z)) = \{((x_1, \dots, x_n), k) \in V_{k_0} \times U_{k_0} : \psi((x_1, \dots, x_n), k) = z\}.$$

Finally, the sets $U_k, k \in K$, cover K , so there exists a finite cover $\{U_{k_i}\}_{i=1}^p$, and, to complete the proof, we can set $V = \bigcap_{i=1}^p V_{k_i}$. \square

CONTROLLABILITY AND STABILIZABILITY OF COUPLED STRINGS WITH CONTROL APPLIED AT THE COUPLED POINTS*

L. F. HO†

Abstract. Controllability and stabilizability of a system of coupled strings with control applied at the coupled points is studied. By investigating the properties of certain exponential series, it is shown that the system is approximate controllable if and only if related systems of uncoupled strings do not share a common eigenvalue. A sufficient condition for exact controllability is also obtained in terms of the Riesz basis properties of those exponential series.

Key words. coupled strings, controllability, stabilizability, nonharmonic Fourier series, Riesz basis

AMS subject classification. 93B05

1. Introduction. Let $L > 0$ and $0 = x_0 < x_1 < \cdots < x_N = L$. We consider the system of coupled strings

$$(1.1) \quad \frac{\partial^2 y}{\partial t^2} = \frac{1}{\rho_i} \frac{\partial}{\partial x} \left(\tau_i \frac{\partial y}{\partial x} \right), \quad x \in (x_{i-1}, x_i),$$

with conditions at the boundary and at the coupled points

$$(1.2a) \quad y(0, t) = y(L, t) = 0,$$

$$(1.2b) \quad y(x_i^+, t) = y(x_i^-, t), \quad i = 1, \dots, N-1,$$

and control applied at the coupled points

$$(1.3) \quad \tau_{i+1}(x_i) \frac{\partial y(x_i^+, t)}{\partial x} - \tau_i(x_i) \frac{\partial y(x_i^-, t)}{\partial x} = u_i(t), \quad i = 1, \dots, N-1,$$

where $u_i \in L^2[0, T]$, $i = 1, \dots, N-1$, and the functions $\rho_i, \tau_i, i = 1, \dots, N$ are continuously differentiable and positive. We will consider the state space $X = H_0^1[0, L] \times L^2[0, L]$ and the space of controls $U = (L^2[0, T])^{N-1}$. We say that the system is *exactly controllable in time* $T > 0$ if given any initial state (f_1, f_2) and terminal state (g_1, g_2) , both in X , there exist controls (u_1, \dots, u_{N-1}) in U such that the corresponding solution of (1.1) with initial conditions

$$(1.4) \quad y(x, 0) = f_1(x); \quad \frac{\partial}{\partial t} y(x, 0) = f_2(x)$$

satisfies

$$y(x, T) = g_1(x); \quad \frac{\partial}{\partial t} y(x, T) = g_2(x).$$

We say that the system is *approximately controllable in time* $T, T > 0$, if given any initial state (f_1, f_2) and terminal state (g_1, g_2) both in X and any $\epsilon > 0$, there exist controls (u_1, \dots, u_{N-1}) in U such that the solution of (1.1) with initial condition (1.4) satisfies

$$\left\| \left(y(\cdot, T), \frac{\partial y(\cdot, T)}{\partial t} \right) - (g_1, g_2) \right\|_X < \epsilon.$$

† Department of Mathematics and Statistics, Wright State University, Dayton, Ohio 45435.

We also consider the related problem of stabilizability with feedback given by

$$u_i(x, t) = k_i \frac{\partial y(x_i, t)}{\partial t}, \quad i = 1, \dots, N-1,$$

where $k_i, i = 1, \dots, N-1$, are positive constants. Controllability of the system will then be established by the “controllability via stabilizability” method of Russell [15]. The stabilizability problem, for the case of constant wave speeds, has been considered by Chen, Coleman, and West [1], Liu [11], and Liu, Huang, and Chen [12]. There is some similarity between their results and the result we obtain in this paper. We will discuss that in the examples given in §5.

In §2, we will establish some results concerning exponential series that we will need for the proof of the main results. In §3, we will state and prove our main results on stabilizability and approximate controllability. Roughly speaking, it says that the whole system is approximately controllable if and only if the uncoupled strings do not share a common eigenvalue. In §4, we consider stabilizability with a uniform exponential decay rate and the related problem of exact controllability. A sufficient condition is given in terms of the Riesz basis property for certain sets of exponential functions. Some examples are discussed in §5.

2. Nonharmonic Fourier series. In this section, we study sequences of exponential functions of the form $\{e^{i\lambda_n t}\}_{n=-\infty}^{\infty}$ where $\lambda_n, -\infty < n < \infty$, are real. Properties of completeness and independence of series of the form $\sum_n a_n e^{i\lambda_n t}$, known as nonharmonic Fourier series, have been investigated by, e.g., Levinson [8] and Riesz and Nagy [13]. Russell has also studied the relationship between the properties of such series and results in control theory [14], [15]. We first recall a definition.

DEFINITION 2.1. Let X be a Hilbert space and let $\{\phi_n\}_{n=-\infty}^{\infty}$ be a sequence in X . We say that $\{\phi_n\}_{n=-\infty}^{\infty}$ is a *Riesz basis* of X if

(RB1) $\overline{\text{span}}\{\phi_n : -\infty < n < \infty\} = X$;

(RB2) there exist constants $d, D > 0$ such that

$$(2.1) \quad d \sum_n |a_n|^2 \leq \left\| \sum_n a_n \phi_n \right\|^2 \leq D \sum_n |a_n|^2$$

for any finite sequence $\{a_n\}_{n=-\infty}^{\infty}$.

If a sequence $\{\phi_n\}_{n=-\infty}^{\infty}$ satisfies the first inequality in (RB2), we say that it is *uniformly independent*. We also have the following weaker sense of independence. (See Levinson and McCalla [9].)

DEFINITION 2.2. Let $\{\phi_n\}_{n=-\infty}^{\infty}$ be a sequence in a Hilbert space X . Suppose for all n there exists a positive constant d_n such that

$$(2.2) \quad \left\| \sum_k a_k \phi_k \right\| \geq d_n |a_n|$$

for all finite sequences $\{a_n\}_{n=-\infty}^{\infty}$; then we say that $\{\phi_n\}_{n=-\infty}^{\infty}$ is *strongly independent* in X .

The following fact is well known.

A sequence $\{\phi_n\}_{n=-\infty}^{\infty}$ is strongly independent if and only if we can find a sequence $\{\psi_n\}_{n=-\infty}^{\infty}$ such that

$$[\psi_m, \phi_n] = \delta_{m,n}.$$

The sequence $\{\psi_n\}_{n=-\infty}^{\infty}$ is said to be *biorthogonal* to $\{\phi_n\}_{n=-\infty}^{\infty}$.

If $f : \mathbb{R} \rightarrow \mathbb{C}$ has compact support, we denote

$$\hat{f}(\lambda) = \int_{-\infty}^{\infty} f(t)e^{i\lambda t} dt.$$

Obviously, \hat{f} is an entire function of λ .

Let $a < b$ and f be any function in $L^2[a, b]$; we may consider f as defined on the whole real line by extending it by zero outside $[a, b]$. In the rest of this paper, we will identify any such function f with its extension in this way.

LEMMA 2.3. *Let $f \in L^2[0, T]$ and let μ be a zero of \hat{f} of order greater than or equal to m , then*

$$\frac{\hat{f}(\lambda)}{(\lambda - \mu)^m} = \hat{g}(\lambda)$$

for some function g in $L^2[0, T]$.

Proof. We prove by induction on m . For $m = 1$, we make the following straightforward calculation:

$$\begin{aligned} \frac{\hat{f}(\lambda)}{\lambda - \mu} &= \frac{\hat{f}(\lambda) - \hat{f}(\mu)}{\lambda - \mu} = \int_0^T f(t) \frac{e^{i\lambda t} - e^{i\mu t}}{\lambda - \mu} dt \\ &= \int_0^T f(t) i \int_0^t e^{i\lambda s + i\mu(t-s)} ds dt \\ &= \int_0^T i \int_s^T f(t) e^{i\mu(t-s)} dt e^{i\lambda s} ds \\ &= \int_0^T g(t) e^{i\lambda t} dt = \hat{g}(\lambda), \end{aligned}$$

where $g(t) = i \int_t^T f(s) e^{i\mu(s-t)} ds$.

Suppose the result holds for $m \leq k$. Let μ be a zero of order greater than or equal to $k + 1$ of \hat{f} . By induction hypothesis,

$$\frac{\hat{f}(\lambda)}{(\lambda - \mu)^k} = \hat{h}(\lambda)$$

for some h in $L^2[0, T]$. Then μ is a zero of order greater than or equal to 1 of \hat{h} . By induction hypothesis once again, we have

$$\frac{\hat{f}(\lambda)}{(\lambda - \mu)^{k+1}} = \frac{\hat{h}(\lambda)}{\lambda - \mu} = \hat{g}(\lambda)$$

for some g in $L^2[0, T]$. This completes the proof of the lemma.

LEMMA 2.4. *If $\{e^{i\lambda_n t} : -\infty < n < \infty\}$ is strongly independent in $L^2[0, T]$, then for any real number ξ and any $T_1 > T$, the set*

$$\{e^{i\lambda_n t} : -\infty < n < \infty\} \cup \{e^{i\xi t}\}$$

is strongly independent in $L^2[0, T_1]$.

Proof. If $\xi = \lambda_n$ for some n , the result is trivial. So let us assume that $\xi \neq \lambda_n$ for all n . Let $\{p_n\}_{n=-\infty}^{\infty}$ be functions in $L^2[0, T]$ biorthogonal to $\{e^{i\lambda_n t} : -\infty < n < \infty\}$. Let $\delta = T_1 - T$ and let $\{g_n : -\infty < n < \infty\}$ and h be functions in $L^2[0, \delta]$ such that

$$\int_0^\delta g_n(t) e^{i\lambda_n t} dt = 1,$$

$$\int_0^\delta g_n(t) e^{i\xi t} dt = 0, \quad -\infty < n < \infty,$$

and

$$\int_0^\delta h(t) e^{i\lambda_0 t} dt = 0.$$

Let $q_n = p_n^* g_n$. (Here $*$ denotes convolution). Then q_n is supported on $[0, T_1]$ and $\hat{q}_n(\lambda) = \hat{p}_n(\lambda) \hat{g}_n(\lambda)$. So we have

$$\int_0^{T_1} q_n e^{i\lambda_m t} dt = \left(\int_0^T p_n e^{i\lambda_m t} dt \right) \left(\int_0^\delta g_n e^{i\lambda_m t} dt \right) = \delta_{m,n},$$

$$\int_0^{T_1} q_n e^{i\xi t} dt = \left(\int_0^T p_n e^{i\xi t} dt \right) \left(\int_0^\delta g_n e^{i\xi t} dt \right) = 0.$$

Let $r_0 = p_0^* h$. Then again r_0 is supported on $[0, T]$ and $\hat{r}_0(\lambda) = \hat{p}_0(\lambda) \hat{h}(\lambda)$. Let ξ be a zero of order m of \hat{r}_0 (m may be zero). By Lemma 2.3, there exists r in $L^2[0, T_1]$ such that $\hat{r}(\lambda) = \hat{r}_0(\lambda)/(\lambda - \xi)^m$. Since $\hat{r}_0(\lambda_n) = 0$ for all n , we have

$$\int_0^{T_1} r(t) e^{i\lambda_n t} dt = \hat{r}(\lambda_n) = 0 \quad \text{for all } n.$$

Because $\hat{r}_0^{(m)}(\xi) \neq 0$,

$$\int_0^{T_1} r(t) e^{i\xi t} dt = \hat{r}(\xi) = \hat{r}_0^{(m)}(\xi)/m! \neq 0.$$

It follows that $\{q_n : -\infty < n < \infty\} \cup \{m! r / \hat{r}_0^{(m)}(\xi)\}$ is biorthogonal to $\{e^{i\lambda_n t} : -\infty < n < \infty\} \cup \{e^{i\xi t}\}$ in $L^2[0, T_1]$. Hence the latter is strongly independent in $L^2[0, T_1]$.

Remark. Clearly, Lemma 2.4 remains valid if the set $\{e^{i\xi t}\}$ is replaced by any finite set $\{e^{i\xi_n t} : 1 \leq n \leq m\}$.

THEOREM 2.5. Suppose that $\{e^{i\lambda_n t}\}_{n=-\infty}^{\infty}$ and $\{e^{i\mu_n t}\}_{n=-\infty}^{\infty}$ are strongly independent in $L^2[0, T_1]$ and $L^2[0, T_2]$, respectively. Then for any $T > T_1 + T_2$, the set

$$S = \{e^{i\lambda_n t} : -\infty < n < \infty\} \cup \{e^{i\mu_n t} : -\infty < n < \infty\}$$

is strongly independent in $L^2[0, T]$.

Proof. It suffices to show the existence of a sequence biorthogonal to S . Let the sequences $\{p_n\}_{n=-\infty}^{\infty}$ and $\{q_n\}_{n=-\infty}^{\infty}$ be biorthogonal to $\{e^{i\lambda_n t}\}_{n=-\infty}^{\infty}$ and $\{e^{i\mu_n t}\}_{n=-\infty}^{\infty}$, respectively. Let $e^{i\eta \cdot} \in S$. We need to find a square integrable function r vanishing outside $[0, T]$ such that

$$(2.3) \quad \int_0^T r(t) e^{i\xi t} dt = \hat{r}(\xi) = 0 \quad \text{if } e^{i\xi \cdot} \in S \quad \text{and} \quad \xi \neq \eta$$

and

$$(2.4) \quad \int_0^T r(t)e^{i\eta t} dt = \hat{r}(\eta) = 1.$$

We consider three cases.

Case 1. $\eta = \lambda_n = \mu_m$ for some m and n .

Let $r = p_n^* q_m$. (Here $*$ again denotes convolution.) Then r vanishes outside $[0, T]$ and $\hat{r}(\lambda) = \hat{p}_n(\lambda)\hat{q}_m(\lambda)$ for any complex number λ . It is easy to see that (2.3) and (2.4) hold.

Case 2. $\eta = \lambda_n$ but does not equal any μ_m . Since $T - T_1 > T_2$, by Lemma 2.4, the set $\{e^{i\mu_m t} : -\infty < m < \infty\} \cup \{e^{i\eta t}\}$ is strongly independent in $L^2[0, T - T_1]$. In particular, we can find a function f in $L^2[0, T - T_1]$ such that $\hat{f}(\mu_m) = 0$ for all m and $\hat{f}(\eta) = 1$. Let $r = p_n^* f$. Then r is in $L^2[0, T]$ and (2.3) and (2.4) hold.

Case 3. $\eta = \mu_m$ for some m but not equal to any λ_n . We can find r in a way similar to that in Case 2.

This completes the proof of the theorem.

It follows immediately from the remark after Lemma 2.4 that Theorem 2.5 can be strengthened slightly as follows.

THEOREM 2.6. *Suppose $\{e^{i\lambda_n t}\}_{n=-\infty}^{\infty}$ and $\{e^{i\mu_n t}\}_{n=-\infty}^{\infty}$ are strongly independent in $L^2[0, T_1]$ and $L^2[0, T_2]$, respectively, and $\{\xi_n : 1 \leq n \leq m\}$ is any finite set of real numbers. Then for any $T > T_1 + T_2$, the set*

$$S = \{e^{i\lambda_n t} : -\infty < n < \infty\} \cup \{e^{i\mu_n t} : -\infty < n < \infty\} \cup \{e^{i\xi_n t} : 1 \leq n \leq m\}$$

is strongly independent in $L^2[0, T]$.

3. Approximate controllability. We first consider the stability of the following closed-loop system:

$$(3.1) \quad \frac{\partial^2 y}{\partial t^2} = \frac{1}{\rho_i} \frac{\partial}{\partial x} \left(\tau_i \frac{\partial y}{\partial x} \right), \quad x \in (x_{i-1}, x_i);$$

$$(3.2a) \quad y(0, t) = y(L, t) = 0,$$

$$(3.2b) \quad y(x_i^+, t) = y(x_i^-, t),$$

$$(3.3) \quad \tau_{i+1}(x_i) \frac{\partial y(x_i^+, t)}{\partial x} - \tau_i(x_i) \frac{\partial y(x_i^-, t)}{\partial x} = k_i \frac{\partial y(x_i, t)}{\partial t}, \quad i = 1, \dots, N-1,$$

$$(3.4) \quad y(x, 0) = f_1(x), \quad \frac{\partial y(x, 0)}{\partial t} = f_2(x),$$

where $k_i, i = 1, \dots, N-1$, are positive constants.

We will show that the stability of the above system is related to the properties of a system of N uncoupled strings.

$$(3.5) \quad \frac{\partial^2 w}{\partial t^2} = \frac{1}{\rho_i} \frac{\partial}{\partial x} \left(\tau_i \frac{\partial w}{\partial x} \right), \quad x \in (x_{i-1}, x_i);$$

$$(3.6) \quad w(x_{i-1}, t) = w(x_i, t) = 0,$$

$i = 1, \dots, N$. We will refer to the i th string in this system as $(S_i), i = 1, \dots, N$. Recall that the functions $\rho_i, \tau_i, i = 1, \dots, N$, are assumed to be continuously differentiable and positive. We first give a result of strong observability for such a system. When the wave speed is constant or when the domain and the wave speeds are both analytic, this result is known, even in higher dimensions. (See Bardos, Lebeau, and Rauch [1], Ho [4], [5], and Kormonik [7]).

THEOREM 3.1. *The systems $(S_i), i = 1, \dots, N - 1$ are strongly observable in some time $T_i > 0$ with observation*

$$(3.7) \quad \theta_i(t) = \frac{\partial}{\partial x} w(x_{i-1}, t)$$

or

$$(3.8) \quad \theta_i(t) = \frac{\partial}{\partial x} w(x_i, t).$$

In other words, for $i = 1, \dots, N$ the inequality

$$\int_0^T \theta_i(t)^2 dt \geq K_i \int_0^L \tau_i \left(\frac{\partial}{\partial x} w(x, 0) \right)^2 + \rho_i \left(\frac{\partial}{\partial t} w(x, 0) \right)^2$$

holds for some positive constants K_i .

Proof. We use a multiplier method similar to that used in Ho [6]. For simplicity of notation, let us drop the subscript i and assume that the string extends from $x = 0$ to $x = L$. We first consider the observation

$$(3.9) \quad \theta(t) = \frac{\partial}{\partial x} w(L, t).$$

Let h be the function satisfying the linear differential equation

$$(3.10) \quad h'(x) = 1 + \max \left\{ -\frac{\rho'}{\rho}, \frac{\tau'}{\tau} \right\} h(x)$$

with initial condition

$$(3.11) \quad h(0) = 0.$$

It is clear that $h(x) > 0$ for $x > 0$. Multiplying (3.1) by $\rho h(\partial w / \partial x)$ and integrating, we have

$$\int_0^T \int_0^L h \frac{\partial w}{\partial x} \left(\rho \frac{\partial^2 w}{\partial t^2} - \frac{\partial}{\partial x} \left(\tau \frac{\partial w}{\partial x} \right) \right) dx dt = 0.$$

Integrating by parts and making use of the boundary conditions for w and h , we have

$$\begin{aligned} \frac{1}{2} \int_0^T \int_0^L \frac{d}{dx} (h\rho) \left(\frac{\partial w}{\partial t} \right)^2 + \frac{d}{dx} \left(\frac{h}{\tau} \right) \left(\tau \frac{\partial w}{\partial x} \right)^2 dx dt + \int_0^L h\rho \frac{\partial w}{\partial x} \frac{\partial w}{\partial t} dx \Big|_{t=0}^{t=T} \\ - \frac{1}{2} h(L)\tau(L) \int_0^T \theta(t)^2 dt = 0. \end{aligned}$$

Then by the differential equation (3.9) and conservation of energy, we have

$$(3.12) \quad \frac{1}{2}h(L)\tau(L) \int_0^T \theta(t)^2 dt \leq TE_0 - KE_0,$$

where

$$E_0 = \frac{1}{2} \int_0^L \tau \left(\frac{\partial}{\partial x} w(x, 0) \right)^2 + \rho \left(\frac{\partial}{\partial t} w(x, 0) \right)^2 dx$$

and K is a constant that only depends on h and ρ . It follows from (3.12) that the system (3.5), (3.6) with observation (3.9) is strongly observable in any T such that $T > K$. The proof for strong observability for the observation $\theta(t) = (\partial/\partial x)w(0, t)$ is similar.

We let $\{\lambda_{n,i}\}_{n=1}^\infty$ be the sequence of eigenvalues of the system (S_i) and $\{\phi_{n,i}\}_{n=1}^\infty$ be the corresponding set of eigenfunctions satisfying

$$(3.13) \quad \frac{1}{\rho_i} \frac{\partial}{\partial x} \left(\tau_i \frac{\partial}{\partial x} \phi_{n,i} \right) + \lambda_{n,i}^2 \phi_{n,i} = 0, \quad \phi_{n,i}(x_{i-1}) = \phi_{n,i}(x_i) = 0,$$

and we assume that $\phi_{n,i}$ is normalized so that

$$(3.14) \quad \int_{x_{i-1}}^{x_i} \tau_i \left(\frac{\partial}{\partial x} \phi_{n,i} \right)^2 dx = \int_{x_{i-1}}^{x_i} \lambda_{n,i}^2 \rho_i \phi_{n,i}^2 dx = 1.$$

It is well known that strong observability is related to the Riesz basis property (more precisely, the property (RB2) in §1) of the exponential functions formed from the eigenvalues of the system (see Russell [14], [15]). The following proposition follows easily from known results but we supply its proof for completeness.

PROPOSITION 3.2. *If the system (S_i) is strongly observable in time T_i with observation $\theta_i(t)$ given by (3.8) or (3.9), then the sequence of exponential functions $\{e^{\pm i\lambda_{n,i}t}\}_{n=1}^\infty$ satisfies condition (RB2) in the space $L^2[0, T_i]$.*

Proof. Suppose the system is strongly observable in time T_i with observation $\theta_i(t)$ given by (3.9), we then have the inequality

$$(3.15) \quad \int_0^{T_i} |\theta_i(t)|^2 dt \geq K_1 E_0,$$

where

$$\begin{aligned} E_0 &= \text{total energy of } w \text{ at } t = 0 \\ &= \frac{1}{2} \int_{x_{i-1}}^{x_i} \rho_i \left(\frac{\partial w(x, 0)}{\partial t} \right)^2 + \tau_i \left(\frac{\partial w(x, 0)}{\partial x} \right)^2 dx, \end{aligned}$$

w is any solution of (3.5), (3.6), and K_1 is a constant independent of w . Also by regularity results (Lasiecka, Lions, and Triggiani [10]), there exists a constant $K_2 > 0$ such that

$$(3.16) \quad \int_0^{T_i} |\theta_i(t)|^2 dt \leq K_2 E_0.$$

Because every function $e^{i\lambda_{n,i}t} \phi_{n,i}(x)$, $1 \leq n < \infty$, is a solution of (3.5), (3.6) and by the normalization condition (3.13), the total energy $E_0 = 1$, it follows that

$$(3.17) \quad K_1 \leq \int_0^{T_i} |e^{i\lambda_{n,i}t} \phi'_{n,i}(x_{i-1})|^2 dt \leq K_2.$$

Hence

$$(3.18) \quad K_1/T_i \leq |\phi'_{n,i}(x_{i-1})|^2 \leq K_2/T_i.$$

Let $\{a_n\}_{n=-\infty, n \neq 0}^\infty$ by a finite sequence and let $b_{\pm n} = a_{\pm n}/\phi'_{n,i}(x_{i-1})$, $n = 1, 2, \dots$. The function

$$(3.19) \quad w(x, t) = \sum_{n=1}^{\infty} (b_n e^{i\lambda_{n,i}t} + b_{-n} e^{-i\lambda_{n,i}t}) \phi_{n,i}(x)$$

is a solution of (3.5), (3.6) with energy

$$(3.20) \quad E_0 = \sum_{n=1}^{\infty} (|b_n|^2 + |b_{-n}|^2)$$

and observation

$$(3.21) \quad \theta_i(t) = \sum_{n=1}^{\infty} a_n e^{i\lambda_{n,i}t} + a_{-n} e^{-i\lambda_{n,i}t}.$$

By (3.18) and (3.20), we have

$$(3.22) \quad (T_i/K_2) \sum_{n=1}^{\infty} |a_n|^2 + |a_{-n}|^2 \leq E_0 \leq (T_i/K_1) \sum_{n=1}^{\infty} |a_n|^2 + |a_{-n}|^2.$$

Hence by (3.15) and (3.16), we have

$$\begin{aligned} \frac{T_i K_1}{K_2} \sum_{n=1}^{\infty} |a_n|^2 + |a_{-n}|^2 &\leq \int_0^{T_i} \left| \sum_{n=1}^{\infty} a_n e^{i\lambda_{n,i}t} + a_{-n} e^{-i\lambda_{n,i}t} \right|^2 dt \\ &\leq \frac{T_i K_2}{K_1} \sum_{n=1}^{\infty} |a_n|^2 + |a_{-n}|^2. \end{aligned}$$

This completes the proof of the proposition when θ_i is given by (3.9). The proof for θ_i given by (3.8) is similar.

Let us now consider the system (3.1)–(3.3). Let $T > 0$. Given any initial state $(f_1, f_2) \in H_0^1[0, L] \times L^2[0, L]$, we can find the solution of (3.1)–(3.3) with initial conditions (3.4). Denote

$$\begin{aligned} \mathcal{E}y(t) &= \text{the total energy of } y \text{ at time } t \\ (3.23) \quad &= \frac{1}{2} \sum_{k=1}^{N-1} \int_{x_i}^{x_{i+1}} \rho_i(x) \left(\frac{\partial y(x, t)}{\partial t} \right)^2 = \tau_i(x) \left(\frac{\partial y(x, t)}{\partial x} \right)^2 dx. \end{aligned}$$

We have

$$\begin{aligned} (3.24) \quad \frac{d\mathcal{E}y(t)}{dt} &= \sum_{k=1}^{N-1} \frac{\partial y(x_i, t)}{\partial t} \left(\tau_i(x_i) \frac{\partial y(x_i^-, t)}{\partial x} - \tau_{i+1}(x_i) \frac{\partial y(x_i^+, t)}{\partial x} \right) \\ &= - \sum_{k=1}^{N-1} k_i \left(\frac{\partial y(x_i, t)}{\partial t} \right)^2 \end{aligned}$$

It follows that for any $t_1, t_2 > 0$, we have

$$(3.25) \quad \mathcal{E}y(t_1) - \mathcal{E}y(t_2) = - \sum_{k=1}^{N-1} \int_{t_1}^{t_2} k_i \left(\frac{\partial y(x_i, t)}{\partial t} \right)^2 dt.$$

Hence in particular,

$$\begin{aligned} \sum_{k=1}^{N-1} \int_0^T k_i \left(\frac{\partial y(x_i, t)}{\partial t} \right)^2 dt &= \mathcal{E}y(0) - \mathcal{E}y(T) \leq \mathcal{E}y(0) \\ &= \frac{1}{2} \sum_{k=1}^{N-1} \int_{x_i}^{x_{i+1}} \rho_i(x) f_2(x)^2 + \tau_i(x) f_1'(x)^2 dx \\ &\leq K \|f_1\|_{H_0^1[0, L]}^2 + \|f_2\|_{L^2[0, L]}^2, \end{aligned}$$

where K is a positive constant. So if we define

$$(3.26) \quad \mathcal{N}_T(f_1, f_2) = \left(\sum_{k=1}^{N-1} \int_0^T k_i \left(\frac{\partial y(x_i, t)}{\partial t} \right)^2 dt \right)^{1/2},$$

then $\mathcal{N}_T(\cdot, \cdot)$ is a seminorm on $H^1[0, L] \times L^2[0, L]$ and by (3.22), we have

$$(3.27) \quad \mathcal{E}y(t) - \mathcal{E}y(t+T) = \mathcal{N}_T \left(y(\cdot, t), \frac{\partial y(\cdot, t)}{\partial t} \right)^2$$

for all $t > 0$.

The following theorem says that a necessary and sufficient condition for \mathcal{N}_T to be a norm for some $T > 0$ is that the following holds:

(C1) The systems $(S_i), i = 1, \dots, N$, do not have a common eigenvalue.

In what follows, $T_i, i = 1, \dots, N$, will denote times for which the conclusion of Theorem 3.1 holds.

THEOREM 3.3. *If condition (C1) does not hold, then we can find nonzero $(f_1, f_2) \in H_0^1[0, L] \times L^2[0, L]$ such that $\mathcal{N}_T(f_1, f_2) = 0$ for all $T > 0$. Conversely, if condition (C1) holds, then $\mathcal{N}_T(\cdot, \cdot)$ defines a norm on $H_0^1[0, L] \times L^2[0, L]$ for any $T > T_0 = \max\{T_i + T_{i+1} : 1 \leq i \leq N-1\}$.*

Proof. Suppose that all the $(S_i), i = 1, \dots, N$ have a common eigenvalue λ and with eigenfunctions $\phi_i, i = 1, \dots, N$. Let $f_1(x) = c_i \phi_i(x)$ if $x \in (x_{i-1}, x_i)$ and let $f_2 \equiv 0$. With appropriate choice of the constants $c_i, i = 1, \dots, N$, we can make

$$c_i \tau_i(x_i) \phi_i'(x_i) = c_{i+1} \tau_{i+1}(x_i) \phi_{i+1}'(x_i), \quad i = 1, \dots, N-1.$$

Then

$$y(x, t) = c_i \cos(\lambda t) \phi_i(x) \quad \text{if } x \in (x_{i-1}, x_i)$$

would be the solution of (3.1)–(3.3) with initial condition $y(x, 0) = f_1(x), \partial y(x, 0)/\partial t = f_2(x)$. Since $y(x_i, t) = 0$, for $i = 1, \dots, N-1$ and $t > 0$, it follows that $\mathcal{N}_T(f_1, f_2) = 0$ for all $T > 0$.

Next, suppose that the system (S_i) has eigenvalues

$$\Lambda_i = \{\lambda_{n,i} : 1 \leq n < \infty\}$$

and normalized eigenfunctions (see (3.14))

$$\{\phi_{n,i}(x) : 1 \leq n < \infty\}$$

$i = 1, \dots, N$. Suppose $\mathcal{N}_T(f_1, f_2) = 0$. Let $y(x, t)$ be the solution of (3.1), (3.4). Then $\partial y(x_i, t)/\partial t = 0$ for $i = 1, \dots, N-1, 0 \leq t \leq T$. So we have $y(x_i, t) = \text{constant} = \alpha_i, i = 1, \dots, N-1$. Let

$$w(x, t) = y(x, t) - \alpha_{i-1} - \frac{(\alpha_i - \alpha_{i-1})(x - x_{i-1})}{x_i - x_{i-1}}.$$

(We take $\alpha_0 = \alpha_N = 0$.) Then w is a solution of $(S_i), i = 1, \dots, N$. So we can expand

$$(3.28) \quad w(x, t) = \sum_{n=1}^{\infty} (a_{n,i} e^{i\lambda_{n,i}t} + a_{-n,i} e^{i\lambda_{-n,i}t}) \phi_{n,i}(x),$$

where $\lambda_{-n,i} = -\lambda_{n,i}$. It follows that

$$\begin{aligned} & \sum_{n=1}^{\infty} (a_{n,i+1} e^{i\lambda_{n,i+1}t} + a_{-n,i+1} e^{i\lambda_{-n,i+1}t}) \phi'_{n,i+1}(x_i) \tau_{i+1}(x_1) \\ & - \sum_{n=1}^{\infty} (a_{n,i} e^{i\lambda_{n,i}t} + a_{-n,i} e^{i\lambda_{-n,i}t}) \phi'_{n,i}(x_i) \tau_i(x_i) \\ (3.29) \quad & = \tau_{i+1}(x_i) \frac{\partial}{\partial x} w(x_i^+, t) - \tau_i(x_i) \frac{\partial}{\partial x} w(x_i^-, t) \\ & = \tau_{i+1}(x_i) \frac{\partial}{\partial x} y(x_i^+, t) - \tau_i(x_i) \frac{\partial}{\partial x} y(x_i^-, t) - \tau_{i+1}(x_i) \frac{\alpha_{i+1} - \alpha_i}{x_{i+1} - x_i} \\ & \quad + \tau_i(x_i) \frac{\alpha_i - \alpha_{i-1}}{x_i - x_{i-1}} \\ & = -\tau_{i+1}(x_i) \frac{\alpha_{i+1} - \alpha_i}{x_{i+1} - x_i} + \tau_i(x_i) \frac{\alpha_i - \alpha_{i-1}}{x_i - x_{i-1}}. \end{aligned}$$

By Theorem 2.6, the set $\{e^{\pm i\lambda_{n,i}t} : 0 < n < \infty\} \cup \{e^{\pm i\lambda_{n,i+1}t} : 0 < n < \infty\} \cup \{1\}$ is strongly independent in $L^2[0, T]$. So by (3.29), we have

$$\begin{aligned} a_{n,i} &= 0 & \text{if } \lambda_{n,i} \notin \Lambda_i \cap \Lambda_{i+1}, \\ a_{n,i+1} &= 0 & \text{if } \lambda_{n,i+1} \notin \Lambda_i \cap \Lambda_{i+1}, \end{aligned}$$

and

$$(3.30) \quad \tau_{i+1}(x_i) \frac{\alpha_{i+1} - \alpha_i}{x_{i+1} - x_i} = \tau_i(x_i) \frac{\alpha_i - \alpha_{i-1}}{x_i - x_{i-1}}.$$

Suppose w is not identically zero. Then there exist some n and i such that $a_{n,i} \neq 0$. It follows that $\lambda_{n,i} \in \Lambda_{i+1}$. Let $\lambda_{n,i} = \lambda_{m,i+1}$. Then we must have $a_{m,i+1} \neq 0$. Hence $\lambda_{n,i} = \lambda_{m,i+1} \in \Lambda_{i+2}$. Proceeding in this way, we can then show that $\lambda_{n,i} \in \Lambda_j$ for all $j > i$. In a similar way, we can prove that $\lambda_{n,i} \in \Lambda_j$ for all $j < i$. Hence $\lambda_{n,i}$ is a common eigenvalue of the systems $(S_i), i = 1, \dots, N$, a contradiction. So we must have $w \equiv 0$. Also, since (3.30) holds for $i = 1, \dots, N-1$, it follows that $\alpha_i - \alpha_{i-1}, i = 1, \dots, N$, all have the same sign. Because $\alpha_0 = \alpha_N = 0$. This forces $\alpha_i = 0$ for $i = 1, \dots, N-1$. Hence we have proved that $y \equiv 0$ and therefore that $(f_1, f_2) = 0$. Thus \mathcal{N}_T is indeed a norm.

Remark. We see from equality (3.27) that if (C1) holds, then \mathcal{N}_T is a norm weaker than the $H_0^1[0, L] \times L^2[0, L]$ norm.

Theorem 3.4 is a consequence of Theorem 3.3.

THEOREM 3.4. *If condition (C1) does not hold, then the system (3.1)–(3.3) is not asymptotically stable. Conversely, if condition (C1) holds, then the solution of the system (3.1)–(3.3) satisfies*

$$\lim_{t \rightarrow +\infty} \mathcal{N} \left(y(\cdot, t), \frac{\partial y(\cdot, t)}{\partial t} \right) = 0,$$

where $\mathcal{N}(\cdot, \cdot)$ is a norm on $H_0^1[0, L] \times L^2[0, L]$.

Proof. The proof of the first part follows easily from the corresponding part in Theorem 3.3. Conversely, if the systems (S_i) do not have a common eigenvalue, then by Theorem 3.3, we can find some $T > 0$ such that \mathcal{N}_T is a norm on $H_0^1[0, L] \times L^2[0, L]$. From equality (3.24), we know that $\mathcal{E}y(t)$ is a nonnegative decreasing function of t . Hence $\alpha = \lim_{t \rightarrow +\infty} \mathcal{E}y(t)$ exists. Also, by (3.26), we have

$$\mathcal{N}_T \left(y(\cdot, t), \frac{\partial y(\cdot, t)}{\partial t} \right)^2 = \mathcal{E}y(t) - \mathcal{E}y(t + T).$$

Hence

$$\lim_{t \rightarrow +\infty} \mathcal{N}_T \left(y(\cdot, t), \frac{\partial y(\cdot, t)}{\partial t} \right)^2 = \alpha - \alpha = 0.$$

This completes the proof of the theorem.

We will use the following elementary result of functional analysis.

PROPOSITION 3.5. *If T is a bounded linear operator on a Hilbert space X satisfying*

$$\|\mathcal{F}x\| < \|x\| \quad \text{for all } x \in X, x \neq 0,$$

then $I - T$ has dense range.

THEOREM 3.6. *If condition (C1) does not hold, then the system (1.1)–(1.3) is not approximately controllable in any time $T > 0$. Conversely, if condition (C1) holds, then the system (1.1)–(1.3) is approximately controllable in any time $T > T_0 = \max\{t_i + T_{i+1} : 1 \leq i \leq N - 1\}$.*

Proof. Suppose that the systems (S_i) , $i = 1, \dots, N$, have a common eigenvalue λ with eigenfunctions ϕ_i , $i = 1, \dots, N$. Let

$$z(x, t) = c_i \phi_i(x) \cos \lambda t \quad \text{if } x \in [x_{i-1}, x_i], i = 1, \dots, N.$$

Then z satisfies

$$\begin{aligned} \frac{\partial^2 z}{\partial t^2} &= \frac{1}{\rho_i} \frac{\partial}{\partial x} \left(\tau_i \frac{\partial z}{\partial x} \right), & x \in (x_{i-1}, x_i); \\ z(0, t) &= z(L, t) = 0, \\ z(x_i^+, t) &= z(x_i^-, t) = 0, & i = 1, \dots, N - 1. \end{aligned}$$

Also, we can choose the constants c_i , $i = 1, \dots, N - 1$, so that

$$\tau_{i+1}(x_i) \frac{\partial z(x_i^+, t)}{\partial x} = \tau_i(x_i) \frac{\partial z(x_i^-, t)}{\partial x}, \quad i = 1, \dots, N - 1.$$

(See the proof of Theorem 3.3.) Let y be a solution of (1.1)–(1.3). It is easy to see that

$$\frac{d}{dt} \sum_{i=1}^{x_i} \rho_i \left(z \frac{\partial y}{\partial t} - y \frac{\partial z}{\partial t} \right) dx = 0.$$

So if y satisfies the initial condition

$$y(x, 0) = \frac{\partial y(x, 0)}{\partial t} = 0,$$

then

$$\sum_{i=1}^N \int_{x_{i-1}}^{x_i} \rho_i(x) \left(z(x, T) \frac{\partial y(x, T)}{\partial t} - y(x, T) \frac{\partial z(x, T)}{\partial t} \right) dx = 0.$$

Hence we have found a nonzero pair of functions orthogonal, in $L^2[0, L] \times L^2[0, L]$, to the set of terminal states $(y(x, T), \partial y(x, T)/\partial x)$. So this set is not dense in $L^2[0, L] \times L^2[0, L]$. Therefore, it is not dense in $H^1[0, L] \times L^2[0, L]$ either and the system is not approximately controllable in time T .

Conversely, suppose that the systems $(S_i), i = 1, \dots, N-1$ do not have a common eigenvalue. Then by Theorem 3.3, the seminorm \mathcal{N}_T is a norm if $T > T_0 = \max\{T_i + T_{i+1} : 1 \leq i \leq N-1\}$. Consider the norm $\|\cdot\|_E$ on $H_0^1[0, L] \times L^2[0, L]$ defined by

$$(3.31) \quad \|(f_1, f_2)\|_E = \left(\frac{1}{2} \sum_{k=1}^{N-1} \int_{x_i}^{x_{i+1}} \rho_i(x) f_1(x)^2 + \tau_i(x) f_2(x)^2 dx \right)^{1/2}.$$

This norm is equivalent with the usual $H_0^1[0, L] \times L^2[0, L]$ norm. Now consider given initial state (f_1, f_2) in $H_0^1[0, L] \times L^2[0, L]$. For (h_1, h_2) in $H_0^1[0, L] \times L^2[0, L]$, let y_1 be the solution of (3.1)–(3.3) with the initial conditions

$$y_1(x, 0) = h_1(x) \quad \text{and} \quad \frac{\partial y_1(x, 0)}{\partial t} = -h_2(x)$$

and let y_2 be the solution of (3.1)–(3.3) with initial conditions

$$y_2(x, 0) = y_1(x, T) - f_1(x) \quad \text{and} \quad \frac{\partial y_2(x, 0)}{\partial t} = -\frac{\partial y_1(x, T)}{\partial t} - f_2(x).$$

Let \mathcal{T} be the mapping that carries (h_1, h_2) to $(y_2(\cdot, T), \partial y_2(\cdot, T)/\partial t)$. It follows from equality (3.27) that because \mathcal{N}_T is a norm, we have $\|\mathcal{T}(h_1, h_2)\|_E < \|(h_1, h_2)\|_E$ for $(h_1, h_2) \neq 0$. Then by Proposition 3.5, $I - \mathcal{T}$ has dense range in $X = H_0^1[0, L] \times L^2[0, L]$. Now let $y(x, t) = y_1(x, T - t) - y_2(x, t)$. Then y is a solution of (1.1)–(1.3) with initial conditions

$$y(x, 0) = f_1(x) \quad \text{and} \quad \frac{\partial y(x, 0)}{\partial t} = f_2(x)$$

and control functions

$$u_i(t) = k_i \left(\frac{\partial y_1(x, T - t)}{\partial t} - \frac{\partial y_2(x, t)}{\partial t} \right), \quad i = 1, \dots, N-1.$$

Because both y_1 and y_2 have finite energy for all time t , by (3.25) we have $u_i \in L^2[0, T], i = 1, \dots, N-1$. Also, the terminal state of y is

$$y(x, T) = h_1(x) - y_2(x, T), \quad \frac{\partial y(x, T)}{\partial t} = h_2(x) - \frac{\partial y_2(x, T)}{\partial t}.$$

Because $I - \mathcal{T}$ has dense range, the set of such terminal states is dense in $H_0^1[0, L] \times L^2[0, L]$. Hence the system (1.1)–(1.3) is approximately controllable.

4. Stabilizability with a uniform exponential decay rate and exact controllability.

In this section, we still consider the closed-loop system (3.1)–(3.3) and the related systems of uncoupled strings $(S_i), i = 1, \dots, N$, with sets of eigenvalues $\{\lambda_{n,i} : 1 \leq n < \infty\}$ and eigenfunctions $\{\phi_{n,i} : 1 \leq n < \infty\}, i = 1, \dots, N$. We will give a sufficient condition under which the system (3.1)–(1.3) will decay with a uniform exponential rate. Then by the “controllability via stabilizability method” of Russell [15], this will, in turn, give us a sufficient condition for the open-loop system (1.1)–(1.3) to be exactly controllable. We consider the following condition:

(C2) There exists $i, 1 \leq i \leq N - 1$, and $T^* > 0$ such that

$$\{\lambda_{n,i} : 1 \leq n < \infty\} \cap \{\lambda_{n,i+1} : 1 \leq n < \infty\} = \emptyset$$

and the set of exponential functions

$$\{e^{\pm i\lambda_{n,i}t} : 1 \leq n < \infty\} \cup \{e^{\pm i\lambda_{n,i+1}t} : 1 \leq n < \infty\}$$

satisfies condition (RB2) in $L^2[0, T^*]$.

Clearly (C2) is a stronger condition than (C1). Let \mathcal{N}_T and T_1, \dots, T_N be as defined in the previous section.

THEOREM 4.1. *If condition (C2) holds, then the seminorm \mathcal{N}_T is a norm equivalent with the $H_0^1[0, L] \times L^2[0, L]$ norm if $T > T_0 = \max\{T^*, T_1, T_2, \dots, T_N\}$.*

To prove Theorem 4.1, we need the following lemma.

LEMMA 4.2. *Let $T > 0$. There exists a positive constant K such that for any v satisfying*

$$(4.1) \quad \rho \frac{\partial^2 v}{\partial t^2} = \frac{\partial}{\partial x} \left(\tau \frac{\partial v}{\partial x} \right), \quad t > 0, a < x < b;$$

$$(4.2) \quad v(x, 0) = \frac{\partial v(x, 0)}{\partial t} = 0, \quad a \leq x \leq b;$$

we have

$$(4.3) \quad \int_0^T \left(\frac{\partial v(a, t)}{\partial x} \right)^2 + \left(\frac{\partial v(b, t)}{\partial x} \right)^2 dt \leq K \int_0^T \left(\frac{\partial v(a, t)}{\partial t} \right)^2 + \left(\frac{\partial v(b, t)}{\partial t} \right)^2 dt.$$

Proof. By a multiplier method, (using, for example, the multiplier $(x - (a+b)/2)\partial w/\partial x$) we can easily prove the following inequality:

$$(4.4) \quad \int_0^s \left(\frac{\partial w(a, t)}{\partial x} \right)^2 + \left(\frac{\partial w(a, t)}{\partial t} \right)^2 + \left(\frac{\partial w(b, t)}{\partial x} \right)^2 + \left(\frac{\partial w(b, t)}{\partial t} \right)^2 dt \\ \leq K_1 \left(\mathcal{E}w(0) + \mathcal{E}w(s) + \int_0^s \mathcal{E}w(t) dt \right)$$

for any function w satisfying

$$(4.5) \quad \rho \frac{\partial^2 w}{\partial t^2} = \frac{\partial}{\partial x} \left(\tau \frac{\partial w}{\partial x} \right), \quad 0 \leq t \leq s, \quad a \leq x \leq b.$$

Here K_1 is a constant independent of w and s . Suppose that in addition,

$$(4.6) \quad w(a, t) = k_1, \quad w(b, t) = k_2,$$

for some constants k_1 and k_2 . Then by conservation of energy and (4.4) we have

$$(4.7) \quad \int_0^s \left(\frac{\partial w(a, t)}{\partial x} \right)^2 + \left(\frac{\partial w(b, t)}{\partial x} \right)^2 dt \leq K_1(2+s)\mathcal{E}w(0) = K_1(2+s)\mathcal{E}w(s).$$

If v satisfies (4.1), (4.2), then

$$\begin{aligned} & \frac{d}{dt} \int_a^b \rho \frac{\partial w}{\partial t} \frac{\partial v}{\partial t} + \tau \frac{\partial w}{\partial x} \frac{\partial v}{\partial x} dx \\ &= \tau(b) \frac{\partial w(b, t)}{\partial x} \frac{\partial v(b, t)}{\partial t} - \tau(a) \frac{\partial w(a, t)}{\partial x} \frac{\partial v(a, t)}{\partial t}. \end{aligned}$$

Hence

$$\begin{aligned} & \int_a^b \rho(x) \frac{\partial w(x, s)}{\partial t} \frac{\partial v(x, s)}{\partial t} + \sigma(x) \frac{\partial w(x, s)}{\partial x} \frac{\partial v(x, s)}{\partial x} dx \\ &= \tau(b) \int_0^s \frac{\partial w(b, t)}{\partial x} \frac{\partial v(b, t)}{\partial t} dt \\ &\quad - \tau(a) \int_0^s \frac{\partial w(a, t)}{\partial x} \frac{\partial v(a, t)}{\partial t} dt \\ &\leq \tau(a) \left(\int_0^s \left(\frac{\partial w(a, t)}{\partial x} \right)^2 dt \right)^{1/2} \left(\int_0^s \left(\frac{\partial v(a, t)}{\partial t} \right)^2 dt \right)^{1/2} \\ &\quad + \tau(b) \left(\int_0^s \left(\frac{\partial w(b, t)}{\partial x} \right)^2 dt \right)^{1/2} \left(\int_0^s \left(\frac{\partial v(b, t)}{\partial t} \right)^2 dt \right)^{1/2} \\ &\leq m(K_1(2+s)\mathcal{E}w(s))^{1/2} \left(\int_0^s \left(\frac{\partial v(a, t)}{\partial t} \right)^2 \right. \\ &\quad \left. + \left(\frac{\partial v(b, t)}{\partial t} \right)^2 dt \right)^{1/2}, \end{aligned}$$

where $m = \max\{\tau(a), \tau(b)\}$. Since this holds for any w satisfying (4.5) and (4.6), we conclude that

$$(4.8) \quad \mathcal{E}v(s) \leq K_2(2+s) \int_0^s \left(\frac{\partial v(a, t)}{\partial t} \right)^2 + \left(\frac{\partial v(b, t)}{\partial t} \right)^2 dt,$$

where K_2 is a constant independent of v and s . Noting that this holds for any arbitrary s , we have, by (4.4) again, that

$$\begin{aligned} & \int_0^T \left(\frac{\partial v(a, t)}{\partial x} \right)^2 + \left(\frac{\partial v(b, t)}{\partial x} \right)^2 dt \\ &\leq K_1 \left(\int_0^T \mathcal{E}v(t) dt + \mathcal{E}v(T) \right) \\ &\leq K_1 K_2 \left(\int_0^T (2+t) \int_0^t \left(\frac{\partial v(a, s)}{\partial t} \right)^2 + \left(\frac{\partial v(b, s)}{\partial t} \right)^2 ds dt \right. \\ &\quad \left. + (2+T) \int_0^T \left(\frac{\partial v(a, t)}{\partial t} \right)^2 + \left(\frac{\partial v(b, t)}{\partial t} \right)^2 dt \right) \end{aligned}$$

$$\leq K_1 K_2 (1+T)(2+T) \int_0^T \left(\frac{\partial v(a,t)}{\partial t} \right)^2 + \left(\frac{\partial v(b,t)}{\partial t} \right)^2 dt.$$

This completes the proof of the lemma.

Proof of Theorem 4.1. Let y satisfy (3.1)–(3.3) with initial condition (3.4). Let v satisfy

$$\begin{aligned} \rho_i \frac{\partial^2 v}{\partial t^2} &= \frac{\partial}{\partial x} \left(\tau_i \frac{\partial v}{\partial x} \right), \quad t > 0, \quad x_{i-1} < x < x_i, \quad i = 1, \dots, N; \\ v(x, 0) &= \frac{\partial v(x, 0)}{\partial t} = 0, \quad \text{for } 0 < x < L; \\ v(x_i^-, t) &= v(x_i^+, t) = y(x, t), \quad i = 1, \dots, N-1; \\ v(0, t) &= v(L, t) = 0. \end{aligned}$$

Then $w = y - v$ satisfies

$$\begin{aligned} \rho_i \frac{\partial^2 w}{\partial t^2} &= \frac{\partial}{\partial x} \left(\tau_i \frac{\partial w}{\partial x} \right), \quad t > 0, \quad x_{i-1} < x < x_i, \quad i = 1, \dots, N; \\ w(x, 0) &= f_1(x), \quad \frac{\partial w(x, 0)}{\partial t} = f_2(x) \quad \text{for } 0 < x < L; \\ w(x_i^-, t) &= w(x_i^+, t) = 0, \quad i = 1, \dots, N-1; \\ w(0, t) &= w(L, t) = 0. \end{aligned}$$

Thus w is a solution of the uncoupled strings $(S_i), i = 1, \dots, N$. Let $1 \leq j \leq N-1$ be such that for $i = j$, condition (C2) is satisfied. We expand

$$(4.9) \quad w(x, t) = \sum_{n=1}^{\infty} (a_{n,i} e^{i\lambda_{n,i}t} + a_{-n,i} e^{i\lambda_{-n,i}t}) \phi_{n,i}(x).$$

Denote $\omega_i(t) = \tau_{i+1}(x_i)(\partial/\partial x)w(x_i^+, t) - \tau_i(x_i)(\partial/\partial x)w(x_i^+, t)$. Then

$$\begin{aligned} \omega_i(t) &= \sum_{n=1}^{\infty} (a_{n,i+1} e^{i\lambda_{n,i+1}t} + a_{-n,i+1} e^{i\lambda_{-n,i+1}t}) \phi'_{n,i+1}(x_i) \tau_{i+1}(x_i) \\ &\quad - \sum_{n=1}^{\infty} (a_{n,i} e^{i\lambda_{n,i}t} + a_{-n,i} e^{i\lambda_{-n,i}t}) \phi'_{n,i}(x_i) \tau_i(x_i). \end{aligned}$$

By the observability result Theorem 3.1 and the fact that the eigenfunctions are normalized, it follows that for all $i, 1 \leq i \leq N$, the sequences $\{\phi'_{n,i}(x_{i-1})\}_{n=1}^{\infty}$ and $\{\phi'_{n,i}(x_i)\}_{n=1}^{\infty}$ are bounded and bounded away from zero. So since the set of exponential functions

$$\{e^{\pm i\lambda_{n,j}t} : 1 \leq n < \infty\} \cup \{e^{\pm i\lambda_{n,j+1}t} : 1 \leq n < \infty\}$$

satisfies condition (RB2) in $L^2[0, T]$, there exist constant $d > 0$ such that

$$(4.10) \quad \int_0^{T^*} |\omega_j(t)|^2 dt \geq d \sum_{n=1}^{\infty} |a_{n,j+1}|^2 + |a_{-n,j+1}|^2 + |a_{n,j}|^2 + |a_{-n,j}|^2.$$

Hence, there exists constant $d_1 > 0$ such that

$$(4.11) \quad \int_0^{T^*} |\omega_j(t)|^2 dt \geq d_1 (E_{j+1} + E_j),$$

where E_i denotes the total (constant) energy of the system $(S_i), i = 1, \dots, N$. By the observability result Theorem 3.1, it follows that for each $i, 1 \leq i \leq N$, there exists constant $K_i > 0$ such that

$$E_i \leq K_i \int_0^{T_i} \left| \frac{\partial}{\partial x} w(x_{i-1}^+, t) \right|^2 dt$$

and

$$E_i \leq K_i \int_0^{T_i} \left| \frac{\partial}{\partial x} w(x_i^-, t) \right|^2 dt.$$

and, by regularity results [10], there exists constant $M_i > 0$ such that

$$\int_0^{T_i} \left| \frac{\partial}{\partial x} w(x_{i-1}^+, t) \right|^2 dt \leq M_i E_i$$

and

$$\int_0^{T_i} \left| \frac{\partial}{\partial x} w(x_i^-, t) \right|^2 dt \leq M_i E_i$$

So for $i, j+1 < i \leq N$,

$$\begin{aligned} E_i &\leq K_i \int_0^{T_i} \left| \frac{\partial}{\partial x} w(x_{i-1}^+, t) \right|^2 dt \\ (4.12) \quad &\leq 2K_i/\tau_i(x_{i-1})^2 \left(\int_0^{T_i} \left| \tau_{i-1}(x_{i-1}) \frac{\partial}{\partial x} w(x_{i-1}^-, t) \right|^2 + |\omega_{i-1}(t)|^2 dt \right) \\ &\leq 2K_i/\tau_i(x_{i-1})^2 \left(M_i \tau_{i-1}(x_{i-1})^2 E_{i-1} + \int_0^{T_i} |\omega_{i-1}(t)|^2 dt \right). \end{aligned}$$

Hence, we have

$$(4.13) \quad E_{j+2} + \dots + E_N \leq C_1 \left(\sum_{i=j+1}^{N-1} \int_0^{T_i} |\omega_i(t)|^2 dt + E_{j+1} \right)$$

for some positive constant C_1 . In a similar way, we can prove that

$$(4.14) \quad E_1 + \dots + E_{j-1} \leq C_2 \left(\sum_{i=1}^{j-1} \int_0^{T_i} |\omega_i(t)|^2 dt + E_j \right)$$

for some positive constant C_2 . Combining (4.11), (4.13), and (4.14), we have

$$(4.15) \quad \|(f_1, f_2)\|_E^2 = \mathcal{E}w(0) = E_1 + E_2 + \dots + E_N \leq C_3 \sum_{i=1}^N \int_0^{T_i} |\omega_i(t)|^2 dt$$

for some positive constant C_3 . But by the definition of ω_i and the conditions on y at the coupled points, we have

$$\omega_i(t) = k_i \frac{\partial}{\partial t} y(x_i, t) - \left(\tau_{i+1}(x_i) \frac{\partial}{\partial x} v(x_i^+, t) - \tau_i(x_i) \frac{\partial}{\partial x} v(x_i^-, t) \right).$$

Hence

$$(4.16) \quad \sum_{i=1}^N \int_0^{T_i} |\omega_i(t)|^2 dt \leq C_4 \sum_{i=1}^N \int_0^{T_i} \left| \frac{\partial y(x_i, t)}{\partial t} \right|^2 + \left| \frac{\partial v(x_{i-1}^+, t)}{\partial x} \right|^2 + \left| \frac{\partial v(x_i^-, t)}{\partial x} \right|^2 dt$$

for some constant $C_4 > 0$. By Lemma 4.2 and the fact that $\partial v(x_i, t)/\partial t = \partial y(x_i, t)/\partial t$, we have

$$(4.17) \quad \sum_{i=1}^N \int_0^{T_i} |\omega_i(t)|^2 dt \leq C_5 \sum_{i=1}^N \int_0^{T_i} \left| \frac{\partial y(x_i, t)}{\partial t} \right|^2 dt \leq C_6 \mathcal{N}_T(f_1, c_2),$$

where C_5 and C_6 are positive constants. Combining (4.15) and (4.17), we see that the norm \mathcal{N}_T is stronger than the $H_0^1[0, L] \times L^2[0, L]$ norm. Since we already know that the norm \mathcal{N}_T is weaker than the $H_0^1[0, L] \times L^2[0, L]$ norm (see the remark after Theorem 3.3) this completes the proof of Theorem 4.1.

From Theorem 4.1, we immediately have the following theorem.

THEOREM 4.3. *If condition (2) holds, then the system (3.1)–(3.3) is asymptotically stable with a uniform exponential rate of decay. In other words, we can find positive constants M and k such that*

$$\mathcal{E}y(t) \leq M e^{-kt} \mathcal{E}y(0)$$

for all y satisfying (3.1)–(3.3).

Proof. Suppose (C2) holds. Let T_0 be as in the statement of Theorem 4.1. Then for $T > T_0$, \mathcal{N}_T is equivalent with the $H_0^1[0, L] \times L^2[0, L]$ norm. Hence we can find a constant $c > 0$ such that

$$(4.18) \quad \mathcal{N}_T(f_1, f_2) \geq c \|(f_1, f_2)\|_E.$$

Then by (3.27), we have, for any $t > 0$,

$$(4.19) \quad \begin{aligned} \mathcal{E}y(t+T) - \mathcal{E}y(t) &= -\mathcal{N}_T \left(y(\cdot, t), \frac{\partial y(\cdot, t)}{\partial t} \right)^2 \\ &\leq -c^2 \left\| \left(y(\cdot, t), \frac{\partial y(\cdot, t)}{\partial t} \right) \right\|_E^2 = -c^2 \mathcal{E}y(t). \end{aligned}$$

Because $\mathcal{E}y(t)$ decreases with t , it follows from the semigroup property that

$$\mathcal{E}y(t) \leq M e^{-kt} \mathcal{E}y(0),$$

where $M = (1 - c^2)^{-1}$ and $k = -\ln M/T$. (Note that from (4.19), we must have $c^2 < 1$.)

Using the “controllability via stabilizability method” of Russell, we can then prove the following theorem.

THEOREM 4.4. *If condition (C2) holds, then the system is exactly controllable in any time $T > T_0 \max\{T^*, T_1, T_2, \dots, T_n\}$.*

5. Examples. We consider a special situation where $N = 2$ and ρ_i, τ_i are constants, $i = 1, 2$. Denoting $c_i = (\tau_i/\rho_i)^{1/2}$ and $L_i = x_i - x_{i-1}$, $i = 1, 2$, the system (1.1)–(1.3) becomes

$$(5.1) \quad \frac{\partial^2 y}{\partial t^2} = c_i^2 \frac{\partial^2 y}{\partial x^2}, \quad x \in (x_{i-1}, x_i), \quad i = 1, 2;$$

$$(5.2) \quad y(0, t) = y(L, t) = 0,$$

$$(5.3) \quad y(x_1^+, t) = y(x_1^-, t),$$

$$(5.4) \quad \tau_2 \frac{\partial y(x_1^+, t)}{\partial x} - \tau_1 \frac{\partial y(x_1^-, t)}{\partial x} = u_1(t).$$

The eigenvalues of the uncoupled strings are

$$\lambda_{n,i} = n\pi c_i/L_i, \quad n = 1, 2, 3, \dots, \quad \text{and} \quad i = 1, 2.$$

It follows that $\lambda_{n,1} = \lambda_{m,2}$ for some m, n if and only if $c_1 L_2/c_2 L_1$ is rational. Hence from Theorem 3.6, we conclude that *the system (5.1)–(5.4) is approximately controllable (in some time $T > 0$) if and only if $c_1 L_2/c_2 L_1$ is irrational*. The time T can be any number greater than

$$(5.5) \quad T_0 = 2 \left(\frac{L_1}{c_1} + \frac{L_2}{c_2} \right).$$

However, we can show that even when $c_1 L_2/c_2 L_1$ is irrational, *the system is not exactly controllable*.

To prove that, let us first consider a function defined by the formula

$$f_\mu(x) = \begin{cases} \sin \frac{\mu L_2}{c_2} \sin \frac{\mu x}{c_1} & \text{if } 0 < x < x_1, \\ \sin \frac{\mu L_1}{c_1} \sin \frac{\mu(L-x)}{c_2} & \text{if } x_1 < x < L. \end{cases}$$

Here μ is a real parameter. It is easy to verify that

$$\tilde{y}(x, t) = \sin \mu(T-t) f_\mu(x)$$

is a solution of (5.1)–(5.4) with

$$\tilde{u}_1(t) = -\mu \frac{F(\mu) \sin \mu(T-t)}{c_1 c_2},$$

where

$$F(\mu) = c_1 \tau_1 \sin \frac{\mu L_1}{c_2} \cos \frac{\mu L_2}{c_2} + c_2 \tau_2 \sin \frac{\mu L_2}{c_2} \cos \frac{\mu L_1}{c_1}.$$

If y is any solution of (5.1)–(5.4), we have

$$(5.6) \quad \frac{d}{dt} \sum_{i=1}^2 \int_{x_{i-1}}^{x_i} \rho_i \frac{\partial y}{\partial t} \frac{\partial \tilde{y}}{\partial t} + \tau_i \frac{\partial y}{\partial x} \frac{\partial \tilde{y}}{\partial x} dx = -\frac{\partial y(x_1, t)}{\partial t} \tilde{u}_1(t) - \frac{\partial \tilde{y}(x_1, t)}{\partial t} u_1(t).$$

Note that if $F(\mu) = 0$, then $\tilde{u}_1(t) = 0$. We now construct a sequence $\{\mu_n\}_{n=0}^\infty$ such that $F(\mu_n) = 0$ for all n .

From a result in number theory, we know that if $c_1 L_2 / c_2 L_1$ is an irrational number, there exist two sequences of integers $\{p_n\}_{n=0}^{\infty}$ and $\{q_n\}_{n=0}^{\infty}$ tending to infinity as n tends to infinity, such that

$$(5.7) \quad \left| \frac{c_1 L_2}{c_2 L_1} - \frac{p_n}{q_n} \right| < 1/q_n^2$$

for all n . (See, e.g., Hardy and Wright [3, Thm. 171, p. 140].) Let $\lambda_n = p_n c_2 \pi / L_2$. Then

$$(5.8) \quad \sin \frac{\lambda_n L_2}{c_2} = 0.$$

also, by (5.7), we have

$$\left| \frac{\lambda_n L_1}{c_1} - q_n \pi \right| < \epsilon_n,$$

where

$$\epsilon_n = \frac{c_2 L_1 \pi}{c_1 L_2 q_n}.$$

So

$$(5.9) \quad \left| \sin \frac{\lambda_n L_1}{c_1} \right| < \epsilon_n \quad \text{for all } n.$$

It follows from (5.8) and (5.9) that we have

$$(5.10) \quad |F(\lambda_n)| < c_1 \tau_1 \epsilon_n \quad \text{for all } n$$

and

$$(5.11) \quad \lim_{n \rightarrow \infty} |F'(\lambda_n)| = \tau_1 L_1 + \tau_2 L_2.$$

Because F'' is a bounded function, we can then find a constant $\delta > 0$, independent of n , such that for all n sufficiently large,

$$(5.12) \quad |F'(\lambda)| > (\tau_1 L_1 + \tau_2 L_2)/2 \quad \text{whenever } |\lambda - \lambda_n| < \delta.$$

From (5.10), (5.12) and the fact that $\lim_{n \rightarrow \infty} \epsilon_n = 0$, we conclude that for all n sufficiently large, there exists μ_n such that

$$(5.13) \quad |\mu_n - \lambda_n| < \frac{2c_1 \tau_1 \epsilon_n}{\tau_1 L_1 + \tau_2 L_2}$$

and

$$(5.14) \quad F(\mu_n) = 0.$$

Let

$$g_n(x) = f_{\mu_n}(x).$$

Let y be a solution of (5.1)–(5.4) with zero initial conditions. Then setting $\mu = \mu_n$ (which makes $\tilde{u}_1 = 0$) and integrating (5.6) from $t = 0$ to $t = T$ and canceling μ_n , we have

$$(5.15) \quad -\sum_{i=1}^2 \int_{x_{i-1}}^{x_i} \rho_i \frac{\partial y(x, T)}{\partial t} g_n(x) dx = g_n(x_1) \int_0^T \cos \mu_n(T-t) u_1(t) dt.$$

If the system (5.1)–(5.4) is exactly controllable, there exists a bounded linear mapping \mathcal{C} from $H_0^1[0, L] \times L^2[0, L]$ into $L^2[0, T]$ that maps the terminal state $(y(\cdot, T), \partial y(\cdot, T)/\partial t)$ to a control function u_1 that steers the zero initial state to this terminal state. Hence (5.15) implies that

$$\begin{aligned} \sum_{i=1}^2 \int_{x_{i-1}}^{x_i} \rho_i \frac{\partial y(x, T)}{\partial t} g_n(x) dx &\leq K |g_n(x_1)| \left(\mathcal{E}y(T) \int_0^T |\cos \mu_n(T-t)|^2 dt \right)^{1/2} \\ &= K |g_n(x_1)| \left(\mathcal{E}y(T) \left(\frac{T}{2} - \frac{\sin 2\mu_n(T-t)}{4\mu_n} \right) \right)^{1/2} \\ &\leq K |g_n(x_1)| \left(\mathcal{E}y(T) \left(\frac{T}{2} + \frac{1}{4\mu_n} \right) \right)^{1/2}. \end{aligned}$$

Here K is a positive constant. Since the terminal state can be arbitrary, this implies that there exists a constant K_1 such that

$$\sum_{i=1}^2 \int_{x_{i-1}}^{x_i} |g_n(x)|^2 dx \leq K_1 |g_n(x_1)|^2.$$

In other words

$$\begin{aligned} \left(\sin \frac{\mu_n L_2}{c_2} \right) \left(\frac{L_1}{2} - \frac{\sin(2\mu_n L_1/c_1)}{4\mu_n/c_1} \right) + \left(\sin \frac{\mu_n L_1}{c_1} \right)^2 \left(\frac{L_2}{2} - \frac{\sin(2\mu_n L_2/c_2)}{4\mu_n/c_2} \right) \\ \leq K_1 \left(\sin \frac{\mu_n L_1}{c_1} \right)^2 \left(\sin \frac{\mu_n L_2}{c_2} \right). \end{aligned}$$

(5.16)

For n sufficiently large, both terms on the left-hand side of the above inequality are nonnegative. Furthermore, because $c_1 L_2 / c_2 L_1$ is irrational, $\sin(\mu_n L_1 / c_1)$ and $\sin(\mu_n L_2 / c_2)$ cannot vanish simultaneously. Suppose there exist infinitely many n such that $\sin(\mu_n L_2 / c_2) \neq 0$. For such n , n sufficiently large, we must have

$$(5.17) \quad \frac{L_1}{2} - \frac{\sin(2\mu_n L_1/c_1)}{4\mu_n/c_1} \leq K_1 \left(\sin \frac{\mu_n L_1}{c_1} \right)^2.$$

But the inequalities (5.9) and (5.13) together imply that

$$\lim_{n \rightarrow \infty} \sin \frac{\mu_n L_1}{c_1} = 0.$$

So letting n tend to infinity in (5.17), we have $L_1/2 \leq 0$, a contradiction. In a similar way, we can show that if there exist infinitely many n such that $\sin(\mu_n L_2 / c_2) \neq 0$, then $L_2/2 \leq 0$, again a contradiction. So the system (5.1)–(5.4) cannot be exactly controllable.

The situation would be different if we change the boundary condition at one of the endpoints (say $x = L$) to

$$(5.18) \quad \frac{\partial}{\partial x} z(L, t) = 0$$

but keeping the boundary condition at the other end the same as before. With obvious modifications in their proofs, we see that Theorems 3.6 and 4.4 remain valid when the boundary condition at $x = L$ is replaced by the condition (5.18). Now, the eigenvalues of the corresponding uncoupled strings are

$$\lambda_{n,1} = n\pi c_1/K_1 \quad \text{and} \quad \lambda_{n,2} = (n - \tfrac{1}{2})\pi c_2/L_2, \quad n = 1, 2, \dots$$

Obviously, if $c_1 L_2/c_2 L_1$ is irrational, $\lambda_{n,1} \neq \lambda_{m,2}$ for any n and m . So the system (5.1)–(5.4) is approximately controllable in time T , with $T > T_0$, T_0 again given by (5.5). But note that if

$$(5.19) \quad \frac{c_1 L_2}{c_2 L_1} = \text{an integer/an odd integer} = \frac{r}{2s-1},$$

where r and s are positive integers, then

$$|\lambda_{n,1} - \lambda_{m,2}| = \left| \frac{\pi c_2}{L_2 2(2s-1)} (2nr - (2m-1)(2s-1)) \right| \geq \frac{\pi c_2}{L_2 2(2s-1)} > 0$$

for any n and m . Therefore, the system (5.1)–(5.4) is approximately controllable in time $T > T_0$, T_0 given by (5.5). Furthermore, all the $\lambda_{n,1}$ and $\lambda_{n,2}$, $n = 1, 2, \dots$, are multiples of a fixed number

$$\alpha = (\pi c_2)/(2L_2(2s-1)).$$

So the set of exponential functions

$$S = \{e^{\pm i\lambda_{n,1}t} : 1 \leq n < \infty\} \cup \{e^{\pm i\lambda_{n,2}t} : 1 \leq n < \infty\}$$

is a subset of the exponential functions

$$\{e^{in\alpha t} : -\infty < n < \infty\},$$

which is orthogonal in $L^2[0, 2\pi/\alpha]$. Hence so is S . So S satisfies (RB2). It follows that if assumption (5.19) is satisfied, then the system (5.1)–(5.4) is exactly controllable in any time T such that

$$T > T^* = \max \left\{ 2 \left(\frac{L_1}{c_1} + \frac{L_2}{c_2} \right), \frac{2\pi}{\alpha} \right\} = \max \left\{ 2 \left(\frac{L_1}{c_1} + \frac{L_2}{c_2} \right), \frac{4L_2(2s-1)}{c_2} \right\}.$$

Because $L_2(2s-1)/c_2 = L_1 r/c_1$, it follows that

$$\frac{L_2(2s-1)}{c_2} = \frac{1}{2} \left(\frac{L_2(2s-1)}{c_2} + \frac{L_1 r}{c_1} \right) \geq \frac{1}{2} \left(\frac{L_1}{c_1} + \frac{L_2}{c_2} \right).$$

Hence $T^* = 4(L_2(2s-1)/c_2)$. If either one of s or r is greater than 1, then T^* is greater than T_0 , the infimum time for approximate controllability. Of course, we have not shown that the time T^* given in Theorem 4.4 is optimal. So we do not know whether we actually

need a greater time for exact controllability than for just approximate controllability, when r or s is greater than 1.

The results in the above examples are consistent with those in [2] and [11]. For example, it was shown in [11] that for the case of “symmetric” boundary conditions

$$(5.20) \quad z(0, t) = z(2, t) = 0,$$

with feedback

$$(5.21) \quad z_t(1^+, t) - z_t(1^-, t) = -K_1 \tau_1 u_x(1^-, t), \quad K_1 > 0$$

the system is asymptotically stable if and only if the ratio of the wave speeds is irrational. (In [11], Liu took $L_1 = L_2 = 1, L = 2$.) However, the system never decays with a uniform exponential rate.

For the case of “unsymmetric” boundary conditions

$$(5.22) \quad z(0, t) - \frac{\partial}{\partial x} z(2, t) = 0$$

the system is asymptotically stable, with feedback (5.21), if and only if

$$c_1/c_2 = \text{an odd integer/an even integer.}$$

However, it decays with a uniform exponential rate if

$$c_1/c_2 = \text{an integer/an odd integer.}$$

This last condition is, of course, the same as (5.19).

SIMULTANEOUS COEFFICIENT ASSIGNMENT OF DISCRETE-TIME MULTI-INPUT MULTI-OUTPUT LINEAR TIME-VARYING SYSTEM: A NEW APPROACH FOR COMPENSATOR DESIGN*

BIJOY K. GHOSH[†] AND PAUL R. BOUTHELLIER[‡]

Abstract. In this paper, a linear time-varying input-output system is considered and its realization as a linear time-varying autoregressive moving average system (ARMA) is studied. A time-varying z -transform is also introduced and its properties are studied. Furthermore a time-varying version of the coefficient assignment problem well known in time invariant system theory as the pole placement problem is posed and analyzed. A r -tuple of discrete time, linear time-varying plants with m inputs and p outputs are considered together with a single p input m output linear time-varying compensator. The design objective is to construct a single compensator that “coefficient assigns,” and hence “bounded input bounded output stabilizes” under suitable additional technical assumptions, the set of r plants simultaneously in the closed loop. Such a problem is useful in robust design of linear time-varying control systems in the closed loop. Among the results, it is shown that a generic r -tuple of $p \times m$ plants (in a suitable topology) is simultaneously coefficient assignable, provided that $r < m/p$. The design procedure involves splitting the closed-loop system into an ARMA system in cascade with a moving average system. The coefficient assignment problem consists of assigning the coefficients of the autoregressive part of the ARMA subsystem. Thereby an algorithm is obtained that is nonrecursive and involves solving for each time instant a system of linear equations with time-varying coefficients. The associated time-varying matrix has the “Sylvester matrix structure.” Such a structure is well-known in pole placement of time-invariant systems by dynamic compensation. Additionally the problem of coefficient assignment of the autoregressive part of the ARMA system is considered in the closed loop, without splitting up into a cascade of two subsystems as before. A new recursive algorithm to analyze this problem has been introduced. The proposed algorithm has no counterpart in the time-invariant system design and thus represents a new design procedure. A special case of this algorithm for the single-input single-output system has been described in detail. An interesting feature of the proposed recursive algorithm is that one obtains a nonlinear recursion on the compensator parameters that would assign a prespecified sequence of coefficients for the closed-loop system. For a specific design problem it is shown that the dynamics of this nonlinear recursion is chaotic.

1. Introduction. Motivated by earlier successes in the field of simultaneous system design (see [1]–[7]) for linear time-invariant systems, in this paper the same general idea is applied to linear time-varying (LTV) systems as well. The motivation for considering time-varying systems is as follows. Many systems are time varying because they switch modes frequently (namely, high-performance aircrafts, power systems undergoing several modes of failure, etc.). Time-varying systems also arise from nonlinear systems linearized along a nominal trajectory. Furthermore, time-varying systems also arise from linear systems, where the parameters are perturbed by a time-varying function. A feedback design strategy that leads to a time-varying system is *adaptive control*, wherein the time variation is a result of real time adaptation. An important pair of problems in the design of time-varying systems is described as follows.

PROBLEM 1.1 (stability criterion). Given a class of linear time-varying systems. What condition on the parameters of the systems would guarantee bounded-input bounded-output (BIBO) stability?

PROBLEM 1.2 (stability criterion). If a linear time-varying system is not already BIBO stable, find a linear time-varying output feedback compensator such that the closed-loop system is BIBO stable.

FIG. 1.1. Closed-loop system corresponding to (G^j, C) .

The main problem of ascertaining stability of a linear time-varying system is that the problem is not equivalent to localizing the eigenvalues of a possibly time-varying matrix to a certain region of the complex plane. In fact, a time-varying system stable in frozen time (i.e., stable for each time instance) is not necessarily a stable time-varying system (see [8] and [9]). Stability can be ascertained, however, if the parameters of the system are varying sufficiently slowly. It has been shown by Desoer [10] that there exists open regions of the parameter space with the property that if the parameter vector of the system resides in such a region for all times, then the associated time-varying system is indeed stable (see also [11]–[13]). A sufficiency criterion for stabilizing a time-varying system is, therefore, one of choosing a compensator that localizes the coefficients of the closed-loop system to within such an open region. For reasons of robustness and fault tolerance, however, one is interested in stabilizing, not just a single plant, but an entire r -tuple of plants. This problem is now described as follows.

PROBLEM 1.3 (simultaneous stabilizability problem). Given an r -tuple of linear time-varying plants G^1, G^2, \dots, G^r , find, if possible, a linear time-varying output feedback compensator C that simultaneously stabilizes each one of the closed-loop systems (G^j, C) , $j = 1, \dots, r$.

In Problem 1.3 (G^j, C) denotes the closed-loop system described in Fig. 1.1. For an introduction to the simultaneous stabilization problem for time-invariant systems, we refer to [1]–[3]. The main idea is that G^1 is a nominal plant, which, as a result of sudden component failures, may take up $r - 1$ additional different modes G^2, \dots, G^r . The design goal is to construct a compensator that stabilizes the nominal plant together with all its failed modes simultaneously. To obtain a tighter control on the response of the closed-loop system, we consider the following problem.

PROBLEM 1.4 (simultaneous coefficient assignment problem). Given an r -tuple of m input p output *autoregressive moving average* (ARMA) models of lag ℓ , denoted by $\{G^j\}$ and defined by

$$(1.1) \quad y_k + \sum_{i=1}^{\ell} D_k^j(i) y_{k-i} = \sum_{i=1}^{\ell} N_k^j(i) v_{k-i}.$$

When does there exist a compensator C of lag q , defined by

$$(1.2) \quad \begin{aligned} u_k^* + \sum_{i=1}^q \bar{D}_k(i) u_{k-i}^* &= \sum_{i=0}^q \bar{N}_k(i) y_{k-i} \\ v_k &= u_k - u_k^*, \end{aligned}$$

that will assign the coefficients $\Delta_k^j(i)$ of the equations of the closed-loop systems that (G^j, C) described as

$$(1.3) \quad \Delta_k^j(0)y_{1,k} + \sum_{i=1}^{\ell+q} \Delta_k^j(i)y_{1,k-i} = \sum_{i=0}^{\ell+q} r_k^j(i)u_{k-i}, j = 1, \dots, r.$$

The main contributions of this paper are now described. In §2 we consider a general linear input–output map and obtain a necessary and sufficient condition as to when such a map is realizable as a linear time-varying ARMA model of finite lag. We introduce left and right fraction representation of an LTV system and show via examples that, unlike the time-invariant case, the existence of one does not imply the existence of the other. However, in a suitable topology on the space of LTV ARMA systems, a generic system is shown to admit either of the two representations. In §3, we pose and analyze a simplified coefficient assignment problem. The proposed problem consists of splitting the closed-loop system into a cascade of ARMA and a moving average subsystem. The problem considered is to assign the coefficients of the autoregressive part of the ARMA subsystem. We show that the solution to the problem consists of analyzing linear equations with time-varying matrices. Under a suitable topology we consider an r -tuple of m -input p -output plants and show that a sufficient condition for the proposed coefficient assignment problem is given by $rp < m + p$. Under an additional technical condition (3.29) the above inequality is shown to be sufficient for simultaneous stabilization of the r -tuple of plants as well. In §4 we consider the closed-loop system as a single ARMA system and propose assigning the coefficients of the autoregressive part. The coefficient assignment problem is considered when $r = 1$ and m and p are arbitrary. A nonlinear time-varying iteration scheme that recursively assigns the coefficients of such time-varying systems in the closed-loop is described. Such an iterative scheme appears to be new in the literature and has no counterpart in the time-invariant system theory.

The main technique that we use in this paper is that of a time-varying version of the z -transform as part of an operational algebra for discrete-time, linear time-varying systems. Such an operational algebra has also been used previously by Kamen, Khargonekar, Poolla, and Hwang [14]–[17]. More recently a continuous-time version of the above operational algebra is being used by Tsakalis and Ioannou [18] and [19].

The main idea of this paper is to describe a time-varying version of the return difference matrix and to ensure that the coefficients of this matrix can be assigned arbitrarily under a sufficiency condition. Such a sufficiency condition in principal is a generalization of the results on “pole placement by dynamic compensation” for linear time-invariant systems (see [20]–[22]). The time-varying nature of the problem considered here imposes restrictions that did not exist in the literature concerning time-invariant systems. For example, we see in this paper that a coefficient-assigning compensator for a single-input single-output plant can be obtained by solving a nonlinear difference equation recursively. When restricted to time-invariant parameters, the difference equation reduces to the well-known linear algebraic equation of the type $Sx = b$, where S is a Sylvester matrix. Stability analysis of the proposed nonlinear difference equation has not been carried out in general and is a subject of future research.

There are other approaches [23] and [24] to stabilization, simultaneous stabilization of linear time-varying systems in the literature. For example, [23] deals with continuous-time systems wherein the input–output time-varying plant is modeled as an operator between two suitable function spaces. Among the results, it is shown that if an r -tuple of linear time-varying plants is internally stabilizable individually, then the r -tuple is simultaneously stabilizable by a stable linear time-varying compensator. The main difference between

this paper and the approach presented in [23] is now described. In this paper, we deal with linear time-varying systems in discrete time. Moreover, the time-varying system is described as a parametric variation on the space of time-invariant systems. Thus, this paper addresses problems in system design that pertain to real time adaptation of the compensator parameters as a result of real time changes in the plant parameters. The main system design problem that we consider is coefficient assignment, wherein no assumption is made about the parameters of the plants and compensators for all future times. In particular, the parameters of the plants and compensators are not assumed to be known completely. In fact, in this paper we assume that the future values of the plant parameters are unknown. Of course, to implement the coefficient assignment algorithms presented, we need to know the values of the plant parameters for an a priori fixed span of time (depending upon the lags of the systems) in the future. This adds a new twist to the problem of compensator design for a time-varying plant. Estimating the parameters of a time-varying plant in the immediate future appears to be an integral part of compensating a time-varying system, in discrete time, and to the best of our knowledge has never been considered before in the literature.

2. Representations of time-varying input–output maps. In this section, we consider a linear time-varying input–output map and study the problem of realizing the map as an impulse response of a linear time-varying *autoregressive moving average* (LTV ARMA) model of finite lag q . LTV ARMA models are of interest because the plants and compensators considered in subsequent sections of this paper are modeled as LTV ARMA systems, i.e., as ARMA systems with time-varying parameters.

Linear time-varying input–output maps are described by their impulse response sequence. We derive condition on the impulse response parameters so that it is realizable as an impulse response of an LTV ARMA system of a given lag q . To derive the realizability condition and also in later sections to describe the compensator that assigns coefficients of the closed-loop system, we find it convenient to introduce the notion of transfer function for an LTV input–output map. Such a transfer function is an obvious generalization of the z -transform methods well known in linear time-invariant discrete-time system design. To describe the transfer function, we need to introduce an operational algebra on the space of infinite power series with time-varying coefficients. Establishing connection between LTV input–output system, LTV ARMA system, and LTV transfer functions form the core of the main results described in this section.

Consider a m -input p -output LTV input–output map described by its impulse response sequence $H_j(i)$, where $H_j(i)$ is a $p \times m$ matrix defined to be the output at time j corresponding to a unit impulse at time $j - i$. To impose causality, we set $H_j(i) = 0$, the zero matrix, for all $i > j$.

Using linearity, it is clear that the impulse response sequence $H_j(i)$ completely specifies the input–output map. In fact, if u_j, u_{j-1}, \dots is a sequence of m vector inputs at time $j, j-1, \dots$, respectively, we have

$$(2.1) \quad y_j = \sum_{\ell=0}^x H_j(\ell) u_{j-\ell},$$

where y_j is the p -vector output at the time instant j . Equation (2.1) will be referred to as the LTV input–output map. The realization problem that we now consider is described as follows.

PROBLEM 2.1. Given a time-varying ARMA model of finite lag ℓ described by

$$(2.2) \quad y_k + \sum_{i=1}^{\ell} D_k(i) y_{k-i} = \sum_{i=0}^{\ell} N_k(i) u_{k-i},$$

where $D_k(i), i = 1, 2, \dots, \ell$ are $p \times p$ matrices and $N_k(i), i = 0, 1, \dots, \ell$ are $p \times m$ matrices. When is it true that the impulse response of a LTV input-output map described by (2.1) coincides with the impulse response of an ARMA model of type (2.2)?

We will see subsequently in this section that a necessary and sufficient condition for the above realization is given by a sequence of recursive conditions on the impulse response sequence H_j^i . The procedure is in principal similar to checking ranks of Hankel matrices in the theory of linear time-invariant systems.

Before we proceed to study Problem 2.1, we introduce an operational algebra and consider the notion of a transfer function for LTV input-output systems and LTV ARMA systems. This is done as follows.

Let y_k be a discrete-time vector sequence. Define a shift operator z^{-i} as follows:

$$(2.3) \quad z^{-i} y_k = y_{k-i}.$$

In the notation of (2.3), extending the operator z^{-i} linearly, we can write (2.1) as

$$(2.4) \quad y_k = \left[\sum_{\ell=0}^x H_k(\ell) z^{-\ell} \right] u_k.$$

The infinite power series

$$(2.5) \quad \mathcal{H}(z^{-1}) = \sum_{\ell=0}^x H_k(\ell) z^{-\ell}$$

is defined to be the transfer function of the LTV input-output map described by (2.1). We now define an operation of multiplication of two infinite power series of the type (2.5). Denote the multiplication operation by \circ .

Let

$$(2.6) \quad \mathcal{J}(z^{-1}) = \sum_{\ell=0}^x J_k(\ell) z^{-\ell}$$

be another infinite power series. We define

$$(2.7) \quad \mathcal{H}(z^{-1}) \circ \mathcal{J}(z^{-1}) = \sum_{\ell_1=0}^{\infty} \sum_{\ell_2=0}^x [(H_k(\ell_1) z^{-\ell_1}) \circ (J_k(\ell_2) z^{-\ell_2})],$$

where

$$(2.8) \quad (H_k(\ell_1) z^{-\ell_1}) \circ (J_k(\ell_2) z^{-\ell_2}) = H_k(\ell_1) J_{k-\ell_1}(\ell_2) z^{-(\ell_1+\ell_2)}.$$

Of course, we assume that $H_k(\ell), J_k(\ell)$ are matrices of compatible dimension so that the product $H_k(\ell_1) J_{k-\ell_1}(\ell_2)$ is defined. The following straightforward properties of the multiplication operation are now stated without proof.

PROPOSITION 2.2. *Let $\mathcal{H}(z^{-1}), \mathcal{J}(z^{-1}), \mathcal{L}(z^{-1})$ be a set of three infinite power series. Assuming that $\mathcal{H}(z^{-1}) \circ \mathcal{J}(z^{-1})$ and $\mathcal{J}(z^{-1}) \circ \mathcal{L}(z^{-1})$ are defined, we have the following:*

1. The multiplication operation \circ is associative, i.e.,

$$[\mathcal{H}(z^{-1}) \circ \mathcal{J}(z^{-1})] \circ \mathcal{L}(z^{-1}) = \mathcal{H}(z^{-1}) \circ [\mathcal{J}(z^{-1}) \circ \mathcal{L}(z^{-1})].$$

2. The multiplication operation is not commutative, i.e.,

$$\mathcal{H}(z^{-1}) \circ \mathcal{J}(z^{-1}) \neq \mathcal{J}(z^{-1}) \circ \mathcal{H}(z^{-1})$$

in general, even when the right-hand side is defined.

3. $[\mathcal{H}(z^{-1}) \circ \mathcal{J}(z^{-1})]y_k = \mathcal{H}(z^{-1})[\mathcal{J}(z^{-1})y_k]$.

We now consider the following definition.

DEFINITION 2.3 (existence of inverse). Let $\mathcal{Q}(z^{-1})$ be an infinite power series with square coefficient matrices of size $\alpha \times \alpha$. If there exists $\mathcal{W}(z^{-1})$, an infinite power series with square coefficient matrices of size $\alpha \times \alpha$ such that

$$\mathcal{Q}(z^{-1}) \circ \mathcal{W}(z^{-1}) = \mathcal{W}(z^{-1}) \circ \mathcal{Q}(z^{-1}) = I_\alpha,$$

where I_α is an identity matrix of size $\alpha \times \alpha$, then $\mathcal{W}(z^{-1})$ is called an *inverse* of $\mathcal{Q}(z^{-1})$ and we write

$$\mathcal{W}(z^{-1}) = \mathcal{Q}^{-1}(z^{-1}).$$

Not all infinite power series would have an inverse. The following proposition is important, but involves straightforward checking. Hence, the proof is omitted.

PROPOSITION 2.4. *Let*

$$\mathcal{D}(z^{-1}) = I_p + \sum_{i=1}^{\ell} D_k(i)z^{-i},$$

where $D_k(i)$ -s are $p \times p$ matrices. Then $\mathcal{D}(z^{-1})$ has an unique inverse given by

$$D^{-1}(z^{-1}) = A_k(0) + A_k(1)z^{-1} + A_k(2)z^{-2} + \cdots,$$

where

$$\begin{aligned} A_k(0) &= I_p \\ A_k(1) &= -A_k(0)D_k(1) \\ A_k(2) &= -A_k(1)D_{k-1}(1) - A_k(0)D_k(2), \text{ etc.} \end{aligned}$$

The LTV ARMA model (2.2) can be written as

$$(2.9) \quad \left[I + \sum_{i=1}^{\ell} D_k(i)z^{-i} \right] y_k = \left[\sum_{i=0}^{\ell} N_k(i)z^{-i} \right] u_k.$$

Using Proposition 2.4, we can now write

$$(2.10) \quad y_k = \left[I + \sum_{i=1}^{\ell} D_k(i)z^{-i} \right]^{-1} \left[\sum_{i=0}^{\ell} N_k(i)z^{-i} \right] u_k$$

$$(2.11) \quad = \Psi(z^{-1})u_k.$$

The power series $\Psi(z^{-1})$ is defined to be the transfer function of an LTV ARMA model of lag ℓ . We would now define the left and right representations of LTV systems as follows.

DEFINITION 2.5. The transfer function (2.5) of the input–output map (2.1) is said to have a left factorization

$$(2.12) \quad \Psi_L(z^{-1}) = \left(I + \sum_{i=1}^{\ell} D_k(i)z^{-i} \right)^{-1} \circ \left(\sum_{j=0}^{\ell} N_k(j)z^{-j} \right)$$

of lag ℓ if

$$(2.13) \quad \left(\sum_{i=0}^{\infty} H_k(i)z^{-i} \right) = \Psi_L(z^{-1})$$

and a right factorization

$$(2.14) \quad \Psi_R(z^{-1}) = \left(\sum_{j=0}^{\ell} \bar{N}_k(j)z^{-j} \right) \circ \left(I + \sum_{i=1}^{\ell} \bar{D}_k(i)z^{-i} \right)^{-1}$$

of lag ℓ , if

$$(2.15) \quad \left(\sum_{i=0}^{\infty} H_k(i)z^{-i} \right) = \Psi_R(z^{-1}).$$

It is clear from (2.9) and (2.10) that Problem 2.1 involves finding conditions under which the transfer function (2.5) admits a left factorization of lag ℓ . The following theorem completely solves the problem.

THEOREM 2.6. *The infinite power series (2.5) admits a left factorization of lag ℓ if and only if there exists $p \times p$ matrices $D_k(1), \dots, D_k(\ell)$ such that*

$$(2.16) \quad \begin{bmatrix} H_k^T(\ell+1) \\ H_k^T(\ell+2) \\ \vdots \end{bmatrix} + \begin{bmatrix} H_{k-1}^T(\ell) & H_{k-1}^T(\ell-1) & \cdots & H_{k-\ell}^T(1) \\ H_{k-1}^T(\ell+1) & H_{k-2}^T(\ell) & \cdots & H_{k-\ell}^T(2) \\ \vdots & \vdots & \vdots & \vdots \end{bmatrix} \begin{bmatrix} D_k(1)^T \\ D_k(2)^T \\ \vdots \\ D_k(\ell)^T \end{bmatrix}.$$

The infinite power series (2.5) admits a right factorization of lag ℓ if and only if there exist $p \times p$ matrices $D_k(1), \dots, D_k(\ell)$ such that

$$(2.17) \quad [H_k^T(\ell+1)H_{k+1}^T(\ell+2)\cdots] \\ = [D_{k-\ell}^T(1)D_{k-\ell+1}^T(2)\cdots D_{k-1}^T(\ell)] \begin{bmatrix} H_k^T(\ell) & H_{k+1}^T(\ell+1) & \cdots \\ H_k^T(\ell-1) & H_{k+1}^T(\ell) & \cdots \\ \vdots & \vdots & \vdots \\ H_k^T(1) & H_{k+1}^T(2) & \cdots \end{bmatrix}.$$

Proof. We prove Theorem 2.6 for the case of left factorizations. The case of right factorizations is similar and is omitted.

The impulse response matrix (2.1) admits a left factorization of lag ℓ if and only if there exists $D_k(i), N_k(i)$ such that (2.13) is satisfied. It follows that

$$(2.18) \quad \left[\left(I + \sum_{i=1}^{\ell} D_k(i)z^{-i} \right) \circ \left(\sum_{i=0}^{\infty} H_k(i)z^{-i} \right) \right] \left(\sum_{i=0}^{\ell} N_k(i)z^{-i} \right).$$

Expanding both sides of (2.18) and equating like powers of z^{-1} yields the desired result. \square

Remark 2.7. For linear time-invariant systems, the notion of left and right factorization is well known [25]. For time-varying systems, these were introduced in [14] and [17]. The realizability condition introduced in Theorem 2.6 is new. Note that if the impulse response sequence is arranged in the form of a matrix

$$(2.19) \quad \begin{bmatrix} \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & H_0(0) & H_1(1) & H_2(2) & H_3(3) & H_4(4) & \cdot & \cdot \\ \cdot & \cdot & O & H_1(0) & H_2(1) & H_3(2) & H_4(3) & \cdot & \cdot \\ \cdot & \cdot & O & O & H_2(0) & H_3(1) & H_4(2) & \cdot & \cdot \\ \cdot & \cdot & O & O & O & H_3(0) & H_4(1) & \cdots & \\ \cdot & \cdot & O & O & O & O & H_4(0) & \cdots & \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \end{bmatrix},$$

the conditions for left (right) factorization can be viewed as a rank condition on the columns (rows) of the above matrix. In time-invariant system theory the above rank condition would reduce to checking ranks of a suitable Hankel matrix. The results are quite standard [26], and, therefore, the details are omitted.

Remark 2.8. It may be noted that, unlike the results in [14] and [17], wherein left and right representations for input-output maps of the form (2.1) have also been given, we do not have to construct state-space realizations of minimal order for (2.1) as an intermediary step.

The following two examples serve to illustrate the important fact that, unlike the time-invariant case, the existence of a left factorization of finite lag for a time-varying system does not imply the existence of a right factorization of finite lag and vice-versa. Both examples are for single-input single-output systems.

Example 2.9. Consider an input-output system defined by the following impulse response sequence

$$(2.20) \quad H_k(0) = 1 \quad k = 0, 1, 2, \dots$$

For $i = 1, 2, 3, \dots$

$$\begin{aligned} H_{k+i}(i) &= 1 \text{ for } k \geq 0, k \text{ even} \\ &= 0 \text{ for } k \geq 0, k \text{ odd.} \end{aligned}$$

Let $H_j(i) = 0$ for all other values of i, j . It is easy to see that (2.20) admits a left factorization of the form (2.12) of lag 1 given by $N_k(0) = 1, N_k(1) = 0, D_k(1) = -1$. On the other hand, (2.20) does not admit a right factorization of finite lag.

Example 2.10. Consider an input-output system defined by the following impulse response sequence:

$$(2.21) \quad H_k(0) = 1 \quad k = 0, 1, 2, \dots$$

For $j = 1, 2, \dots$

$$(2.22) \quad H_k(j) = 1 \quad k \geq 0, k \text{ even}$$

$$(2.23) \quad = 0 \quad k \geq 0, k \text{ odd.}$$

Let $H_j(i) = 0$ for all other values of i, j . It is straightforward to check that (2.21) admits no left factorization, but admits a right factorization of lag 1 given by

$$(1 + N_k(1)z^{-1})(1 - z^{-1})^{-1},$$

where

$$N_k(1) = -1 + H_k(1).$$

Remark 2.11. Left factorizations of finite lag always admit ARMA representations of finite lag as well as state-space realizations of finite order [14], [27].

Example 2.10 raises the concern that right factorizations, unlike left factorizations, may be difficult to implement. For this reason, we will conclude this section by showing that a right factorization

$$(2.24) \quad \mathcal{N} \circ \mathcal{D}^{-1} \equiv \left(\sum_{i=0}^{\bar{\ell}} \bar{\mathcal{N}}_k(i) z^{-i} \right) \circ \left(I + \sum_{i=1}^{\bar{\ell}} \bar{\mathcal{D}}_k(i) z^{-i} \right)^{-1}$$

of finite lag (i) generically admits a left factorization of finite lag and (ii) can always be realized in state space form.

We now consider the following topology for the space of right factorization of lag $\leq \bar{\ell}$. Note that the vector of matrices

$$(\bar{N}_k(0), \dots, \bar{N}_k(\ell), \bar{D}_k(1), \dots, \bar{D}_k(\ell)) \in \mathbb{R}^N,$$

where

$$N = \bar{\ell} p^2 + (\bar{\ell} + 1) p m$$

for each $k = 0, 1, 2, \dots$. Thus, every right factorization of the form (2.24) is a point in the product space

$$(2.25) \quad \prod_{j=0}^{\infty} \mathbb{R}^N = \mathcal{P}.$$

We now equip \mathcal{P} with the product topology (see [28]).

DEFINITION 2.12. A set \mathcal{G} of right factorizations is said to be generic if \mathcal{G} can be written as an intersection of a countable number of open and dense sets in \mathcal{P} .

The ARMA realization of a system of the form (2.24) is given by the following theorem.

THEOREM 2.13. *Consider a generic element in the space of right factorizations of lag $\leq \bar{\ell}$ with m inputs and p outputs. There always exists a left factorization of lag ℓ , where ℓ is the smallest integer satisfying $\ell p \geq \bar{\ell} m$ such that the two factorizations correspond to the same infinite power series for all $k \geq \ell$.*

Proof. See Appendix I.

Note 2.14. The basic interpretation of Theorem 2.13 is that almost all LTV transfer functions with a right factorization also have a left factorization and, therefore, can be realized as an LTV ARMA system. Of course, we could also define a generic set of left factorizations to show that generically a transfer function has left factorization (right factorization) if it has a right factorization (respectively, left factorization).

We will now state that right factorizations of finite lag (2.24) can always be realized in state-space form. This realization has not been used subsequently in this paper. It is stated only to satisfy our curiosity that even though a right factorization may not have a left factorization, it can still be realized as a state-space system, but possibly not as an ARMA system. The result follows with modifications from [14] and [16].

THEOREM 2.15 (state-space realization). *The right factorization given by (2.24) can always be realized as an ℓ th-order state-space system*

$$\begin{aligned}x(k+1) &= F(k)x(k) + G(k)u(k); x(0) = 0 \\ y(k) &= H(k)x(k) + J(k)u(k),\end{aligned}$$

where

$$(2.26) \quad F(k) \equiv \begin{bmatrix} O & O & O & O & -\bar{D}_k(\ell) \\ I & O & O & O & -\bar{D}_{k-1}(\ell-1) \\ O & I & O & O & -\bar{D}_{k-2}(\ell-2) \\ & & \dots & \vdots & \vdots \\ O & O & I & O & -\bar{D}_{k-\ell+2}(2) \\ O & O & O & I & -\bar{D}_{k-\ell+1}(1) \end{bmatrix},$$

$$(2.27) \quad G \equiv \text{col} [I, O, O, \dots, O],$$

$$(2.28) \quad H(k) \equiv [W_k(1), W_k(2), \dots, W_k(\ell-1), W_k(\ell)],$$

and

$$(2.29) \quad J(k) \equiv W_k(0),$$

where $W_k(i)$ is the coefficient of z^{-i} in the formal power series expansion of (2.24).

Proof. We refer the interested reader to [14] and [16].

The main contributions of this section are now summarized. Starting from the impulse response sequence of an input–output map, we introduce a formal infinite power series. We then completely answer the question as to when such a power series can be represented as a left (right) factorization. Existence of a left factorization enables us to construct an LTV ARMA system that realizes the impulse response sequence. Right factorization, on the other hand, can be realized as a state-space system. This fact is of independent interest, but is not used subsequently in this paper. Finally, we show that the existence of left (right) factorization in general does not imply the existence of respectively right (left) factorization, although, for a generic transfer function, that is indeed the case. This fact should be contrasted with linear time-invariant transfer functions, wherein existence of one implies the existence of the other.

3. A nonrecursive compensator design technique for simultaneous coefficient assignment. In this section, we shall consider Problem 1.4 regarding simultaneous coefficient assignment of an r -tuple of m input p output LTV ARMA systems by a single LTV ARMA compensator. We also show that the coefficient assignment problem can be used to analyze Problem 1.3 as well.

To introduce the problem, let us consider the r -tuple of plants defined in (1.1). Assume that the transfer function of the j th plant is given by

$$(3.1) \quad G^j(z^{-1}) = \mathcal{D}^{j-1}(z^{-1})\mathcal{N}^j(z^{-1}),$$

where

$$(3.2) \quad \begin{aligned} \mathcal{D}^j(z^{-1}) &= I + \sum_{i=1}^{\ell} D_k^j(i)z^{-i}, \\ \mathcal{N}^j(z^{-1}) &= \sum_{i=1}^{\ell} N_k^j(i)z^{-i}, \end{aligned}$$

FIG. 3.1. A two-input two-output configuration of the closed-loop system.

$j = 1, 2, \dots, r$. Furthermore, consider a compensator with transfer function

$$(3.3) \quad \mathcal{C}(z^{-1}) = \bar{\mathcal{N}}(z^{-1})\bar{\mathcal{D}}^{-1}(z^{-1}),$$

where

$$(3.4) \quad \begin{aligned} \bar{\mathcal{D}}(z^{-1}) &= I + \sum_{i=1}^q \bar{D}_k(i)z^{-i}, \\ \bar{\mathcal{N}}(z^{-1}) &= \sum_{i=0}^q \bar{N}_k(i)z^{-i}. \end{aligned}$$

It may be noted that the compensator (3.3) may not have a left representation, and therefore, may not have an LTV ARMA realization unless it satisfies the generic conditions of Theorem 2.13. Assume that the plants and the compensator are put in the configuration given by Fig. 3.1.

The following is the transfer function of the closed-loop system with respect to the j th plant.

$$(3.5) \quad \begin{bmatrix} y_{1,k} \\ y_{2,k} \end{bmatrix} = \begin{bmatrix} (\bar{\mathcal{D}} \circ (\mathcal{D}^j \circ \bar{\mathcal{D}} + \mathcal{N}^j \circ \bar{\mathcal{N}})^{-1} \circ \mathcal{N}^j) & (-I + \bar{\mathcal{D}} \circ (\mathcal{D}^j \circ \bar{\mathcal{D}} + \mathcal{N}^j \circ \bar{\mathcal{N}})^{-1} \circ \mathcal{D}^j) \\ (\bar{\mathcal{N}} \circ (\mathcal{D}^j \circ \bar{\mathcal{D}} + \mathcal{N}^j \circ \bar{\mathcal{N}})^{-1} \circ \mathcal{N}^j) & (\bar{\mathcal{N}} \circ (\mathcal{D}^j \circ \bar{\mathcal{D}} + \mathcal{N}^j \circ \bar{\mathcal{N}})^{-1} \circ \mathcal{D}^j) \end{bmatrix} \cdot \begin{bmatrix} u_{1,k} \\ u_{2,k} \end{bmatrix} \quad j = 1, 2, \dots, r.$$

Note that in (3.5), $\bar{\mathcal{D}}, \bar{\mathcal{N}}, \mathcal{D}^j, \mathcal{N}^j$ stands for $\bar{\mathcal{D}}(z^{-1}), \bar{\mathcal{N}}(z^{-1}), \mathcal{D}^j(z^{-1}), \mathcal{N}^j(z^{-1})$ defined in (3.2) and (3.4). Whenever convenient, in the future we will suppress z^{-1} . We now consider the following simultaneous coefficient assignment problem.

PROBLEM 3.1 (coefficient assignment problem). Given an r -tuple of plants described by (3.1), find a compensator of the type (3.3) such that

$$(3.6) \quad \mathcal{D}^j \circ \bar{\mathcal{D}} + \mathcal{N}^j \circ \bar{\mathcal{N}} = I + \sum_{i=1}^{\ell+q} \Delta_k^j(i)z^{-i}$$

for a prespecified set of coefficients $\Delta_k^j(i), j = 1, \dots, r; i = 1, \dots, \ell + q$.

For time-invariant systems, the quantity in the left-hand side of (3.6) is the *return difference*, determinant of which is the closed-loop characteristic polynomial. Thus, Problem 3.1 is the analogue of the pole placement problem for time-invariant systems.

It is not a priori clear how the coefficients $\Delta_k^j(i)$ are related to the input–output response of the closed-loop system (3.5). In particular, we might ask the following question: *If a plant is coefficient assignable by some choice of a compensator, is the closed loop-system stable in the bounded input bounded output sense?* For a time-invariant system, the answer to this question is always affirmative. For a time-varying system, the BIBO stability is not necessarily guaranteed. To ascertain the BIBO stability of the closed-loop system, the compensator coefficients have to be uniformly bounded. To examine this question, let us consider the transfer function between $y_{1,k}$ and $u_{1,k}$ for the j th plant given by

$$(3.7) \quad y_{1,k} = [\bar{\mathcal{D}} \circ (\mathcal{D}^j \circ \bar{\mathcal{D}} + \mathcal{N}^j \circ \bar{\mathcal{N}})^{-1} \circ \mathcal{N}^j] u_{1,k},$$

which may be written as a cascade of two interconnected subsystems given by

$$(3.8) \quad y_{1,k} = \bar{\mathcal{D}} u_{1,k}^*,$$

$$(3.9) \quad [\mathcal{D}^j \circ \bar{\mathcal{D}} + \mathcal{N}^j \circ \bar{\mathcal{N}}] u_{1,k}^* = \mathcal{N}^j u_{1,k}.$$

Clearly, (3.7) is BIBO stable if each of the two subsystems (3.8) and (3.9) are BIBO stable. If we assume that the coefficients of the plants $D_k^j(i)$ and $N_k^j(i)$ are bounded uniformly in k , then an important question to ask is whether or not Problem 3.1 can be solved by a compensator with coefficients $\bar{D}_k(i)$, $\bar{N}_k(i)$, bounded uniformly in k . We therefore consider the following problem.

PROBLEM 3.2 (bounded coefficient assignment problem). Given an r -tuple of plants described by (3.1), find a compensator with coefficients $\bar{D}_k(i)$, $\bar{N}_k(i)$ uniformly bounded in time k such that (3.6) is satisfied for a prespecified set of coefficients $\Delta_k^j(i)$.

Note that if N^j is uniformly bounded, then for an appropriate choice of $\Delta_k^j(i)$, the input–output system (3.9) can be made BIBO stable provided that the coefficients $\Delta_k^j(i)$ are assignable. This fact follows easily from Desoer [10] and has been subsequently studied in detail by Bouthellier [27]. The basic idea is to choose $\Delta_k^j(i)$ such that they are slowly varying in between any two consecutive times. Following [10] and [27], we could construct a chain of open neighborhood Ω_k in the space of coefficients such that for all k , we have

$$(\Delta_k^j(1), \Delta_k^j(2), \dots, \Delta_k^j(\ell + q)) \in \Omega_k.$$

For the above choice of coefficients, Problem 3.2 would guarantee simultaneous BIBO stabilizability of the r -tuple of plants. The main result of this section is described below.

THEOREM 3.3. *A generic r -tuple of $p \times m$ plant is coefficient assignable if and only if*

$$(3.10) \quad p + m > rp.$$

Furthermore, if (3.10) is satisfied, then the r -tuple is coefficient assignable by a compensator of lag q where q is the smallest integer satisfying

$$(3.11) \quad q[m + p - rp] \geq rp\ell - m,$$

where ℓ is the lag of each of the r plants.

To get an idea as to how tight the bounds (3.10) and (3.11) are, we consider the following theorem.

THEOREM 3.4. *A generic r -tuple of $p \times m$ plants can be assigned with bounded coefficients uniformly for all k and for all plants in the generic set by some choice of feedback*

compensator (where the compensator can depend on the choice of the r -tuple of plants) if and only if (3.10) is satisfied.

Thus, for a generic set of r -tuple of plants, if (3.10) is not satisfied, then not only is it not possible to assign coefficients simultaneously, but it is also not possible to restrict the coefficients to a bounded set uniformly in k for all plants in a generic set. We now consider the proofs of Theorems 3.3 and 3.4.

Proof of Theorem 3.3. Consider the r -tuple of plants (3.1) together with the compensator (3.3). In the notation described by (3.2), (3.4) we can equate the like powers of z^{-1} in (3.6) to obtain the following linear equations:

$$(3.12) \quad M_k^j \nu_k = \Delta_k^j,$$

where

$$(3.13) \quad \nu_k = \text{col} [I, \bar{D}_{k+1}(1), \bar{D}_{k+2}(2), \dots, \bar{D}_{k+q}(q), \bar{N}_k(0), \bar{N}_{k+1}(1), \dots, \bar{N}_{k+q}(q)],$$

$$(3.14) \quad \Delta_k^j = \text{col} [\Delta_{k+1}^j(1), \Delta_{k+2}^j(2), \dots, \Delta_{k+\ell+q}^j(\ell+q)],$$

$$M_k^j =$$

$$(3.15) \quad \begin{bmatrix} D_{k+1}^j(1) & I & O & N_{k+1}^j(1) & O & O \\ D_{k+2}^j(2) & D_{k+2}^j(1) & \vdots & N_{k+2}^j(2) & N_{k+2}^j(1) & \vdots \\ \vdots & D_{k+3}^j(2) & O & \vdots & N_{k+3}^j(2) & \vdots \\ \cdot & \cdot & \dots & I & \cdot & O \\ D_{k+\ell}^j(\ell) & \vdots & D_{k+q+1}^j(1) & N_{k+\ell}^j(\ell) & \vdots & N_{k+q+1}^j(1) \\ O & D_{k+\ell+1}^j(\ell) & D_{k+q+2}^j(2) & O & N_{k+\ell+1}^j(\ell) & N_{k+q+2}^j(2) \\ O & O & \vdots & \vdots & O & \cdot \\ O & \vdots & \cdot & \cdot & \vdots & \vdots \\ O & O & D_{k+q+\ell}^j(\ell) & O & O & N_{k+q+\ell}^j(\ell) \end{bmatrix}$$

for $j = 1, 2, \dots, r$. If we now define the matrix

$$(3.16) \quad M_k = \text{col} (M_k^1, M_k^2, \dots, M_k^r)$$

and the matrix

$$(3.17) \quad \Delta_k = \text{col} (\Delta_k^1, \Delta_k^2, \dots, \Delta_k^r)$$

we can combine the r linear equations (3.12) as

$$(3.18) \quad M_k \nu_k = \Delta_k.$$

It is easy to check that M_k is a $rp(\ell+q) \times (q+1)(m+p)$ matrix, ν_k is a $(q+1) \times (m+p) \times p$ matrix, and Δ_k is a $rp(\ell+q) \times p$ matrix. It follows that given M_k and Δ_k we can solve (3.18) for a suitable ν_k if and only if

$$(3.19) \quad rp(\ell+q) \leq (q+1)(m+p) - p,$$

and M_k is of full column rank for each k . The inequality (3.19) follows from the requirement that (3.18) is solvable if and only if the matrix M_k after deleting the first p columns has more columns than rows. Note that the inequality (3.19) is the same as the inequality (3.11). The proof of this theorem is now complete by noting that generically the rows of M_k^* obtained from M_k by deleting the first p columns are all independent. The proof of this last statement is technical, and we refer to [27] for details. The basic idea is to choose a minor for M_k with nonidentically vanishing determinant. \square

Proof of Theorem 3.4. The sufficiency part of Theorem 3.2 follows from Theorem 3.1. We now have to prove the necessity part.

Let λ be a variable that takes on values $1, 2, 3, \dots$. Assume that the r -tuple of plants (3.1) is generically coefficient assignable by the compensator (3.3) and assume that the coefficients $\Delta_k^j(i)$ are all bounded with respect to some matrix norm; i.e., there exists $M > 0$ such that

$$(3.20) \quad \|\Delta_k^j(i)\| \leq M$$

for all $j = 1, \dots, r; i = 1, 2, \dots, l + q$ and $k = 0, 1, \dots$. Let \mathcal{P}^r be the space of r -tuples of plants equipped with the product topology similar to that described in (2.25). We now describe a map Ψ_λ for each λ given by

$$(3.21) \quad \Psi_\lambda : \mathcal{P}^r \rightarrow \mathcal{P}^r$$

described as

$$\begin{aligned} D_k^j(i) &\mapsto \lambda^{-i} D_k^j(i), \\ N_k^j(i) &\mapsto \lambda^{-i} N_k^j(i). \end{aligned}$$

It follows that Ψ_λ maps a generic set of r -tuples of plants to a generic set of r -tuples of plants. For each λ we now define the compensator

$$C_\lambda(z^{-1}) = \bar{N}_\lambda(z^{-1})\bar{D}_\lambda^{-1}(z^{-1}),$$

where

$$\begin{aligned} (3.22) \quad \bar{D}_\lambda(z^{-1}) &= I + \sum_{i=1}^q \lambda^{-i} \bar{D}_k(i) z^{-i}, \\ \bar{N}_\lambda(z^{-1}) &= \sum_{i=0}^q \lambda^{-i} \bar{N}_k(i) z^{-i}. \end{aligned}$$

Thus, we conclude that for each λ , there exists an open and dense set S_λ such that every r -tuple of plants in S_λ can be assigned with coefficients $\Delta_k^j(i)$, by a compensator of type (3.22), such that

$$(3.23) \quad \|\lambda^i \Delta_k^j(i)\| \leq M$$

for $i = 1, 2, \dots, \ell + q$. Define

$$(3.24) \quad U = \cap_{\lambda=1}^x S_\lambda.$$

Thus, for every r -tuple of plants in U , there is a sequence of compensators such that the corresponding closed-loop system has coefficients in an arbitrary small neighborhood of 0. However, the map from the space of compensators to the space of coefficients is a linear

map described by (3.18). It follows that the image of this linear map is closed. Hence, for every r -tuple of plants in U , there exists a compensator that places the coefficients $\Delta_k^j(i)$ at 0. In other words, we can solve the system of equation

$$(3.25) \quad M_k \nu_k = 0.$$

The proof of Theorem 3.4 is now completed by showing that there exist open sets of r -tuples of plants for which (3.25) is not satisfied if $rp \geq p + m$. This is done as follows.

Define

$$(3.26) \quad \begin{aligned} D_j^*(i) &= \text{col} [D_j^1(i), D_j^2(i), \dots, D_j^r(i)], \\ N_j^*(i) &= \text{col} [N_j^1(i), N_j^2(i), \dots, N_j^r(i)]. \end{aligned}$$

We now make specific choices of $D_j^*(i), N_j^*(i)$ as follows. As $m + p \leq rp$, which implies $rp\ell > m$, we set

(i) the $rp\ell \times m$ matrix

$$(3.27) \quad \text{col} [N_{k+1}^*(1), N_{k+2}^*(2), \dots, N_{k+\ell}^*(\ell)] \equiv [e_1, e_2, \dots, e_m],$$

where e_i is the i th standard basis vector in $\mathbb{R}^{rp\ell}$, $i = 1, \dots, m$;

(ii) the first column of the matrix

$$\text{col} [-D_{k+1}^*(1), -D_{k+2}^*(2), \dots, -D_{k+\ell}^*(\ell)]$$

to be e_{m+1} , where e_{m+1} is the $m+1$ st standard basis vector in $\mathbb{R}^{rp\ell}$; and

(iii) the $rp \times (p + m)$

$$(3.28) \quad [D_{k+\ell+j}^*(\ell), N_{k+\ell+j}^*(\ell)] \equiv [e_1, e_2, \dots, e_{m+p}],$$

where e_i is the i th standard basis vector in \mathbb{R}^{rp} , $i = 1, \dots, m + p$ for $j = 1, \dots, q$.

For the above choice of r -tuple of plants, it can be shown that (3.25) cannot be solved (see [27] for details). Furthermore, in any neighborhood of the coefficient space of the above r -tuple of plants, (3.25) has no solution. This concludes the proof. \square

Remark. The proof of Theorem 3.4 is an adaptation of a technique due originally to Anderson and Byrnes [29].

Remark 3.5. We now state and prove a result that addresses Problem 3.2.

THEOREM 3.6. *A bounded set S of r -tuple of $p \times m$ plants is coefficient assignable simultaneously by a compensator with bounded coefficients if (3.10) is satisfied and if*

$$(3.29) \quad \det [M_k M_k^T] > \epsilon$$

for some $\epsilon > 0$, which is independent of k , and for all r -tuples of plants in S .

Note that as a result of condition (3.29), S fails to be a generic set. The proof of Theorem 3.6 follows from the following simple and well-known proposition.

PROPOSITION 3.7. *Let z be an m vector and A be an m by n matrix of rank m . The n vector x such that $Ax = z$ and $x^T x$ is minimum is given by*

$$(3.30) \quad x = A^T (AA^T)^{-1} z$$

For a proof of the above proposition see Brockett [30, p. 127].

Proof of Theorem 3.6. Our basic problem is to solve (3.18) for a uniformly bounded ν_k . Clearly, in view of Proposition 3.7, the solution

$$(3.31) \quad \nu_k^* = M_k^T (M_k M_k^T)^{-1} \Delta_k$$

has the property that the columns of ν_k^* have minimum norm. Since the r -tuple of plants and the coefficients Δ_k are all bounded uniformly in k , it follows that under the assumption (3.29), ν_k^* is uniformly bounded as well. \square

To conclude this section, we reiterate the three important questions that we address in this section.

(a) For a generic set of r -tuple of $p \times m$ plants, when is it possible to coefficient assign simultaneously?

(b) For a generic set of r -tuple of $p \times m$ plants, when is it possible to assign a bounded set of coefficients simultaneously?

(c) For a set of r -tuple of $p \times m$ plants, when is it possible to assign coefficients simultaneously by a compensator with coefficients bounded uniformly in k ?

4. A recursive formulation of the coefficient assignment problem. We begin this section with the remark that, so far in this paper, Problem 1.4 has not been considered. Instead, in § 3, the closed-loop system was decomposed into ARMA and moving average subsystems. The design problem considered has been to assign the coefficients of the ARMA subsystem while maintaining an uniform bound on the coefficients of the compensators. Such a design problem leads to a simplified algorithm. To implement the algorithm, we need to solve linear equations.

We now consider Problem 1.4 for a single plant. The case for an r -tuple of plants is analogous and is not described in detail. Assume that the plants and the compensator are put in the configuration given by Fig. 3.1. For simplicity, we only consider the transfer function between y_1 and u_1 . However, unlike that in § 3, we will not decompose the transfer function (3.7) into a cascade of two transfer functions (3.8), (3.9). We will see shortly in this section that this introduces new problems, namely, the compensator parameters are not obtained by solving static linear equations one for each time. In general, Problem 1.4 reduces to a nonlinear discrete iteration on the parameter space of compensators. The algorithm, although more complicated, iteratively solves this coefficient assignment problem.

Consider the transfer function (3.7) for a single plant (i.e., assume $j = 1$). Define

$$(4.1) \quad \mathcal{X}(z^{-1}) = \sum_{i=0}^q X_k(i) z^{-i},$$

$$(4.2) \quad \Delta(z^{-1}) = \sum_{i=0}^{\ell+q} \Delta_k(i) z^{-i}$$

such that

$$(4.3) \quad \bar{\mathcal{D}} \circ (\mathcal{D} \circ \bar{\mathcal{D}} + \mathcal{N} \circ \bar{\mathcal{N}})^{-1} = \Delta^{-1} \circ \mathcal{X}.$$

The transfer function (3.7) can be written as

$$(4.4) \quad \Delta(z^{-1}) y_k = \mathcal{X}(z^{-1}) \circ \mathcal{N}(z^{-1}) u_k$$

PROBLEM 4.1 (the coefficient assignment problem). Given $\mathcal{N}(z^{-1})$ and $\mathcal{D}(z^{-1})$, find, if possible, an $\bar{\mathcal{N}}(z^{-1})$, $\bar{\mathcal{D}}(z^{-1})$ such that $\Delta_k(i)$, $i = 1, \dots, \ell+q$ can be assigned a prespecified set of coefficients.

Problem 4.1 can be stated equivalently by rewriting (4.3) as

$$(4.5) \quad \mathcal{X} \circ (\mathcal{D} \circ \bar{\mathcal{D}} + \mathcal{N} \circ \bar{\mathcal{N}}) = \Delta \circ \bar{\mathcal{D}}$$

To solve (4.5) we equate like powers of z^{-1} , $i = 0, 1, \dots, \ell + 2q$ for all $k \geq i$ and solve for $\bar{\mathcal{D}}$ and $\bar{\mathcal{N}}$. This will be accomplished by considering two sets of equations.

(A) The set of equations derived by equating like powers of z^{-1} , $i = \ell + q, \dots, \ell + 2q$ in (4.5), and

(B) The set of equations derived by equating like powers of z^{-1} , $i = 0, \dots, \ell + q - 1$ in (4.5).

Using the above two sets of equations, we derive an iterative scheme that will allow us to solve (4.5). From the set of equations (A) as described above, we get the matrix equation

$$(4.6) \quad S_k \phi_k = \psi_k,$$

where S_k is a $(q+1)p \times (q+1)p$ matrix defined by

$$(4.7) \quad \begin{bmatrix} \zeta_{k+\ell+q-1}^T(\ell+q) & \zeta_{k+\ell+q-2}^T(\ell+q-1) & \zeta_{k+\ell+q-3}^T(\ell+q-2) & \cdots & \zeta_{k+\ell}^T(\ell+1) & \zeta_{k+\ell-1}^T(\ell) \\ 0 & \zeta_{k+\ell+q-2}^T(\ell+q) & \zeta_{k+\ell+q-3}^T(\ell+q-1) & \cdots & \zeta_{k+\ell}^T(\ell+2) & \zeta_{k+\ell-1}^T(\ell+1) \\ 0 & 0 & \zeta_{k+\ell+q-3}^T(\ell+q) & \cdots & \zeta_{k+\ell}^T(\ell+3) & \zeta_{k+\ell-1}^T(\ell+2) \\ & & \vdots & & & \\ 0 & 0 & 0 & 0 & \zeta_{k+\ell}^T(\ell+q) & \zeta_{k+\ell-1}^T(\ell+q-1) \\ 0 & 0 & 0 & 0 & 0 & \zeta_{k+\ell-1}^T(\ell+q) \end{bmatrix}$$

and where we define

$$(4.8) \quad \mathcal{D}_k \circ \bar{\mathcal{D}}_k + \mathcal{N}_k \circ \bar{\mathcal{N}}_k = \sum_{i=0}^{\ell+q} \zeta_k(i) z^{-i}.$$

Moreover, ϕ_k and ψ_k are defined as follows. Note that ϕ_k is a $(q+1)p \times p$ matrix given by

$$(4.9) \quad \phi_k = \text{col} [X_{k+\ell+q-1}^T(0), X_{k+\ell+q-1}^T(1), \dots, X_{k+\ell+q-1}^T(q-1), X_{k+\ell+q-1}^T(q)]$$

and ψ_k is a $(q+1)p \times p$ matrix given by

$$(4.10) \quad \psi_k = \text{col} \left[\sum_{j=0}^q \bar{D}_{k+q-j-1}^T(q-j) \Delta_{k+\ell+q-1}^T(\ell+j), \right. \\ \cdot \sum_{j=0}^{q-1} \bar{D}_{k+q-j-2}^T(q-j) \Delta_{k+\ell+q-1}^T(\ell+j+1), \dots, \\ \cdot \sum_{j=0}^{q-i} \bar{D}_{k+q-j-i-1}^T(q-j) \Delta_{k+\ell+q-1}^T(\ell+j+i), \dots, \bar{D}_{k-1}^T(q) \Delta_{k+\ell+q-1}^T(\ell+q) \left. \right].$$

Similarly, from the set of equations (B) we obtain

$$(4.11) \quad M_k \nu_k = O,$$

where ν_k is defined as follows:

$$\nu_k = \text{col} [\bar{D}_k(0), \bar{D}_{k+1}(1), \dots, \bar{D}_{k+q}(q); \bar{N}_k(0), \bar{N}_{k+1}(1), \dots, \bar{N}_{k+q}(q)].$$

The matrix M_k is a $(\ell + q)p \times (q + 1)(p + m)$ matrix that can be shown to be a function of x_k, Δ_k and the plant parameters. If we assume that

$$(q + 1)m > p(\ell - 1),$$

it follows that (4.11) can be solved for a nonzero solution.

Using (4.6) and (4.11), we are now in a position to solve (4.5), and hence, the coefficient assignment problem, in an iterative fashion. However, before we consider the following coefficient assignment algorithm, for the sake of clarity, we will provide an overview of the basic idea. First, we will initialize the algorithm by choosing suitable (timewise) values of the plant, compensator, and parameters to be assigned (i.e., the $\Delta_j(i)$). Having obtained these values, we are then able to solve for the next set (timewise) of compensator parameters ν_k via (4.11). These values of ν_k are then used in (4.6) to solve for the next set of $X_k(i) i = 0, \dots, q$. These values of X_k are then substituted into (4.11) to solve for ν_{k+1} , which is used in turn to solve for X_{k+1} etc. ... It will be assumed that in the following coefficient assignment algorithm (4.6) and (4.11) admit solutions for all times k and that $\det \bar{D}_k(0) \neq 0$ for all k so that \bar{D}^{-1} always exists.

The coefficient assignment algorithm

Step I (initialize the algorithm). Choose values for

- (i) $\bar{D}_j(i), \bar{N}_j(i) i = 0, \dots, q, j \leq i - 1$
- (ii) $D_j(i), N_j(i) i = 0, \dots, \ell - 1, j \leq q + i - 1; i = \ell, j \leq \ell + q - 1$
- (iii) $\Delta_j(i) i = 0, 1, \dots, \ell - 1, j \leq q + i; i = \ell, \dots, \ell + q, j \leq \ell + q - 1$

Step II. Solve (4.6) for $X_j(i) i = 0, \dots, q, j = 0, 1, \dots, \ell + q - 1$ and

Step III. Using the values of $X_j(i)$ computed in Step II compute ν_0 using (4.11).

Step IV. Set $k = 0$

Step V. Obtain an estimate of the future values of the plant parameters

(1) $D_{k+q+i+1}(i), N_{k+q+i+1}(i), i = 0, 1, \dots, \ell - 1$ and $D_{k+q+\ell}(\ell), N_{k+q+\ell}(\ell)$ and choose values for

(2) $\Delta_{k+q+i+1}(i) i = 0, 1, \dots, \ell - 1$ and $\Delta_{k+q+\ell}(i) i = \ell, \dots, \ell + q$

Step VI. Solve (4.6) for $X_{k+\ell+q}(i) i = 0, \dots, q$

Step VII. Solve (4.11) for ν_{k+1}

Step VIII. Set $k = k + 1$ and return to Step V.

Remark 4.2. The values required in Step I could be based on the available knowledge of the plant parameters $D_k(i), N_k(i) i = 0, \dots, \ell$ at time $k = 0$ and the values of $\Delta_k(i) i = 0, 1, \dots, \ell + q$, which have been specified. It should also be noted that the lag q of the compensator computed via the above algorithm is the smallest nonnegative integer, which satisfies $q > [p(\ell - 1) - m]/m$.

Remark 4.3. It can be shown that, using techniques similar to those of §3, that the above algorithm can be extended to simultaneously coefficient assign an r -tuple of $p \times m$ systems, where $r < m/p + 1$. We will not elaborate on this further and refer the interested reader to [31].

We now consider two illustrative examples of the above coefficient assignment algorithm.

Example 4.4. Consider the closed-loop system given by Fig. 1.1 (assume $j = 1$) where the plant G is given by

$$y_k + a_k y_{k-1} = b_k u_k + c_k u_{k-1}$$

and the compensator C is given by the gain feedback

$$u_k^* = \bar{d}_k^{-1} y_k.$$

Writing the plant as

$$y_k = (d_k^{-1} \circ n_k) u_k,$$

where

$$d_k(z^{-1}) = 1 + a_k z^{-1}; n_k(z^{-1}) = b_k + c_k z^{-1},$$

we obtain by Theorem 3.3 the equation of the closed-loop system as follows:

$$(4.12) \quad ([d_k \circ \bar{d}_k + n_k] \circ \bar{d}_k^{-1}) y_k = n_k u_k.$$

Writing

$$(4.13) \quad (d_k \circ \bar{d}_k + n_k) \circ \bar{d}_k^{-1} = f_k^{-1} \circ (1 + e_k z^{-1}),$$

(4.12) reduces to

$$y_k + e_k y_{k-1} = f_k b_k u_k + f_k c_k u_{k-1}.$$

From (4.13) it follows that

$$f_k \circ (d_k \circ \bar{d}_k + n_k) = (1 + e_k z^{-1}) \circ \bar{d}_k,$$

i.e., equating like powers of z^{-1}

$$(4.14) \quad f_k(\bar{d}_k + b_k) = \bar{d}_k \quad \forall k \geq 0$$

and

$$(4.15) \quad f_k(a_k \bar{d}_{k-1} + c_k) = e_k \bar{d}_{k-1} \quad \forall k \geq 1.$$

Eliminating \bar{d}_k in (4.14) and (4.15), we obtain

$$(4.16) \quad f_{k+1} = \frac{f_k b_k e_{k+1}}{c_{k+1} - f_k [c_{k+1} - a_{k+1} b_k]} \quad \forall k \geq 0$$

and

$$(4.17) \quad \bar{d}_k = \frac{f_k b_k}{1 - f_k} \quad \forall k \geq 0.$$

Given the plants parameters a_k, b_k , and c_k , and given e_k , the coefficient of the closed-loop system to be assigned, (4.16) describes a nonlinear recursion in f_k . Equation (4.17), on the other hand, is a nonlinear function that computes the feedback gain in real time.

Among several questions that we might ask about (4.16) and (4.17), an important one in terms of understanding the properties of the coefficient assignment algorithm is the following.

Question 4.5. If a_k, b_k, c_k , and e_k are time invariant and given, respectively, by a, b, c , and e , what is the asymptotic behavior of (4.16) and (4.17)?

Defining $\alpha = be$, $\beta = c$, and $\gamma = -[c - ab]$, we obtain the following recursion from (4.16):

$$(4.18) \quad f_{k+1} = \frac{\alpha f_k}{\beta + f_k \gamma}.$$

Note that (4.18) has two stationary points 0 and $(\alpha - \beta)/\gamma$. It is easy to show that the second stationary point corresponds to the time-invariant solution; i.e., the corresponding value of the gain \bar{d} equals the value of the gain, which assigns the parameter e in the closed-loop system if a, b, c , and e were time invariant and known. The stationary point 0, on the other hand, corresponds to an infinite gain.

To examine the trajectory of f_{k+1} as defined by (4.18), we write

$$(4.19) \quad f_k = \frac{g_k}{h_k}$$

Substituting (4.19) into (4.18) yields

$$\frac{g_{k+1}}{h_{k+1}} = \frac{\alpha g_k}{\beta h_k + \gamma g_k},$$

which may be rewritten as

$$\begin{bmatrix} g_{k+1} \\ h_{k+1} \end{bmatrix} = \begin{bmatrix} \alpha & 0 \\ \gamma & \beta \end{bmatrix} \begin{bmatrix} g_k \\ h_k \end{bmatrix}.$$

With an initial (nonzero) estimate f_0 of the true value of $f = (\alpha - \beta)/\gamma$ we may write

$$\begin{bmatrix} g_k \\ h_k \end{bmatrix} = -f_0 \alpha^k \begin{bmatrix} \alpha - \beta \\ \gamma \end{bmatrix} + [(\beta - \alpha) + \gamma f_0] \beta^k \begin{bmatrix} 0 \\ 1 \end{bmatrix}.$$

Therefore, if $|\alpha| > |\beta|$ (i.e., $|be| > |c|$)

$$\lim_{k \rightarrow \infty} f_k = \lim_{k \rightarrow \infty} \frac{g_k}{h_k} = \frac{\alpha - \beta}{\gamma}.$$

On the other hand, if $|\alpha| < |\beta|$,

$$\lim_{k \rightarrow \infty} f_k = 0.$$

We may summarize the above results as follows: for choices of a, b, c , and e for which $|be| < |c|$, the adaptive gain \bar{d} tends toward 0, the infinite gain. For choices of a, b, c , and e for which $|be| > |c|$, the adaptive gain converges to the unique time-invariant solution.

Remark 4.6. Example 4.4 illustrates that under suitable conditions on the coefficients of a time-invariant plant, the coefficient assignment algorithm may be viewed as a globally convergent adaptive controller. It may also be noted that when $\alpha = \beta = 1$ or when $\alpha = \beta = -1$, $|f_k|$ converges to 0 as k tends to infinity. On the other hand, when $\alpha = -\beta = 1$, f_k is periodic of period 2.

Example 4.7. Consider the closed-loop system defined by Fig. 1.1 (assume $j = 1$), where the plant G is given by

$$(4.20) \quad y_k + d_k(1)y_{k-1} + d_k(2)y_{k-2} = n_k(1)u_{k-1} + n_k(2)u_{k-2}$$

and the compensator C is given by

$$(4.21) \quad u_k^* + \bar{d}_k(1)u_{k-1}^* = \bar{n}_k(0)y_k + \bar{n}_k(1)y_{k-1}.$$

Define $\mathcal{X}_k(z^{-1})$ given by (4.1)–(4.3) as follows:

$$\mathcal{X}_k(z^{-1}) = 1 + X_k z^{-1}.$$

It can be shown that by writing the parameters of the compensator (4.21) in terms of the plant parameters and the $\Delta_j(i)$ it is possible to derive the following recursive equation for X_k :

$$(4.22) \quad X_{k+4} = \frac{f(X_{k+3}, X_{k+2}, X_{k+1})}{g(X_{k+3}, X_{k+2}, X_{k+1})},$$

where

$$\begin{aligned} f(X_{k+3}, X_{k+2}, X_{k+1}) = & \phi_k(1)X_{k+3} + \phi_k(2)X_{k+2} + \phi_k(3)X_{k+1} + \phi_k(4)X_{k+3}X_{k+2} \\ & + \phi_k(5)X_{k+2}X_{k+1} + \phi_k(6)X_{k+3}X_{k+2}X_{k+1} + \phi_k(7) \end{aligned}$$

and

$$\begin{aligned} g(X_{k+3}, X_{k+2}, X_{k+1}) = & \phi_k(8)X_{k+3} + \phi_k(9)X_{k+2} + \phi_k(10)X_{k+1} + \phi_k(11)X_{k+3}X_{k+2} \\ & + \phi_k(12)X_{k+3}X_{k+1} + \phi_k(13)X_{k+2}X_{k+1} + \phi_k(14)X_{k+3}X_{k+2}X_{k+1} + \phi_k(15). \end{aligned}$$

In the above equation, $\phi_k(i)i = 1, \dots, 15$ are nonlinear functions of the plant parameters and the parameters to be assigned at times $k+1, k+2, k+3$.

A complete analysis of recursions of the type (4.22) is a subject of future research. We would analyze (4.22) under certain special cases. If we denote X_k by y_k/ζ_k , we can rewrite the recursion (4.22) as follows.

$$\begin{aligned} y_{k+4} = & \phi_k(1)y_{k+3}\zeta_{k+2}\zeta_{k+1} + \phi_k(2)\zeta_{k+3}y_{k+2}\zeta_{k+1} \\ & + \phi_k(3)\zeta_{k+3}\zeta_{k+2}y_{k+1} + \phi_k(4)y_{k+3}y_{k+2}\zeta_{k+1} \\ & + \phi_k(5)\zeta_{k+3}y_{k+2}y_{k+1} + \phi_k(6)y_{k+3}y_{k+2}y_{k+1} + \phi_k(7)\zeta_{k+3}\zeta_{k+2}\zeta_{k+1} \cdot \\ \zeta_{k+4} = & \phi_k(8)y_{k+3}\zeta_{k+2}\zeta_{k+1} + \phi_k(9)\zeta_{k+3}y_{k+2}\zeta_{k+1} + \phi_k(10)\zeta_{k+3}\zeta_{k+2}y_{k+1} \\ & + \phi_k(11)y_{k+3}y_{k+2}\zeta_{k+1} + \phi_k(12)\zeta_{k+3}y_{k+2}y_{k+1} \\ & + \phi_k(13)y_{k+3}\zeta_{k+2}y_{k+1} + \phi_k(14)\zeta_{k+3}\zeta_{k+2}\zeta_{k+1} + \phi_k(15)y_{k+3}y_{k+2}y_{k+1}. \end{aligned}$$

If we assume without any loss of generality that $y_k^2 + \zeta_k^2 = 1$, we can reparameterize $y_k = \cos \theta_k, \zeta_k = \sin \theta_k$. Furthermore, if we choose

$$(4.23) \quad \begin{aligned} \phi_k(1) = \phi_k(2) = \phi_k(3) = -1, \phi_k(6) = \phi_k(4) = \phi_k(5) = \phi_k(7) = 0, \\ \phi_k(8) = \phi_k(9) = \phi_k(10) = \phi_k(15) = 0, \\ \phi_k(11) = \phi_k(12) = \phi_k(13) = 1, \phi_k(14) = -1, \end{aligned}$$

we have

$$\begin{aligned}\cos \theta_{k+4} &= \cos(\theta_{k+3} + \theta_{k+2} + \theta_{k+1}), \\ \sin \theta_{k+4} &= \sin(\theta_{k+3} + \theta_{k+2} + \theta_{k+1}).\end{aligned}$$

Thus, for the special choices of $\phi_k(\cdot)$ given by (4.23), the recursion (4.22) reduces to

$$(4.24) \quad \theta_{k+4} = \theta_{k+3} + \theta_{k+2} + \theta_{k+1}.$$

We now claim that (4.24) describes an Anosov flow [32] on T^3 , the three-dimensional torus. Consider the system

$$(4.25) \quad \begin{bmatrix} \alpha_{k+1} \\ \beta_{k+1} \\ \nu_{k+1} \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 1 & 1 \end{bmatrix} \begin{bmatrix} \alpha_k \\ \beta_k \\ \nu_k \end{bmatrix}$$

on \mathbb{R}^3 , where $\alpha_0 = \theta_0$, $\beta_0 = \theta_1$, and $\nu_0 = \theta_2$. It follows that $\nu_k = \theta_{k+2}$. Let the 3×3 matrix in (4.25) be denoted by A . Since all entries of A are integers, $\det A = 1$ and A is hyperbolic, it follows that the map induced on T^3 by A is a hyperbolic toral automorphism, which we denote by L_A . It follows from [32, Thm. 4.8] that periodic points of L_A are dense in T^3 , L_A is topologically transitive, and L_A has sensitive dependence on initial conditions. Thus, the hyperbolic toral automorphism is chaotic on all of T^3 (see [32, p. 197]).

What we conclude, therefore, is that for choices of $\phi_k(\cdot)$ given by (4.23), the time-varying coefficient assignment problem is chaotic. Thus, if we use adaptive coefficient assignment as a strategy for compensation, we must carefully avoid chaotic dynamics.

5. Conclusion. In this paper, we have given conditions under which an input–output map for a time-varying system admits left and/or right matrix fraction representations. Using these representations, we have described procedures for the simultaneous coefficient assignment of a family of time-varying systems using nonrecursive algebraic techniques. It is important to note that these techniques are generalizations of well-known design methodologies in time-invariant system theory [1]–[3] to the time-varying case. When the number of input and output channels is such that the conditions of the nonrecursive coefficient assignment scheme is not satisfied, recursive procedures to coefficient assign time-varying systems are given in the form of a recursive algorithm. These recursive procedures have no analogues in the time-invariant case, and thus, represent a new design procedure. For certain special cases, solution of the proposed recursive algorithm is shown to be chaotic. This fact indicates that further work needs to be done and a complete analysis of the algorithms given in §4 is a subject of future research.

6. Appendix I. The purpose of this appendix is to prove Theorem 2.13. Let us consider a right factorization of lag $\bar{\ell}$ given by (2.24). Let us also consider a left factorization of the form (2.12) of lag ℓ . The two representations have the same input–output properties provided:

$$(6.1) \quad \left[\sum_{i=0}^{\bar{\ell}} \bar{N}_k(i) z^{-i} \right] \circ \left[I + \sum_{i=1}^{\bar{\ell}} \bar{D}_k(i) z^{-i} \right]^{-1} = \left[I + \sum_{i=1}^{\ell} D_k(i) z^{-i} \right]^{-1} \circ \left[\sum_{i=0}^{\ell} N_k(i) z^{-i} \right]$$

or, equivalently,

$$\left[I + \sum_{i=1}^{\ell} D_k(i) z^{-i} \right] \circ \left[\sum_{i=0}^{\bar{\ell}} \bar{N}_k(i) z^{-i} \right] - \left[\sum_{i=0}^{\ell} N_k(i) z^{-i} \right] f \circ \left[I + \sum_{i=1}^{\bar{\ell}} \bar{D}_k(i) z^{-i} \right] = 0. \quad (6.2)$$

Expanding (6.2) and equating like powers of z^{-1} , we obtain

$$N_k(0) = \bar{N}_k(0) \text{ for } k = 0, 1, 2, \dots$$

and

$$\nu_k M_k = \phi_k \text{ for } k = 0, 1, 2, \dots, \quad (6.3)$$

where

$$\begin{aligned} \nu_k &= [D_k(1), D_k(2), \dots, D_k(\ell), N_k(1), N_k(2), \dots, N_k(\ell)], \\ \phi_k &= [\bar{N}_k(0)\bar{D}_k(1) - \bar{N}_k(1), \dots, \bar{N}_k(0)\bar{D}_k(\bar{\ell}) - \bar{N}_k(\bar{\ell}); 0, \dots, 0], \end{aligned}$$

$$M(k) =$$

$$\begin{bmatrix} \bar{N}_{k-1}(0) & \bar{N}_{k-1}(1) & \bar{N}_{k-1}(2) & \cdots & \bar{N}_{k-1}(\bar{\ell}) & O & O & O \\ O & \bar{N}_{k-2}(0) & \bar{N}_{k-2}(1) & \cdots & \cdots & \bar{N}_{k-2}(\bar{\ell}) & O & O \\ & & \vdots & & & & & \\ O & O & \bar{N}_{k-\ell}(0) & \cdots & \cdots & & & \bar{N}_{k-\ell}(\bar{\ell}) \\ -I & -\bar{D}_{k-1}(1) & -\bar{D}_{k-1}(2) & \cdots & -\bar{D}_{k-1}(\bar{\ell}) & O & O & O \\ O & -I & -\bar{D}_{k-2}(1) & \cdots & \cdots & -\bar{D}_{k-2}(\bar{\ell}) & O & O \\ & & \vdots & & & & & \\ O & O & \cdots & -I & -\bar{D}_{k-\ell}(1) & \cdots & & -\bar{D}_{k-\ell}(\bar{\ell}) \end{bmatrix}. \quad (6.4)$$

As ν_k is a $p \times \ell(p+m)$ matrix, ϕ_k is a $p \times (\ell + \bar{\ell})m$ matrix and M_k is a $\ell(p+m) \times (\ell + \bar{\ell})m$ matrix; it follows that a sufficient condition for (6.3) to have a solution ν_k is that M_k is of full row rank and $\ell(p+m) \geq (\ell + \bar{\ell})m$, i.e., if $\ell p \geq \bar{\ell}m$.

It is not too hard to check (see [27] for details) that the condition that M_k is not of full row rank is given by a proper algebraic set in \mathcal{P} (in the topology described in §2 (25)). In fact, for $k = \ell + \tau$, the condition that M_k is not of full row rank is obtained as proper algebraic set in the restriction of \mathcal{P} to

$$\prod_{j=\tau}^{\ell-1+\tau} \mathbb{R}^N$$

for $\tau = 0, 1, 2, \dots$. Thus, there is a countable intersection of open and dense set in \mathcal{P} for which M_k is of full row rank for all $k \geq \ell$.

Remark. In general, it is not entirely obvious why the associated algebraic sets in \mathcal{P} that makes M_k singular is proper. The proof consists of picking a minor of M_k with nonidentically vanishing determinant. The details being technical are relegated to [27].

ON THE NECESSARY CONDITIONS OF OPTIMAL CONTROLS FOR STOCHASTIC PARTIAL DIFFERENTIAL EQUATIONS*

XUN YU ZHOU†

Abstract. This paper concerns optimal control of systems governed by stochastic partial differential equations in which drift and diffusion terms are second- and first-order differential operators, respectively. Necessary conditions for an optimal control are derived for both nondegenerate and degenerate systems, and all the coefficients appearing in the equations are allowed to depend on the control variables. Furthermore, the results obtained in the paper can also be used to derive necessary conditions of optimality for partially observed diffusions with correlation between the signals and the observation noises.

Key words. stochastic partial differential equations (SPDEs), optimal control, adjoint equations, necessary conditions of optimality, partially observed diffusions.

AMS subject classifications. 60H15, 93E20

1. Introduction. Let us consider a stochastic control problem, in which the state equation is a linear stochastic partial differential equation (SPDE):

$$(1.1) \quad \begin{aligned} dq(t, x) &= [\partial_i(a^{ij}(t, x, U(t))\partial_j q(t, x)) + b^i(t, x, U(t))\partial_i q(t, x) + c(t, x, U(t))q(t, x) \\ &\quad + f(t, x, U(t))]dt + [\sigma^{ik}(t, x, U(t))\partial_i q(t, x) + h^k(t, x, U(t))q(t, x) \\ &\quad + g^k(t, x, U(t))]dW_k(t), \quad x \in R^d, \quad t \in [0, 1], \\ q(0, x) &= q_0(x), \quad x \in R^d, \end{aligned}$$

where $W := (W_1, W_2, \dots, W_{d'})$ is a d' -dimensional standard Brownian motion with $W(0) = 0$, $\{U(t) : 0 \leq t \leq 1\}$ is an admissible control (the precise definition will be given later) and $\partial_i := \partial/\partial x_i$, $i = 1, 2, \dots, d$. Throughout the paper, the conventional repeated indices for summation are used.

The optimal control problem is to minimize a given cost functional over the set of admissible controls.

The purpose of this paper is to study necessary conditions of an optimal control for the controlled system (1.1). It is well known that the so-called adjoint equations play a key role in dealing with the problem. Adjoint equations are, in general, *backward* equations with given terminal states. In stochastic problems, adjoint equations cannot be obtained simply by inverting the time, because the adaptiveness must be considered. For stochastic differential equations (SDEs), Bismut [5] introduced an adjoint equation with an additional martingale term. His method is based on the invertibility of certain fundamental matrices in finite dimensions and cannot be carried over to SPDEs whose state spaces are *infinite* dimensions. Using a finite-dimensional approximation method, Bensoussan [3] derived an adjoint equation of a nondegenerate SPDE (in a form more abstract than (1.1)) with its diffusion being a bounded operator. In the present paper, we solve the adjoint equation of (1.1) with $\sigma^{ik} \neq 0$ (i.e., the diffusion operator is unbounded), which is important in both theory and application. To handle the problem, the basic approach we employ is still the finite-dimensional approximation. It should be noted that, while this is a very natural approach to infinite-dimensional problems, the difficulty is how to obtain certain *compactness* of the approximate solutions, which may vary from case to case. For explicit equations like

† Department of Mathematics, Fudan University, Shanghai, China. This research was completed during a visit by the author to Department of Mathematics, Faculty of Science, Kobe University, Kobe 657, Japan.

(1.1), some delicate estimates of differential operators, originally due to Krylov and Rozovskii [8]–[10], will be used in this paper to show the compactness. Therefore, an adjoint equation of (1.1) as well as existence and uniqueness of its solutions will be derived.

Having obtained the adjoint equation, we derive necessary conditions of optimality for system (1.1) in which *all* the coefficients are allowed to depend on the control variable. Furthermore, the results obtained can be applied directly to a general model of partially observed diffusions with *correlation* between the signals and the observation noises. Therefore the existing results of Bensoussan [3], [4], Haussmann [7], and Baras, Elliott, and Kohlmann [1] are improved and extended considerably.

It should be mentioned that, in addition to the finite-dimensional approximation approach, there is a “time change” technique, which Bensoussan [4] used to solve the adjoint equation and study the necessity of optimality for the SPDE (1.1) with $\sigma^{ik} = 0$. Its main idea is to turn (1.1) into a P -almost surely *deterministic* PDE, basing on a transformation $e^{M^k W_k(t)}$, where M^k represents the diffusion operator (see (2.2), below). When $\sigma^{ik} \neq 0$, transformations of the same kind are also available, provided that the Brownian motion involved is one-dimensional; see [6], [15]. However, this method fails to work in general when $\sigma^{ik} \neq 0$ and the Brownian motion is multidimensional; refer to [15, §5.1] for a detailed discussion on this point.

The paper is organized as follows. In §2 we formulate our problem and introduce some basic notation and assumptions. In §3 we state a few fundamental results of SPDEs in the form convenient for us to use in the paper. Sections 4 and 5 are the main part of the paper. In §4 we derive an adjoint equation and prove existence and uniqueness of its solutions, and in §5 we investigate necessary conditions of optimality for system (1.1). The results in these two sections are valid, assuming that the system is nondegenerate (i.e., $S := (a^{ij} - \frac{1}{2} \sum_{k=1}^{d'} \sigma^{ik} \sigma^{jk})$ is uniformly positive definite). In §6 we discuss the degenerate case (i.e., S is nonnegative definite) and apply the main results to partially observed diffusions. Finally, §7 concludes the paper.

2. Problem formulation. Let Γ be a Borel set in some Euclidean space R^M . We define a family of second-order differential operators $\{A(t, u) : t \in [0, 1], u \in \Gamma\}$ and a family of first-order differential operators $\{M^k(t, u) : t \in [0, 1], u \in \Gamma, k = 1, 2, \dots, d'\}$ by

$$(2.1) \quad A(t, u)\phi(x) := \partial_i(a^{ij}(t, x, u)\partial_j\phi(x)) + b^i(t, x, u)\partial_i\phi(x) + c(t, x, u)\phi(x)$$

and

$$(2.2) \quad M^k(t, u)\phi(x) := \sigma^{ik}(t, x, u)\partial_i\phi(x) + h^k(t, x, u)\phi(x) \quad \text{for } x \in R^d, \phi \in C_0^\infty(R^d),$$

where $a^{ij}, b^i, c, \sigma^{ik}$, and h^k are given real-valued functions, $i, j = 1, 2, \dots, d$ and $k = 1, 2, \dots, d'$.

We also consider the formal adjoints of the operators $A(t, u)$ and $M^k(t, u)$

$$(2.3) \quad \begin{aligned} A^*(t, u)\phi(x) := & \partial_i(a^{ij}(t, x, u)\partial_j\phi(x)) - b^i(t, x, u)\partial_i\phi(x) \\ & + [c(t, x, u) - \partial_i b^i(t, x, u)]\phi(x), \end{aligned}$$

$$(2.4) \quad M^{k*}(t, u)\phi(x) := -\sigma^{ik}(t, x, u)\partial_i\phi(x) + [h^k(t, x, u) - \partial_i \sigma^{ik}(t, x, u)]\phi(x).$$

Let us now recall the definition of the Sobolev spaces. For $m = 0, 1, 2, \dots$, define $H^m := \{\phi : D^\alpha \phi \in L^2(R^d) \text{ for any } \alpha := (\alpha_1, \dots, \alpha_d) \text{ with } |\alpha| := |\alpha_1| + \dots + |\alpha_d| \leq m\}$,

with the norm

$$\|\phi\|_m := \left\{ \sum_{|\alpha| \leq m} \int_{R^d} |D^\alpha \phi(x)|^2 dx \right\}^{1/2}.$$

For $m = -1, -2, \dots$, define $H^m := (H^{-m})^*$. The Hilbert space H^m for any integer m is called a Sobolev space. For any integer m , let us consider the Gelfand triple $H^{m+1} \hookrightarrow H^m \hookrightarrow H^{m-1}$. We denote by $\langle \cdot, \cdot \rangle_m$ the duality pairing between H^{m-1} and H^{m+1} , and by $(\cdot, \cdot)_m$ the inner product in H^m .

For any second-order differential operator L that has the same form as (2.1), if we write $\langle L\phi, \psi \rangle_m$, then L is understood to be an operator from H^{m+1} to H^{m-1} by formally using Green's formula. For example, for the operator $A(t, u)$ defined by (2.1), we have

$$(2.5) \quad \begin{aligned} \langle A(t, u)\phi, \psi \rangle_m &:= -(a^{ij}(t, \cdot, u)\partial_j \phi, \partial_i \psi)_m + (b^i(t, \cdot, u)\partial_i \phi, \psi)_m \\ &\quad + (c(t, \cdot, u)\phi, \psi)_m \quad \text{for } \phi, \psi \in H^{m+1}. \end{aligned}$$

Remark 2.1. It is clear that $\langle A(t, u)\phi, \psi \rangle_0 = \langle \phi, A^*(t, u)\psi \rangle_0$ and $(M(t, u)\phi, \psi)_0 = (\phi, M^*(t, u)\psi)_0$ hold for $\phi, \psi \in H^1$. However, neither $\langle A(t, u)\phi, \psi \rangle_m = \langle \phi, A^*(t, u)\psi \rangle_m$ nor $(M(t, u)\phi, \psi)_m = (\phi, M^*(t, u)\psi)_m$ holds when $m \geq 1$.

For $\alpha, \beta \in (-\infty, +\infty)$ with $\alpha < \beta$, we are given a filtered probability space $(\Omega, \mathcal{F}, P, \mathcal{F}_t : \alpha \leq t \leq \beta)$ and a Hilbert space X . For $p \in [1, +\infty]$, define $L_{\mathcal{F}}^p(\alpha, \beta, X) := \{\phi : \phi \text{ is an } X\text{-valued, } \mathcal{F}_t\text{-adapted process on } [\alpha, \beta], \text{ and } \phi \in L^p([\alpha, \beta] \times \Omega; X)\}$. We identify ϕ and ϕ' in $L_{\mathcal{F}}^p(\alpha, \beta; X)$ whenever $D \int_{\alpha}^{\beta} \|\phi(t) - \phi'(t)\|_X^p dt = 0$.

Now we recall the definition of admissible controls. By the set U_{ad} of admissible controls, we mean the collection of (i) standard probability spaces (Ω, \mathcal{F}, P) and d' -dimensional Brownian motions $\{W(t) : 0 \leq t \leq 1\}$ with $W(0) = 0$; (ii) Γ -valued, \mathcal{F}_t -adapted measurable processes $\{U(t) : 0 \leq t \leq 1\}$, where $\mathcal{F}_t := \sigma\{W(s) : 0 \leq s \leq t\}$. We denote $(\Omega, \mathcal{F}, P, W, U) \in U_{\text{ad}}$, but on occasion we will only write $U \in U_{\text{ad}}$ if no ambiguity arises.

Given $(\Omega, \mathcal{F}, P, W, U) \in U_{\text{ad}}$, we rewrite (1.1) in the following form, omitting the variable x :

$$(2.6) \quad \begin{aligned} dq(t) &= [A(t, U(t))q(t) + f(t, U(t))]dt \\ &\quad + [M^k(t, U(t))q(t) + g^k(t, U(t))]dW_k(t), \quad t \in [0, 1], \\ q(0) &= q_0. \end{aligned}$$

A process $q = q^U \in L_{\mathcal{F}}^2(0, 1; H^1)$ is called a solution of (2.6) or a response for the control U if, for each $\eta \in C_0^\infty(R^d)$ and almost all $(t, \omega) \in [0, 1] \times \Omega$,

$$(2.7) \quad \begin{aligned} (q(t), \eta)_0 &= (q_0, \eta)_0 + \int_0^t \langle A(s, U(s))q(s) + f(s, U(s)), \eta \rangle_0 ds \\ &\quad + \int_0^t (M^k(s, U(s))q(s) + g^k(s, U(s)), \eta)_0 dW_k(s). \end{aligned}$$

The optimal control problem is to choose $(\Omega, \mathcal{F}, P, W, U) \in U_{\text{ad}}$ to minimize the following cost functional:

$$(2.8) \quad J(U) := E \left[\int_0^1 \langle F(t, U(t)), q^U(t) \rangle_0 dt + (G, q^U(1))_0 \right],$$

where $F : [0, 1] \times \Gamma \rightarrow H^{-1}$ and $G \in H^0$ are given.

Remark 2.2. The cost functional (2.8) includes the following one as a special case:

$$J(U) := E \left\{ \int_0^1 [(F^0(t, U(t)), q^U(t))_0 + (F^i(t, U(t)), \partial_i q^U(t))_0] dt + (G, q^U(1))_0 \right\}.$$

Let us fix an integer $m \geq 0$ and two positive constants K and δ . We introduce the following conditions:

(A1) $_m$ $a^{ij}, b^i, c, \sigma^{ik}, h^k : [0, 1] \times R^d \times \Gamma \rightarrow R^1$ are measurable in (t, x, u) and continuous in u . Furthermore, the functions $a^{ij}, b^i, c, \sigma^{ik}, h^k, \partial_j \sigma^{ik}$, and $\partial_j h^k$ and their derivatives in x up to the order $\max(2, m)$ do not exceed K in absolute value;

(A2) $a^{ij} = a^{ji}, i, j = 1, 2, \dots, d$, and the matrix $S := (a^{ij} - \frac{1}{2} \sum_{k=1}^{d'} \sigma^{ik} \sigma^{jk}) \geq 0$ for all (t, x, u) ;

(A2)' $a^{ij} = a^{ji}, i, j = 1, 2, \dots, d$, and the matrix S is uniformly positive definite:

$$\xi^T S \xi \geq \delta |\xi|^2 \quad \text{for any } (t, x, u) \text{ and any } \xi \in R^d;$$

(A3) $F(t, u) \in H^{-1}, G \in H^0$ and $\|F(t, u)\|_{-1} + \|G\|_0 \leq K$;

(A4) $f, g^k : [0, 1] \times R^d \times \Gamma \rightarrow R^1$ are measurable in (t, x, u) and continuous in $u, k = 1, 2, \dots, d'$. Furthermore, $f(t, \cdot, u) \in H^1, g^k(t, \cdot, u) \in H^2$, and

$$|f(t, x, u)| + |g^k(t, x, u)| + \|f(t, \cdot, u)\|_1 + \|g^k(t, \cdot, u)\|_2 \leq K, \quad k = 1, 2, \dots, d';$$

(A5) $q_0 \in H^1$.

3. Fundamental theory of SPDEs. In this section, we recall some fundamental facts about SPDEs, which are originally due to Krylov and Rozovskii [8]–[10]. We state the results and give some variants that are convenient to our later discussion.

PROPOSITION 3.1. (Krylov and Rozovskii [9]). *Let \tilde{A} be any second-order differential operator having the same form as (2.1), and let \tilde{M}^k be any first-order differential operator having the same form as (2.2). Assume that the coefficients of \tilde{A} and \tilde{M}^k satisfy (A1) $_m$ and (A2). Then there is a constant N_1 that depends only on K and m such that*

$$2[\langle \tilde{A}\phi, \phi \rangle_{\tilde{m}} + (\tilde{f}, \phi)_{\tilde{m}}] + \sum_{k=1}^{d'} \|\tilde{M}^k \phi + \tilde{g}^k\|_{\tilde{m}}^2 \leq N_1 \left(\|\phi\|_{\tilde{m}}^2 + \|\tilde{f}\|_{\tilde{m}}^2 + \sum_{k=1}^{d'} \|\tilde{g}^k\|_{\tilde{m}+1}^2 \right) \\ \text{for any } \phi \in H^{\tilde{m}+1}, \tilde{f} \in H^{\tilde{m}}, \text{ and } \tilde{g}^k \in H^{\tilde{m}+1}, \tilde{m} = 0, \dots, m. \quad (3.1)$$

Remark 3.1. Estimate (3.1) is slightly different in form from the original result of Krylov and Rozovskii [9]. We may consult Nagase and Nisio [12, §3 and Appendix] for an explicit proof of (3.1).

COROLLARY 3.1. *In Proposition 3.1., let us assume, in addition, that the operator \tilde{M}^k is of order zero. Then there is a constant N_2 that depends only on K and m such that*

$$2[\langle \tilde{A}\phi, \phi \rangle_{\tilde{m}} + (\tilde{f}, \phi)_{\tilde{m}}] + \sum_{k=1}^{d'} \|\tilde{M}^k \phi + \tilde{g}^k\|_{\tilde{m}}^2 \leq N_2 \left(\|\phi\|_{\tilde{m}}^2 + \|\tilde{f}\|_{\tilde{m}}^2 + \sum_{k=1}^{d'} \|\tilde{g}^k\|_{\tilde{m}}^2 \right) \\ \text{for any } \phi \in H^{\tilde{m}+1}, \text{ and } \tilde{f}, \tilde{g}^k \in H^{\tilde{m}}, \tilde{m} = 0, 1, \dots, m. \quad (3.2)$$

Proof. From (3.1), it follows that

$$2[\langle \tilde{A}\phi, \phi \rangle_{\tilde{m}} + (\tilde{f}, \phi)_{\tilde{m}}] \leq N_1 (\|\phi\|_{\tilde{m}}^2 + \|\tilde{f}\|_{\tilde{m}}^2). \quad (3.3)$$

By the hypotheses of the corollary, \tilde{M}^k becomes a bounded operator on $H^{\bar{m}}$. Hence

$$(3.4) \quad \|\tilde{M}^k \phi + \tilde{g}^k\|_{\bar{m}}^2 \leq 2(K^2 \|\phi\|_{\bar{m}}^2 + \|\tilde{g}^k\|_{\bar{m}}^2).$$

Therefore, estimate (3.2) follows from (3.3) and (3.4). \square

COROLLARY 3.2. *In Proposition 3.1, let us assume, in addition, that (A2)' is satisfied. Then there is a constant N_3 that depends only on K, m , and δ such that*

$$(3.5) \quad \begin{aligned} & 2[\langle \tilde{A}\phi, \phi \rangle_{\bar{m}} + \langle \tilde{f}, \phi \rangle_{\bar{m}}] + \sum_{k=1}^{d'} \|\tilde{M}^k \phi + \tilde{g}^k\|_{\bar{m}}^2 \\ & \leq -\delta \|\phi\|_{\bar{m}+1}^2 + N_3 \left(\|\phi\|_{\bar{m}}^2 + \|\tilde{f}\|_{\bar{m}-1}^2 + \sum_{k=1}^{d'} \|\tilde{g}^k\|_{\bar{m}}^2 \right) \\ & \quad \text{for } \phi \in H^{\bar{m}+1}, \tilde{f} \in H^{\bar{m}-1} \text{ and } \tilde{g}^k \in H^{\bar{m}}, \bar{m} = 0, 1, \dots, m. \end{aligned}$$

Proof. The result can be easily derived by applying Proposition 3.1 to the operator $A - \delta \Delta$, where Δ is the Laplacian. \square

Remark 3.2. When $m = 0$ (3.5) holds even if all the coefficients of \tilde{A} and \tilde{M}^k are only bounded measurable in x -variable; see Pardoux [13].

Let $\tilde{F}, \tilde{G}^k : [0, 1] \times R^d \times \Omega \rightarrow R^1, \xi_0 : R^d \times \Omega \rightarrow R^1$ be given. We now consider the following SPDE on an interval $[\alpha, \beta] \subset [0, 1]$:

$$(3.6) \quad \begin{aligned} d\xi(t) &= [A(t, U(t))\xi(t) + \tilde{F}(t)]dt \\ &\quad + [M^k(t, U(t))\xi(t) + \tilde{G}^k(t)]dW_k(t), \quad t \in [\alpha, \beta], \\ \xi(\alpha) &= \xi_0, \end{aligned}$$

PROPOSITION 3.2 (Krylov and Rozovskii [9], [10]). *Assume that (A1) $_m$ and (A2) ($m \geq 1$) are satisfied and that $\tilde{F} \in L^2_{\mathcal{F}}(0, 1; H^m), \tilde{G}^k \in L^2_{\mathcal{F}}(0, 1; H^{m+1})$, and $\xi_0 \in L^2(\Omega, \mathcal{F}_\alpha, P; H^m)$. Then (3.6) has a unique solution $\xi \in L^2_{\mathcal{F}}(\alpha, \beta; H^m) \cap L^2(\Omega; C(\alpha, \beta; H^{m-1}))$, and there is a constant N_4 that depends only on K and m such that*

$$(3.7) \quad E \left(\sup_{\alpha \leq t \leq \beta} \|\xi(t)\|_{\bar{m}}^2 \right) \leq N_4 E \left\{ \|\xi_0\|_{\bar{m}}^2 + \int_{\alpha}^{\beta} \left[\|\tilde{F}(t)\|_{\bar{m}}^2 + \sum_{k=1}^{d'} \|\tilde{G}^k(t)\|_{\bar{m}+1}^2 \right] dt \right\},$$

$\bar{m} = 0, 1, \dots, m.$

COROLLARY 3.3. *Assume that (A1) $_m$ and (A2) ($m \geq 1$) are satisfied with $\sigma^{ik} = 0$ and that $\tilde{F}, \tilde{G}^k \in L^2_{\mathcal{F}}(0, 1; H^m)$ and $\xi_0 \in L^2(\Omega, \mathcal{F}_\alpha, P; H^m)$. Then (3.6) has a unique solution $\xi \in L^2_{\mathcal{F}}(\alpha, \beta; H^m) \cap L^2(\Omega; C(\alpha, \beta; H^{m-1}))$, and estimate (3.7) can be strengthened to*

$$(3.8) \quad E \left(\sup_{\alpha \leq t \leq \beta} \|\xi(t)\|_{\bar{m}}^2 \right) \leq N_5 E \left\{ \|\xi_0\|_{\bar{m}}^2 + \int_{\alpha}^{\beta} \left[\|\tilde{F}(t)\|_{\bar{m}}^2 + \sum_{k=1}^{d'} \|\tilde{G}^k(t)\|_{\bar{m}}^2 \right] dt \right\},$$

$\bar{m} = 0, 1, \dots, m.$

Proof. Note that estimate (3.2) is available as $\sigma^{ik} = 0$; hence the result can be proved in a way analogous to that in Krylov and Rozovskii [9]. \square

PROPOSITION (3.3) (Krylov and Rozovskii [8]). Assume that $(A1)_m$ and $(A2)' (m \geq 0)$ are satisfied and that $\tilde{F} \in L^2_{\mathcal{F}}(0, 1; H^{m-1})$, $\tilde{G}^k \in L^2_{\mathcal{F}}(0, 1; H^m)$, and $\xi_0 \in L^2(\Omega, \mathcal{F}_\alpha, P; H^m)$. Then (3.6) has a unique solution $\xi \in L^2_{\mathcal{F}}(\alpha, \beta; H^{m+1}) \cap L^2(\Omega; C(\alpha, \beta; H^m))$, and there is a constant N_6 that depends only on K, m , and δ such that

$$E \left(\sup_{\alpha \leq t \leq \beta} \|\xi(t)\|_{\tilde{m}}^2 \right) \leq N_6 E \left\{ \|\xi_0\|_{\tilde{m}}^2 + \int_{\alpha}^{\beta} \left[\|\tilde{F}(t)\|_{\tilde{m}-1}^2 + \sum_{k=1}^{d'} \|\tilde{G}^k(t)\|_{\tilde{m}}^2 \right] dt \right\},$$

$\tilde{m} = 0, 1, \dots, m.$

(3.9)

4. Adjoint equation. In this section, we derive an adjoint equation and study existence and uniqueness of its solutions. We fix an admissible control $(\Omega, \mathcal{F}, P, W, U)$ throughout this section.

THEOREM 4.1. Assume that $(A1)_0$, $(A2)'$, and $(A3)$ are satisfied. Then there exists a unique solution pair $(\lambda, r) \in L^2_{\mathcal{F}}(0, 1; H^1) \times [L^2_{\mathcal{F}}(0, 1; H^0)]^{d'}$, where $r := (r^1, r^2, \dots, r^{d'})$, of the following backward SPDE:

$$d\lambda(t) = - \left[A^*(t, U(t))\lambda(t) + \sum_{k=1}^{d'} M^{k*}(t, U(t))r^k(t) + F(t, U(t)) \right] dt$$

$$+ \sum_{k=1}^{d'} r^k(t) dW_k(t), \quad t \in [0, 1],$$

(4.1)

$$\lambda(1) = G.$$

Moreover, there is a constant N_7 that depend only on K and δ such that

$$E \int_0^1 \left[\|\lambda(t)\|_1^2 + \sum_{k=1}^{d'} \|r^k(t)\|_0^2 \right] dt \leq N_7 E \left[\int_0^1 \|F(t, U(t))\|_{-1}^2 dt + \|G\|_0^2 \right].$$

(4.2)

Remark 4.1. Solutions of (4.1) are defined in a way similar to those of the SPDE (2.6). More precisely, $(\lambda, r) \in L^2_{\mathcal{F}}(0, 1; H^1) \times [L^2_{\mathcal{F}}(0, 1; H^0)]^{d'}$ is called a solution pair of (4.1) if, for each $\eta \in C_0^\infty(R^d)$ and almost all $(t, \omega) \in [0, 1] \times \Omega$,

$$(\lambda(t), \eta)_0 = (G, \eta)_0 + \int_t^1 \left[(\lambda(s), A(s, U(s))\eta)_0 + \sum_{k=1}^{d'} (r^k(s), M^k(s, U(s))\eta)_0 \right. \\ \left. + (F(s, U(s)), \eta)_0 \right] ds - \sum_{k=1}^{d'} \int_t^1 (r^k(s), \eta)_0 dW_k(s).$$

So (4.1) can be regarded as in the H^{-1} space.

Proof of Theorem 4.1. To avoid notational complexity, we prove the theorem for $d' = 1$ (there is no essential difficulty when $d' > 1$). Thus the index “ k ” will be dropped. On the other hand, we also omit to write the control $U(t)$ since it is fixed.

Uniqueness. Suppose that $(\lambda, r) \in L^2_{\mathcal{F}}(0, 1; H^1) \times L^2_{\mathcal{F}}(0, 1; H^0)$ satisfies

$$d\lambda(t) = -[A^*(t)\lambda(t) + M^*(t)r(t)]dt + r(t)dW(t), \quad t \in [0, 1],$$

(4.3)

$$\lambda(1) = 0.$$

Consider the following auxiliary SPDE, which admits a unique solution $\rho \in L^2_{\mathcal{F}}(0, 1; H^1) \cap L^2(\Omega; C(0, 1; H^0))$ by virtue of Proposition 3.3:

$$\begin{aligned} d\rho(t) &= [A(t)\rho(t) + \lambda(t)]dt + [M(t)\rho(t) + r(t)]dW(t), \quad t \in [0, 1], \\ \rho(0) &= 0. \end{aligned}$$

Applying Ito's formula, we obtain

$$\begin{aligned} d(\rho(t), \lambda(t))_0 &= [\|\lambda(t)\|_0^2 + \|r(t)\|_0^2]dt \\ &\quad + [(M(t)\rho(t) + r(t), \lambda(t))_0 + (\rho(t), r(t))_0]dW(t). \end{aligned}$$

Hence, $E \int_0^1 [\|\lambda(t)\|_0^2 + \|r(t)\|_0^2]dt = 0$. This implies the uniqueness.

Before proceeding to the proof of the existence, we introduce an adjoint equation in finite dimension, which was originally obtained by Bismut [5]; see also [2], [3].

LEMMA 4.1. *Let n be a fixed positive integer. Suppose that we are given $A_n, M_n \in L^\infty_{\mathcal{F}}(0, 1; R^{n \times n})$, $F_n \in L^2_{\mathcal{F}}(0, 1; R^n)$, and $G_n \in R^n$. Then there exists uniquely a pair $(\lambda_n, r_n) \in L^2_{\mathcal{F}}(0, 1; R^n) \times L^2_{\mathcal{F}}(0, 1; R^n)$ satisfying the following backward SDE:*

$$(4.4) \quad \begin{aligned} d\lambda_n(t) &= -[A_n^T(t)\lambda_n(t) + M_n^T(t)r_n(t) + F_n(t)]dt + r_n(t)dW(t), \quad t \in [0, 1], \\ \lambda_n(1) &= G_n. \end{aligned}$$

Let us now continue proving Theorem 4.1.

Existence. Consider the Gelfand triple $H^1 \hookrightarrow H^0 \hookrightarrow H^{-1}$. Let $e_1, e_2, \dots, e_n, \dots$, be a Hilbert basis of H^1 , which is orthonormal as a basis of H^0 .

Fix a positive integer n . By Lemma 4.1, there is a unique pair

$$\tilde{\lambda}_n := (\lambda_{n1}, \lambda_{n2}, \dots, \lambda_{nn})^T \in L^2_{\mathcal{F}}(0, 1; R^n)$$

and

$$\tilde{r}_n := (r_{n1}, r_{n2}, \dots, r_{nn})^T \in L^2_{\mathcal{F}}(0, 1; R^n)$$

satisfying

$$(4.5) \quad \begin{aligned} d\lambda_{ni}(t) &= - \left[\sum_{j=1}^n \langle e_j, A(t)e_i \rangle_0 \lambda_{nj}(t) + \sum_{j=1}^n \langle e_j, M(t)e_i \rangle_0 r_{nj}(t) \right. \\ &\quad \left. + \langle F(t), e_i \rangle_0 \right] dt + r_{ni}(t)dW(t), \quad t \in [0, 1], \\ \lambda_{ni}(1) &= G_{ni}, \quad i = 1, 2, \dots, n, \end{aligned}$$

where $\sum_{i=1}^n G_{ni}e_i := G_n \rightarrow G$ in H^0 as $n \rightarrow \infty$. Define

$$(4.6) \quad \lambda_n := \sum_{i=1}^n \lambda_{ni}e_i \in L^2_{\mathcal{F}}(0, 1; H^1)$$

and

$$(4.7) \quad r_n := \sum_{i=1}^n r_{ni}e_i \in L^2_{\mathcal{F}}(0, 1; H^1).$$

Applying Ito's formula to (4.5) and adding up in i from 1 to n , we have

$$(4.8) \quad d\|\lambda_n(t)\|_0^2 = -2[\langle \lambda_n(t), A(t)\lambda_n(t) \rangle_0 + (r_n(t), M(t)\lambda_n(t))_0 + \langle F(t), \lambda_n(t) \rangle_0]dt \\ + 2(r_n(t), \lambda_n(t))_0 dW(t) + \|r_n(t)\|_0^2 dt.$$

Hence,

$$(4.9) \quad E\|\lambda_n(t)\|_0^2 \\ = E\|G_n\|_0^2 + 2E \int_t^1 [\langle A(s)\lambda_n(s), \lambda_n(s) \rangle_0 + (r_n(s), M(s)\lambda_n(s))_0 \\ + \langle F(s), \lambda_n(s) \rangle_0 - \frac{1}{2} \cdot \|r_n(s)\|_0^2] ds \\ \leq E\|G_n\|_0^2 + E \int_t^1 [2\langle A(s)\lambda_n(s), \lambda_n(s) \rangle_0 + \|M(s)\lambda_n(s)\|_0^2 + 2\langle F(s), \lambda_n(s) \rangle_0] ds \\ \leq E\|G_n\|_0^2 + E \int_t^1 [-\delta\|\lambda_n(s)\|_1^2 + N_3\|\lambda_n(s)\|_0^2 + 2/\delta \cdot \|F(s)\|_{-1}^2 + \delta/2 \cdot \|\lambda_n(s)\|_1^2] ds \\ \leq -\delta/2 \cdot E \int_t^1 \|\lambda_n(s)\|_1^2 ds + E\|G_n\|_0^2 + N_8 E \int_t^1 [\|\lambda_n(s)\|_0^2 + \|F(s)\|_{-1}^2] ds.$$

So Gronwall's inequality yields

$$(4.10) \quad \sup_{0 \leq t \leq 1} E\|\lambda_n(t)\|_0^2 + \delta/2 \cdot E \int_0^1 \|\lambda_n(t)\|_1^2 dt \leq N_9 E \left(\int_0^1 \|F(t)\|_{-1}^2 dt + \|G_n\|_0^2 \right),$$

where N_9 depends only on K and δ .

Now let $\rho_n := (\rho_{n1}, \rho_{n2}, \dots, \rho_{nn})^T \in L^2_{\mathcal{F}}(0, 1; R^n)$ be the solution of the following SDE in R^n :

$$(4.11) \quad d\rho_{ni}(t) = \sum_{j=1}^n \langle A(t)e_j, e_i \rangle_0 \rho_{nj}(t) dt + \left[\sum_{j=1}^n (M(t)e_j, e_i)_0 \rho_{nj}(t) + r_{ni}(t) \right] dW(t), \\ \rho_{ni}(0) = 0, \quad i = 1, 2, \dots, n.$$

Define $\rho_n := \sum_{i=1}^n \rho_{ni} e_i \in L^2_{\mathcal{F}}(0, 1; H^1)$. By a calculation similar to the above, we have

$$(4.12) \quad E\|\rho_n(t)\|_0^2 = E \int_0^t [2\langle A(s)\rho_n(s), \rho_n(s) \rangle_0 + \|M(s)\rho_n(s) + r_n(s)\|_0^2] ds \\ \leq -\delta E \int_0^t \|\rho_n(s)\|_1^2 ds + N_3 E \int_0^t [\|\rho_n(s)\|_0^2 + \|r_n(s)\|_0^2] ds.$$

Applying again Gronwall's inequality, we obtain

$$(4.13) \quad \sup_{0 \leq t \leq 1} E\|\rho_n(t)\|_0^2 + \delta E \int_0^1 \|\rho_n(t)\|_1^2 dt \leq N_3 \exp(N_3) E \int_0^1 \|r_n(t)\|_0^2 dt.$$

On the other hand, Ito's formula gives

$$(4.14) \quad d \sum_{i=1}^n \lambda_{ni}(t) \rho_{ni}(t) = \sum_{i=1}^n \{ -[\langle A^*(t)\lambda_n(t), e_i \rangle_0 + (M^*(t)r_n(t), e_i)_0 \\ + \langle F(t), e_i \rangle_0] \rho_{ni}(t) + \lambda_{ni}(t) \langle A(t)\rho_n(t), e_i \rangle_0 \\ + r_{ni}(t) [(M(t)\rho_n(t), e_i)_0 + r_{ni}(t)] \} dt + \{ \dots \} dW(t) \\ = [\|r_n(t)\|_0^2 - \langle F(t), \rho_n(t) \rangle_0] dt + \{ \dots \} dW(t).$$

Integrating from 0 to 1 and taking expectation, we have

$$\begin{aligned}
 E \int_0^1 \|r_n(t)\|_0^2 dt &= E \left[\int_0^1 \langle F(t), \rho_n(t) \rangle_0 dt + (G_n, \rho_n(1))_0 \right] \\
 &\leq \left(E \int_0^1 \|F(t)\|_{-1}^2 dt \right)^{1/2} \left(E \int_0^1 \|\rho_n(t)\|_1^2 dt \right)^{1/2} \\
 &\quad + (E \|G_n\|_0^2)^{1/2} (E \|\rho_n(1)\|_0^2)^{1/2} \\
 (4.15) \quad &\leq \left(N_{10} E \int_0^1 \|r_n(t)\|_0^2 dt \right)^{1/2} \\
 &\quad \cdot \left\{ \left(E \int_0^1 \|F(t)\|_{-1}^2 dt \right)^{1/2} + (E \|G_n\|_0^2)^{1/2} \right\},
 \end{aligned}$$

where $N_{10} = \max\{N_3 \exp(N_3), 1/\delta \cdot N_3 \exp(N_3)\}$. Consequently,

$$(4.16) \quad E \int_0^1 \|r_n(t)\|_0^2 dt \leq 2N_{10} E \left[\int_0^1 \|F(t)\|_{-1}^2 dt + \|G_n\|_0^2 \right].$$

By (4.10) and (4.16), there exist a subsequence $\{n'\}$ of $\{n\}$ and a pair $(\lambda, r) \in L^2_{\mathcal{F}}(0, 1; H^1) \times L^2_{\mathcal{F}}(0, 1; H^0)$ such that

$$(4.17) \quad \lambda_{n'} \rightarrow \lambda \text{ weakly in } L^2([0, 1] \times \Omega; H^1)$$

and

$$(4.18) \quad r_{n'} \rightarrow r \text{ weakly in } L^2([0, 1] \times \Omega; H^0) \text{ as } n' \rightarrow \infty.$$

We show that (λ, r) satisfies (4.1). To this end, let γ be an absolutely continuous function from $[0, 1]$ to R^1 with $\dot{\gamma} := d\gamma/dt \in L^2[0, 1]$ and $\gamma(0) = 0$. Set $\gamma_i(t) := \gamma(t)e_i$. Multiplying (4.5) by $\gamma_i(t)$ and using Ito's formula, we have

$$\begin{aligned}
 &\int_0^t (\lambda_n(t), \dot{\gamma}_i(t))_0 dt + \int_0^1 (r_n(t), \gamma_i(t))_0 dW(t) \\
 &= (G_n, \gamma_i(1))_0 + \int_0^1 [\langle \lambda_n(t), A(t)\gamma_i(t) \rangle_0 + (r_n(t), M(t)\gamma_i(t))_0 + \langle F(t), \gamma_i(t) \rangle_0] dt.
 \end{aligned}$$

(4.19)

Letting n' go to infinity and observing (4.17) and (4.18), we conclude that

$$\begin{aligned}
 &\int_0^t (\lambda(t), \phi)_0 \dot{\gamma}(t) dt + \int_0^1 (r(t), \phi)_0 \gamma(t) dW(t) \\
 (4.20) \quad &= (G, \phi)_0 \gamma(1) + \int_0^1 [\langle \lambda(t), A(t)\phi \rangle_0 + (r(t), M(t)\phi)_0 + \langle F(t), \phi \rangle_0] \gamma(t) dt
 \end{aligned}$$

for any $\phi \in H^1$.

For any $t \in (0, 1)$, let

$$\gamma_\varepsilon(s) := \begin{cases} 0 & \text{if } s \leq t - \varepsilon/2, \\ 1/\varepsilon \cdot (s - t + \varepsilon/2) & \text{if } t - \varepsilon/2 < s < t + \varepsilon/2, \\ 1 & \text{if } s \geq t + \varepsilon/2. \end{cases}$$

Substituting (4.20) with γ_ε and letting $\varepsilon \rightarrow 0$, we arrive at

$$\begin{aligned} (\lambda(t), \phi)_0 + \int_t^1 (r(s), \phi)_0 dW(s) &= (G, \phi)_0 \\ &+ \int_t^1 [\langle \lambda(s), A(s)\phi \rangle_0 + (r(s), M(s)\phi)_0 \\ &+ \langle F(s), \phi \rangle_0] ds \\ &\text{for any } \phi \in H^1, \text{ a.e. } t \in [0, 1]. \end{aligned}$$

This implies that (λ, r) satisfies (4.1). Finally, (4.2) is obtained by letting $n' \rightarrow \infty$ in (4.10) and (4.16). \square

COROLLARY 4.1. *Let the same assumptions as in Theorem 4.1 be satisfied. Given $\tilde{f} \in L^2_{\mathcal{F}}(0, 1; H^{-1})$ and $\tilde{g}^k \in L^2_{\mathcal{F}}(0, 1; H^0)$, $k = 1, 2, \dots, d'$, suppose that*

$$\xi \in L^2_{\mathcal{F}}(0, 1; H^1) \cap L^2(\Omega; C(0, 1; H^0))$$

satisfies

$$d\xi(t) = [A(t, U(t))\xi(t) + \tilde{f}(t)]dt + [M^k(t, U(t))\xi(t) + \tilde{g}^k(t)]dW_k(t), \quad t \in [0, 1],$$

(4.21)

and that (λ, r) satisfies (4.1). Then, for any $[\alpha, \beta] \subset [0, 1]$,

$$\begin{aligned} (4.22) \quad &E \left[\int_\alpha^\beta \langle F(t, U(t)), \xi(t) \rangle_0 dt + (\lambda(\beta), \xi(\beta))_0 \right] \\ &= E \left\{ \int_\alpha^\beta \left[\langle \lambda(t), f(t) \rangle_0 + \sum_{k=1}^{d'} (r^k(t), g^k(t))_0 \right] dt + (\lambda(\alpha), \xi(\alpha))_0 \right\}. \end{aligned}$$

Proof. The result is easily derived by applying Ito's formula to $(\lambda(t), \xi(t))_0$. \square

Remark 4.2. In Theorem 4.1 and Corollary 4.1, condition (A1)₀ can be weakened by assuming that all the coefficients a^{ij} , and so forth, are only bounded measurable in x . However, under such a weaker condition, the adjoint operators A^* and M^{k*} can be no longer written explicitly as (2.3) and (2.4), respectively. Instead, as operators mapping H^1 into H^{-1} , they can be determined by the following formulae:

$$\langle A^*(t, u)\phi, \psi \rangle_0 := \langle \phi, A(t, u)\psi \rangle_0 \text{ and}$$

$$\langle M^{k*}(t, u)\phi, \psi \rangle_0 := \langle \phi, M^k(t, u)\psi \rangle_0 \text{ for } \phi, \psi \in H^1.$$

It should be also noted that the definition of solutions of (4.1) does not require explicit expressions of A^* and M^{k*} ; see Remark 4.1.

5. Necessary conditions of optimality. We study in this section necessary conditions of an optimal control for the general system (2.6) with the cost functional (2.8).

THEOREM 5.1. *Assume that (A1)₂, (A2)', (A3), (A4), and (A5) are satisfied and that $(\Omega, \mathcal{F}, P, W, \hat{U})$ is an optimal control along with the corresponding optimal state \hat{q} . Then, for almost every $t \in [0, 1]$, we have the maximum condition*

$$(5.1) \quad H(t, \hat{q}(t), \hat{U}(t), \lambda(t), r(t)) = \max_{u \in I'} H(t, \hat{q}(t), u, \lambda(t), r(t)), \quad P - \text{a.s.},$$

where (λ, r) is the solution pair of (4.1) with $U(t) \equiv \hat{U}(t)$, and the Hamiltonian H is defined by

$$\begin{aligned} H(t, \phi, u, \zeta, \eta) &:= -\langle A(t, u)\phi, \zeta \rangle_0 - \langle f(t, u), \zeta \rangle_0 \\ &\quad - \sum_{k=1}^{d'} [(M^k(t, u)\phi, \eta^k)_0 + (g^k(t, u), \eta^k)_0] - \langle F(t, u), \phi \rangle_0, \\ &\quad \text{for } (t, \phi, u, \zeta, \eta) \in [0, 1] \times H^1 \times \Gamma \times H^1 \times (H^0)^{d'}. \end{aligned} \quad (5.2)$$

Proof. We assume that $d' = 1$ and set $\hat{A}(t) := A(t, \hat{U}(t))$, and so on, for simplicity. From Proposition 3.3, it follows that $\hat{q} \in L^2_{\mathcal{F}}(0, 1; H^2) \cap L^2(\Omega; C(0, 1; H^1))$. Hence $\hat{q}(t) \in L^2(\Omega; H^2)$ for almost every $t \in [0, 1]$. Fix a time $\bar{t} \in [0, 1]$ such that $\hat{q}(\bar{t}) \in L^2(\Omega; H^2)$, along with a Γ -valued, $\mathcal{F}_{\bar{t}}$ -measurable random variable u . For any $\varepsilon \in (0, 1 - \bar{t})$, define $U_\varepsilon \in U_{ad}$ by

$$U_\varepsilon(t) := \begin{cases} u, & t \in [\bar{t}, \bar{t} + \varepsilon], \\ \hat{U}(t), & t \in [0, 1] \setminus [\bar{t}, \bar{t} + \varepsilon]. \end{cases}$$

Let q_ε be the response for U_ε , namely,

$$q_\varepsilon(t) = \hat{q}(t), \quad t \in [0, \bar{t}], \quad (5.3)$$

$$q_\varepsilon(t) = \hat{q}(\bar{t}) + \int_{\bar{t}}^t [A(s, u)q_\varepsilon(s) + f(s, u)]ds + \int_{\bar{t}}^t [M(s, u)q_\varepsilon(s) + g(s, u)]dW(s), \quad t \in [\bar{t}, \bar{t} + \varepsilon], \quad (5.4)$$

and

$$q_\varepsilon(t) = q_\varepsilon(\bar{t} + \varepsilon) + \int_{\bar{t} + \varepsilon}^t [\hat{A}(s)q_\varepsilon(s) + \hat{f}(s)]ds + \int_{\bar{t} + \varepsilon}^t [\hat{M}(s)q_\varepsilon(s) + \hat{g}(s)]dW(s), \quad t \in [\bar{t} + \varepsilon, 1]. \quad (5.5)$$

It follows from Proposition 3.3 that $q_\varepsilon \in L^2(\Omega; C(\bar{t}, 1; H^2))$ and

$$\begin{aligned} E \left(\sup_{\bar{t} \leq t \leq \bar{t} + \varepsilon} \|q_\varepsilon(t)\|_2^2 \right) &\leq N_6 E \left\{ \|\hat{q}(\bar{t})\|_2^2 + \int_{\bar{t}}^{\bar{t} + \varepsilon} [\|f(t, u)\|_1^2 + \|g(t, u)\|_2^2] dt \right\} \\ &\leq N_6 E(\|\hat{q}(\bar{t})\|_2^2 + 2K^2\varepsilon). \end{aligned} \quad (5.6)$$

Define $\xi_\varepsilon(t) := q_\varepsilon(t) - \hat{q}(t)$ for $t \in [0, 1]$. Then ξ_ε satisfies

$$\begin{aligned} d\xi_\varepsilon(t) &= [\hat{A}(t)\xi_\varepsilon(t) + (A(t, u) - \hat{A}(t))q_\varepsilon(t) + f(t, u) - \hat{f}(t)]dt \\ &\quad + [\hat{M}(t)\xi_\varepsilon(t) + (M(t, u) - \hat{M}(t))q_\varepsilon(t) + g(t, u) - \hat{g}(t)]dW(t), \\ &\quad t \in [\bar{t}, \bar{t} + \varepsilon] \end{aligned} \quad (5.7)$$

and

$$d\xi_\varepsilon(t) = \hat{A}(t)\xi_\varepsilon(t)dt + \hat{M}(t)\xi_\varepsilon(t)dW(t), \quad t \in [\bar{t} + \varepsilon, 1]. \quad (5.8)$$

Since \hat{U} is optimal, we have

$$\begin{aligned}
 0 \leq J(U_\varepsilon) - J(\hat{U}) &= E \left\{ \int_{\bar{t}}^1 [\langle F(t, U_\varepsilon(t)), q_\varepsilon(t) \rangle_0 - \langle \hat{F}(t), \hat{q}(t) \rangle_0] dt \right. \\
 &\quad \left. + (G, q_\varepsilon(1) - \hat{q}(1))_0 \right\} \\
 (5.9) \quad &= E \int_{\bar{t}}^{\bar{t}+\varepsilon} [\langle F(t, u) - \hat{F}(t), q_\varepsilon(t) \rangle_0 + \langle \hat{F}(t), \xi_\varepsilon(t) \rangle_0] dt \\
 &\quad + E \left[\int_{\bar{t}+\varepsilon}^1 \langle \hat{F}(t), \xi_\varepsilon(t) \rangle_0 dt + (G, \xi_\varepsilon(1))_0 \right] = I_1 + I_2.
 \end{aligned}$$

Applying Corollary 4.1 to (5.8) and (4.1), we have $I_2 = E(\lambda(\bar{t} + \varepsilon), \xi_\varepsilon(\bar{t} + \varepsilon))_0$. Thus we can rewrite (5.9) as

$$\begin{aligned}
 0 \leq E \int_{\bar{t}}^{\bar{t}+\varepsilon} \langle F(t, u) - \hat{F}(t), q_\varepsilon(t) \rangle_0 dt \\
 (5.10) \quad + E \left[\int_{\bar{t}}^{\bar{t}+\varepsilon} \langle \hat{F}(t), \xi_\varepsilon(t) \rangle_0 dt + (\lambda(\bar{t} + \varepsilon), \xi_\varepsilon(\bar{t} + \varepsilon))_0 \right].
 \end{aligned}$$

Applying Corollary 4.1 again to (5.7) and (4.1), we obtain

$$\begin{aligned}
 0 \leq E \int_{\bar{t}}^{\bar{t}+\varepsilon} [\langle F(t, u) - \hat{F}(t), q_\varepsilon(t) \rangle_0 + \langle \lambda(t), (A(t, u) - \hat{A}(t))q_\varepsilon(t) \rangle_0 \\
 (5.11) \quad + (\lambda(t), f(t, u) - \hat{f}(t))_0 \\
 + (r(t), (M(t, u) - \hat{M}(t))q_\varepsilon(t) + g(t, u) - \hat{g}(t))_0] dt.
 \end{aligned}$$

On the other hand, we have

$$\begin{aligned}
 (1/\varepsilon) \int_{\bar{t}}^{\bar{t}+\varepsilon} E \langle \lambda(t), (A(t, u) - \hat{A}(t))(q_\varepsilon(t) - \hat{q}(t)) \rangle_0 dt \\
 (5.12) \quad \leq \text{const } (1/\varepsilon) \int_{\bar{t}}^{\bar{t}+\varepsilon} E(\|\lambda(t)\|_1 \|\xi_\varepsilon(t)\|_1) dt.
 \end{aligned}$$

Recall that ξ_ε satisfies (5.7) on $[\bar{t}, \bar{t} + \varepsilon]$ with $\xi_\varepsilon(\bar{t}) = 0$. Hence Proposition 3.3 gives

$$\begin{aligned}
 E \left(\sup_{\bar{t} \leq t \leq \bar{t}+\varepsilon} \|\xi_\varepsilon(t)\|_1^2 \right) \\
 (5.13) \quad \leq N_6 E \int_{\bar{t}}^{\bar{t}+\varepsilon} [\|(A(t, u) - \hat{A}(t))q_\varepsilon(t) + f(t, u) - \hat{f}(t)\|_0^2 \\
 + \|(M(t, u) - \hat{M}(t))q_\varepsilon(t) + g(t, u) - \hat{g}(t)\|_1^2] dt \\
 \leq \text{const } E \int_{\bar{t}}^{\bar{t}+\varepsilon} (\|q_\varepsilon(t)\|_2^2 + 1) dt \\
 \leq \text{const } (E\|\hat{q}(\bar{t})\|_2^2 + 1)\varepsilon \quad (\text{by (5.6)}) \\
 \leq \text{const } \varepsilon \quad (\text{Note that we have fixed } \bar{t} \text{ such that } E\|\hat{q}(\bar{t})\|_2^2 < +\infty).
 \end{aligned}$$

Thus, (5.12) reduces to

$$\begin{aligned}
 (1/\varepsilon) \int_{\bar{t}}^{\bar{t}+\varepsilon} E \langle \lambda(t), (A(t, u) - \hat{A}(t))(q_\varepsilon(t) - \hat{q}(t)) \rangle_0 dt \\
 (5.14) \quad \leq \text{const } (1/\varepsilon) \int_{\bar{t}}^{\bar{t}+\varepsilon} \{(\varepsilon^{1/3}/2)E\|\lambda(t)\|_1^2 + [1/(2\varepsilon^{1/3})]E\|\xi_\varepsilon(t)\|_1^2\} dt \\
 \leq \text{const } \left[\varepsilon^{1/3} \cdot (1/\varepsilon) \int_{\bar{t}}^{\bar{t}+\varepsilon} E\|\lambda(t)\|_1^2 dt + (1/\varepsilon)\varepsilon(1/\varepsilon^{1/3})\varepsilon \right] \\
 \rightarrow 0 \text{ as } \varepsilon \rightarrow 0,
 \end{aligned}$$

provided that \bar{t} is a Lebesgue point of the function $t \rightarrow E\|\lambda(t)\|_1^2$. Similarly, we have

$$(5.15) \quad \begin{aligned} (1/\varepsilon)E \int_{\bar{t}}^{\bar{t}+\varepsilon} [\langle F(t, u) - \hat{F}(t), q_\varepsilon(t) - \hat{q}(t) \rangle_0 \\ + \langle r(t), (M(t, u) - \hat{M}(t))(q_\varepsilon(t) - \hat{q}(t)) \rangle_0] dt \\ \rightarrow 0 \text{ as } \varepsilon \rightarrow 0, \end{aligned}$$

provided that \bar{t} is a Lebesgue point of the function $t \rightarrow E\|r(t)\|_0^2$. Thus (5.11) becomes

$$(5.16) \quad \begin{aligned} 0 \leq E \int_{\bar{t}}^{\bar{t}+\varepsilon} [\langle F(t, u) - \hat{F}(t), \hat{q}(t) \rangle_0 + \langle \lambda(t), (A(t, u) - \hat{A}(t))\hat{q}(t) \rangle_0 \\ + \langle \lambda(t), f(t, u) - \hat{f}(t) \rangle_0 + \langle r(t), (M(t, u) - \hat{M}(t))\hat{q}(t) \\ + g(t, u) - \hat{g}(t) \rangle_0] dt + o(\varepsilon). \end{aligned}$$

Dividing (5.16) by ε and letting $\varepsilon \rightarrow 0$, we obtain

$$(5.17) \quad EH(\bar{t}, \hat{q}(\bar{t}), \hat{U}(\bar{t}), \lambda(\bar{t}), r(\bar{t})) \geq EH(\bar{t}, \hat{q}(\bar{t}), u, \lambda(\bar{t}), r(\bar{t})).$$

Therefore, the desired result (5.1) follows from a standard argument; see, for example, [11]. This concludes the theorem. \square

Remark 5.1. In Theorem 5.1, all the coefficients appearing in the control problem are allowed to depend on the control variable.

Remark 5.2. By the above proof (especially the argument between (5.12) and (5.17)), it is easy to see that, if a^{ij} and σ^{ik} contain no control variable, then the assumptions of Theorem 5.1 can be considerably relaxed. More precisely, (A1)₂ can be replaced by the assumption that all the coefficients a^{ij} , and so forth, are bounded measurable in x , and (A4) and (A5) together can be replaced by the assumptions that $q_0 \in H^0$, $f(t, u) \in H^{-1}$, $g^k(t, u) \in H^0$, and that their respective norms are bounded. Therefore, all the regularity restrictions imposed in Bensoussan [4] can be removed. It should be also noted that M^k is allowed to be unbounded in our results, compared with [4].

6. Discussion and application.

6.1. Degenerate cases. The main results in §§4 and 5 are derived under assumption (A2)'; namely, system (2.6) is nondegenerate. There seems to be some essential difficulties in treating possibly degenerate systems, and the adjoint equation (4.1) may no longer admit a solution pair, no matter how high regularity assumptions to be imposed on the functions F and G . At least the method of proving Theorem 4.1 no longer applies. Indeed, the basic idea behind the proof of Theorem 4.1 is to approximate the infinite-dimensional equation by certain finite-dimensional equations and to use estimate (3.5) to prove that the approximate solutions are weakly compact. However, when the systems are possibly degenerate, we have only estimate (3.1) available, which could not ensure the above compactness. On the other hand, estimate (3.1) is the "best one" in that it cannot be further improved.

However, our approach still works in the degenerate case if M^k is of order zero, for which a stronger estimate (3.2) is available.

Let us now introduce the following assumptions:

(B1) $F(t, u) \in H^1$, $G \in H^1$, and $\|F(t, u)\|_1 + \|G\|_1 \leq K$;

(B2) $f, g^k : [0, 1] \times R^d \times \Gamma \rightarrow R^1$ are measurable in (t, x, u) and continuous in $u, k = 1, 2, \dots, d'$. Furthermore, $f(t, \cdot, u), g^k(t, \cdot, u) \in H^3$; and

$$|f(t, x, u)| + |g^k(t, x, u)| + \|f(t, \cdot, u)\|_3 + \|g^k(t, \cdot, u)\|_3 \leq K, k = 1, 2, \dots, d';$$

(B3) $q_0 \in H^3$.

THEOREM 6.1. Assume that (B1), (A1)₁, and (A2) are satisfied with $\sigma^{ik} = 0$. Then, for any $(\Omega, \mathcal{F}, P, W, U) \in U_{ad}$, there exists a unique solution pair $(\lambda, r) \in L^2_{\mathcal{F}}(0, 1; H^1) \times [L^2_{\mathcal{F}}(0, 1; H^1)]^{d'}$ of the adjoint equation (4.1). Moreover, there is a constant N_{11} that depends only on K such that

$$(6.1) \quad E \int_0^1 \left[\|\lambda(t)\|_1^2 + \sum_{k=1}^{d'} \|r^k(t)\|_1^2 \right] dt \leq N_{11} E \left[\int_0^1 \|F(t, U(t))\|_1^2 dt + \|G\|_1^2 \right].$$

Proof. Once estimate (3.2) is observed, the theorem can be proved in a way similar to that of Theorem 4.1. The proof is left to the reader. \square

THEOREM 6.2. Assume that (B1)–(B3), (A1)₃, and (A2) are satisfied with $\sigma^{ik} = 0$ and that $(\Omega, \mathcal{F}, P, W, \hat{U}) \in U_{ad}$ is an optimal control along with the optimal state \hat{q} . Then for almost every $t \in [0, 1]$,

$$(6.2) \quad H(t, \hat{q}(t), \hat{U}(t), \lambda(t), r(t)) = \max_{u \in \Gamma} H(t, \hat{q}(t), u, \lambda(t), r(t)), \quad P - \text{a.s.},$$

where (λ, r) is the solution pair of (4.1) with the control $U = \hat{U}$, and the Hamiltonian H is defined by (5.2).

Proof. Basing on Theorem 6.1, we only need to slightly modify the proof of Theorem 5.1. From Corollary 3.3, it follows that $\hat{q} \in L^2_{\mathcal{F}}(0, 1; H^3) \cap L^2(\Omega; C(0, 1; H^2))$. Hence $\hat{q}(t) \in L^2(\Omega; H^3)$ for almost every $t \in [0, 1]$. Fix $\bar{t} \in [0, 1)$ such that $\hat{q}(\bar{t}) \in L^2(\Omega; H^3)$. For $\varepsilon \in (0, 1 - \bar{t})$, define q_ε by (5.3)–(5.5). By virtue of Corollary 3.3, we have

$$\begin{aligned} E \left(\sup_{\bar{t} \leq t \leq \bar{t} + \varepsilon} \|q_\varepsilon(t)\|_3^2 \right) &\leq N_4 E \left\{ \|\hat{q}(\bar{t})\|_3^2 + \int_{\bar{t}}^{\bar{t} + \varepsilon} [\|f(s, u)\|_3^2 + \|g(s, u)\|_3^2] ds \right\} \\ &\leq N_4 E (\|\hat{q}(\bar{t})\|_3^2 + 2K^2 \varepsilon). \end{aligned}$$

Define $\xi_\varepsilon(t) := q_\varepsilon(t) - \hat{q}(t)$. Then ξ_ε satisfies (5.7) on $[\bar{t}, \bar{t} + \varepsilon]$. Hence,

$$\begin{aligned} E \left(\sup_{\bar{t} \leq t \leq \bar{t} + \varepsilon} \|\xi_\varepsilon(t)\|_1^2 \right) &\leq N_4 E \int_{\bar{t}}^{\bar{t} + \varepsilon} [\|(A(t, u) - \hat{A}(t))q_\varepsilon(t) + f(t, u) - \hat{f}(t)\|_1^2 \\ &\quad + \|(M(t, u) - \hat{M}(t))q_\varepsilon(t) + g(t, u) - \hat{g}(t)\|_1^2] dt \\ &\leq \text{const } E \int_{\bar{t}}^{\bar{t} + \varepsilon} (\|q_\varepsilon(t)\|_3^2 + 1) dt \\ &\leq \text{const } (E \|\hat{q}(\bar{t})\|_3^2 + 1) \varepsilon \leq \text{const } \varepsilon. \end{aligned}$$

In what follows, we must only repeat the arguments in the proof of Theorem 5.1 to obtain the desired result. \square

Remark 6.1. Theorem 6.2 requires the higher regularity on the coefficients a^{ij} , f , and so forth, as well as on the initial state q_0 . However, if the second-order coefficients of the operator $A(t, u)$ contain no control variable, then it is easy to verify by the proof of Theorem 6.2 that all the regularity conditions can be reduced by two orders. It should be also noted that Theorem 6.2 extends the results of Bensoussan [4] to possibly degenerate systems.

6.2. Application to partially observed diffusions. The optimal control problem of partially observed diffusions with general nonlinear cost functionals can be formulated as a control problem of linear SPDEs (Zakai's equations) with linear cost functionals. Hence the results obtained in the previous sections can be applied directly to partially observed diffusions.

First, let us remark that the results in §§5 and 6 can be easily extended to the following class of systems:

$$(6.3) \quad \begin{aligned} dq(t) &= [A(t, W(t), U(t))q(t) + f(t, W(t), U(t))]dt \\ &\quad + [M^k(t, W(t), U(t))q(t) + g^k(t, W(t), U(t))]dW_k(t), \quad t \in [0, 1], \\ q(0) &= q_0, \end{aligned}$$

where

$$\begin{aligned} A(t, w, u)\phi(x) &:= \partial_i(a^{ij}(t, x, w, u)\partial_j\phi(x)) + b^i(t, x, w, u)\partial_i\phi(x) + c(t, x, w, u)\phi(x), \\ M^k(t, w, u)\phi(x) &:= \sigma^{ik}(t, x, w, u)\partial_i\phi(x) + h^k(t, x, w, u)\phi(x), \quad k = 1, 2, \dots, d'. \end{aligned}$$

Note only the continuity of the coefficients a^{ij} and so forth in $w \in R^{d'}$ will be needed later.

Let W and \tilde{W} be two independent Brownian motions on a probability space (Ω, \mathcal{F}, P) , with values in R^d and $R^{d'}$, respectively. Consider the following SDE in R^d :

$$(6.4) \quad \begin{aligned} dX(t) &= \gamma(t, X(t), Y(t), U(t))dt + \alpha(t, X(t), Y(t), U(t))dW(t) \\ &\quad + \sigma(t, X(t), Y(t), U(t))d\tilde{W}(t), \quad t \in [0, 1], \\ X(0) &= \xi, \end{aligned}$$

with the observation

$$(6.5) \quad \begin{aligned} dY(t) &= \kappa(t, X(t), Y(t), U(t))dt + d\tilde{W}(t), \quad t \in [0, 1], \\ Y(0) &= 0, \end{aligned}$$

where U is an admissible control, namely, $\{U(t) : 0 \leq t \leq 1\}$ is a Γ -valued, $\sigma\{Y(s) : 0 \leq s \leq t\}$ -adapted measurable process. Note σ is the correlation between the state and the observation noises.

Let $F : [0, 1] \times R^d \times R^{d'} \times \Gamma \rightarrow R^1$, $G : R^d \times R^{d'} \rightarrow R^1$ be given. The objective is to minimize the cost functional defined by

$$(6.6) \quad J(U) := E \left[\int_0^1 F(t, X(t), Y(t), U(t))dt + G(X(1), Y(1)) \right]$$

over the set of admissible controls.

Note that W and Y are independent Brownian motions under a new probability \tilde{P} defined by $d\tilde{P} := \rho^{-1}(1)dP$, where

$$\rho(t) := \exp \left[\int_0^t \kappa(s, X(s), Y(s), U(s))dY(s) - \frac{1}{2} \int_0^t |\kappa(s, X(s), Y(s), U(s))|^2 ds \right].$$

Consider the following SPDE:

$$(6.7) \quad \begin{aligned} dq(t) &= A(t, Y(t), U(t))q(t)dt + M^k(t, Y(t), U(t))q(t)dY_k(t), \quad t \in [0, 1], \\ q(0) &= q_0, \end{aligned}$$

where $Y_k, k = 1, 2, \dots, d'$, are the components of Y , and

$$\begin{aligned} A(t, y, u)\phi(x) &:= \partial_i(a^{ij}(t, x, y, u)\partial_j\phi(x)) - \partial_i(a^i(t, x, y, u)\phi(x)), \\ M^k(t, y, u)\phi(x) &:= -\sigma^{ik}(t, x, y, u)\partial_i\phi(x) + h^k(t, x, y, u)\phi(x), \\ (a^{ij}(t, x, y, u))_{ij} &\equiv a(t, x, y, u) := [\sigma\sigma^T(t, x, y, u) + \alpha\alpha^T(t, x, y, u)]/2, \\ a^i(t, x, y, u) &:= \gamma^i(t, x, y, u) - \partial_j a^{ij}(t, x, y, u), \\ h^k(t, x, y, u) &:= \kappa^k(t, x, y, u) - \partial_i \sigma^{ik}(t, x, y, u), \quad i, j = 1, 2, \dots, d \quad k = 1, 2, \dots, d', \\ q_0 &:= \text{the density of } \xi. \end{aligned}$$

Then $q(t)$ proves to be the unnormalized conditional probability density of the state process $X(t)$, and the cost functional (6.6) reduces to

$$(6.8) \quad J(U) = \tilde{E} \left[\int_0^1 (F(t, \cdot, Y(t), U(t)), q(t))_0 dt + (G(\cdot Y(1)), q(1))_0 \right];$$

see Pardoux [13], Rozovskii [14], and Nagase and Nisio [12] for details.

Now we have turned problem (6.4)–(6.6) to the one already solved in §§5 and 6, observing the remark at the beginning of this section. So we can obtain the necessary conditions for an optimal solution to problem (6.4)–(6.6) by appropriately interpreting the assumptions and conclusions. Here we omit this simple interpretative work and only remark that, in the present case, (A2) is satisfied automatically; (A2)' is also satisfied, provided that $\alpha\alpha^T$ is uniformly positive definite.

7. Concluding remarks. In this paper, a finite-dimensional approximation approach and some a priori estimates of differential operators are employed to solve the adjoint equations of linear SPDEs, based on which necessary conditions of optimality for controlled SPDEs are derived. For some sufficient conditions for the existence of an optimal control, refer to [12], [15].

The adjoint equations of SPDEs may also be applied to some other important problems besides the necessity of optimality. For example, a relationship between the adjoint process λ and the value function is given in [16], which enables us to gain some insight into the deep connection between the adjoint equations and the dynamic programming equations (Hamilton-Jacobi-Bellman equations). Further research on the analytical and qualitative properties of solutions of the adjoint equations together with their applications to linear SPDEs is carried out in [17].

Let us conclude the paper by noting that our results on the adjoint equations are by no means optimal. In view of the observation at the beginning of §6.1, it remains a challenging open problem to solve the adjoint equations of degenerate SPDEs in which diffusion terms contain first-order differential operators.

Acknowledgments. This research was carried out when I was visiting Kobe University. I would like to express my hearty thanks to Professor M. Nisio for her constant encouragement and kind hospitality. Thanks are also due to the referees for their helpful comments and suggestions.

TRACE REGULARITY IN THE BOUNDARY CONTROL OF A WAVE EQUATION*

JONG UHN KIM†

Abstract. The regularity of the boundary control of a wave equation when the control is obtained by the methods of Russell and Lagnese is investigated.

Key words. trace regularity, boundary control, wave equation, wave front

AMS subject classifications. 35L05, 35B37, 35B65, 93B05, 93C20

Introduction. In this paper we will discuss the regularity of the boundary control of a wave equation when the boundary control is obtained through the methods of Russell [16], [17], and Lagnese [8], [9].

For a space dimension that is an odd integer larger than one, Russell [16] applied Huyghen's principle directly to obtain the boundary control of a wave equation. For a space dimension that is even, he set forth a mathematical framework where the question of exact boundary controllability is reduced to the invertibility of a certain linear operator. He also showed that this can be achieved by the decay of local energy; however, the use of energy decay requires sufficiently large control time. This was improved by Lagnese [8] who used a different method to prove the invertibility, provided that the control time is larger than the diameter of the space domain. In fact, this is the optimal control time. Littman [14], [15] also made a contribution to this approach for exact boundary controllability of hyperbolic equations.

The above methods have been overshadowed by the more recent Hilbert uniqueness method. However, the above methods give rise to a very interesting analysis problem on the regularity of boundary control. Our purpose is to investigate this problem. This makes it necessary to study the trace regularity of solutions to a general second-order differential equation, which is interesting in its own light. This is done in §1 and the main result is Theorem 1.1. In §2, we apply this to the regularity of the boundary control when the control is obtained according to [8] and [16] under the assumption that the initial data have compact support. Our result in §1 does not apply to the boundary control obtained in [15], which we will not discuss in this paper.

As a simple byproduct, we also have application to the trace regularity of solutions to a hyperbolic equation with the Neumann boundary condition when the space domain is a half space and the initial data have compact support. If the coefficients of the equation are constants, this problem has been already discussed by Symes [18] and Lasiecka and Triggiani [10] using different methods. In §3, we extend their results to the case of variable coefficients which satisfy some restrictive conditions.

After the first version of this paper was completed, Professor I Lasiecka informed me of the work of Bao and Symes [2]. They established a result similar to our Theorem 1.1 in a more general setting. But our analysis is more elementary from a technical viewpoint and is applicable to the boundary control of a wave equation in a more straightforward manner.

Our method is microlocal analysis. In particular, Hörmander's result [5] on the propagation of singularities plays a crucial role. Microlocal analysis has become a powerful tool in control theory since the work of Bardos, Lebeau, and Rauch [4]. Using microlocal analysis, they obtained sharp conditions for the boundary control and stabilization of a wave equation. Its utility has been also manifested in [2], [3], [7], and [11].

† Department of Mathematics, Virginia Polytechnic Institute, Blacksburg, Virginia 24061.

Finally we remark that when the support of initial data is not compact, the question addressed in this paper is still open, which we hope to investigate in the future.

Notation. Let Ω be an open subset of R^N . $\mathcal{D}'(\Omega)$ is the space of distributions over Ω and $H^s(\Omega)$, and $s \in R$ denotes a Sobolev space as defined in [13]. $H_c^s(\Omega)$ is the space of elements of $H^s(\Omega)$ which have compact support in Ω . $H_{\text{loc}}^s(\Omega)$ denotes the space of distributions u in Ω such that $\psi u \in H^s(\Omega)$ for each $\psi \in C_0^\infty(\Omega)$. If Ω is a C^∞ manifold with boundary, $H^s(\Omega)$ and $H_{\text{loc}}^s(\Omega)$ are defined by means of coordinate patches and a partition of unity. For $u \in \mathcal{D}'(\Omega)$, we use the following notation: $\text{supp } u$ = the support of u , $\text{sing supp } u$ = the singular support of u , $WF(u)$ = the wave front set of u . D_{x_i} and D_y stand for $-i \partial / \partial x_i$ and $-i \partial / \partial y$, respectively, and $D_x^\alpha = D_{x_1}^{\alpha_1} \cdots D_{x_N}^{\alpha_N}$, for $\alpha = (\alpha_1, \dots, \alpha_N)$. If m is a real number, then

$$S_{1,0}^m(R^N) = \text{the set of all } a(x, \xi) \in C^\infty(R^N \times R^N),$$

which satisfies

$$|\partial_\xi^\alpha \partial_x^\beta a(x, \xi)| \leq C_{\alpha, \beta} (1 + |\xi|)^{m - |\alpha|},$$

for all $(x, \xi) \in R^N \times R^N$, for some positive constant $C_{\alpha, \beta}$. Here,

$$\partial_\xi^\alpha = \left(\frac{\partial}{\partial \xi_1} \right)^{\alpha_1} \cdots \left(\frac{\partial}{\partial \xi_N} \right)^{\alpha_N} \quad \text{and} \quad |\alpha| = \alpha_1 + \cdots + \alpha_N.$$

Next we set

$$OPS^m(R^N) = \text{the set of all pseudodifferential operators of order } m \\ \text{whose symbols belong to } S_{1,0}^m(R^N).$$

If $p \in OPS^m(R^N)$, then

$$ES(p) = \text{the essential support of } p.$$

For its definition, see [19].

When $p \in OPS^{m_1}(R^N)$ and $q \in OPS^{m_2}(R^N)$, we write $[p, q] = pq - qp$. Finally, if the two sets G_1 and G_2 are disjoint, we write $G_1 \cap G_2 = \phi$.

1. Trace regularity of solutions to a second-order differential operator. In this section, Ω is an open subset of R^{n+1} and (y, x) denotes the variables in R^{n+1} with $y \in R$ and $x \in R^n$. We denote the dual variables by (η, ξ) with $\eta \in R$ and $\xi \in R^n$. We will consider a second-order differential operator of the form

$$(1.1) \quad D_y^2 u = P_2(y, x, D_x)u + P_1(y, x, D_x, D_y)u + f \quad \text{in } \Omega,$$

where

$$(1.2) \quad P_2(y, x, D_x) = \sum_{|\alpha|=2} a_\alpha(y, x) D_x^\alpha,$$

$$(1.3) \quad P_1(y, x, D_x, D_y) = \sum_{|\alpha| \leq 1} b_\alpha(y, x) D_x^\alpha + b(y, x) D_y.$$

We assume that all coefficients belong to $C^\infty(\Omega)$ and that $a_\alpha(y, x)$'s are real valued. Our main result in this section is the following theorem.

THEOREM 1.1. *Let $u \in D'(\Omega)$ be a solution of (1.1) in Ω and let $s \in \mathbb{R}$ be given. Suppose that $(y_0, x_0) \in \Omega$, $u \in H_{\text{loc}}^s(\Omega)$, and $f \in H_{\text{loc}}^{s-1}(\Omega)$. If we assume that*

$$(1.4) \quad (y_0, x_0, 0, \xi) \notin WF(u) \quad \text{for all } \xi \in \mathbb{R}^n \setminus \{0\}$$

and

$$(1.5) \quad f \text{ is microlocally } H^\mu \text{ at } (y_0, x_0, \pm 1, 0) \text{ for some } \mu > -\frac{3}{2},$$

then there is $\epsilon > 0$ and a neighborhood B of x_0 in \mathbb{R}^n such that

$$(1.6) \quad u \in C((y_0 - \epsilon, y_0 + \epsilon); H^s(B)).$$

If we further assume that

$$(1.7) \quad f \text{ is microlocally } H^\mu \text{ at } (y_0, x_0, \pm 1, 0) \text{ for some } \mu > -\frac{1}{2},$$

then

$$(1.8) \quad D_y u \in C((y_0 - \epsilon, y_0 + \epsilon); H^{s-1}(B)).$$

Remark 1.2. If $s > -\frac{1}{2}$, (1.5) is redundant and if $s > \frac{1}{2}$, (1.7) is redundant.

The remainder of this section is devoted to the proof of the above theorem. The strategy of the proof is to decompose u microlocally into three parts:

- (i) microlocally C^∞ part;
- (ii) elliptic part;
- (iii) hyperbolic part.

We then estimate each part separately. For this, we need some preparation. According to the above assumption (1.4), there are $\epsilon_1 > 0$, $0 < \delta_1 < \frac{1}{3}$ and a neighborhood B_1 of x_0 in \mathbb{R}^n such that

$$(1.9) \quad \Omega_1 \stackrel{\text{def}}{=} (y_0 - \epsilon_1, y_0 + \epsilon_1) \times B_1 \quad \text{and} \quad \overline{\Omega}_1 \subset \Omega,$$

$$(1.10) \quad \{\Omega_1 \times (\eta, \xi)\} \cap WF(u) = \emptyset, \quad \text{for all } (\eta, \xi) \in S^n \text{ satisfying } |\eta| \leq 3\delta_1.$$

Here $\overline{\Omega}_1$ is the closure of Ω_1 and S^n denotes the unit sphere in \mathbb{R}^{n+1} . Since we are interested in the behavior of u near (y_0, x_0) , we may assume that

$$(1.11) \quad u \in H^s(\mathbb{R}^{n+1}) \quad \text{with support in } \Omega,$$

$$(1.12) \quad f \in H^{s-1}(\mathbb{R}^{n+1}) \quad \text{with support in } \Omega,$$

and

$$(1.13) \quad D_y^2 u = P_2(y, x, D_x)u + P_1(y, x, D_x, D_y)u + f \quad \text{in } \Omega_1,$$

where we can also assume that

$$(1.14) \quad a_\alpha(y, x), b_\alpha(y, x), b(y, x) \in C_0^\infty(\mathbb{R}^{n+1}) \quad \text{with support in } \Omega.$$

Next we define

$$(1.15) \quad Q_1 = \{(y, x, \eta, \xi) : (y, x) \in \Omega_1, (\eta, \xi) \in S^n, |\eta| < 3\delta_1\},$$

$$(1.16) \quad Q_2 = \{(y, x, \eta, \xi) : (y, x) \in \Omega_1, (\eta, \xi) \in S^n, |\eta| > 2\delta_1, P_2(y, x, \xi) < \frac{1}{2}\eta^2\},$$

$$(1.17) \quad Q_3 = \{(y, x, \eta, \xi) : (y, x) \in \Omega_1, (\eta, \xi) \in S^n, |\eta| > 2\delta_1, P_2(y, x, \xi) > \frac{1}{3}\eta^2\}.$$

Then, $Q_1 \cup Q_2 \cup Q_3 = \Omega_1 \times S^n$.

We can find $q_i \in C_0^\infty(R^{n+1} \times S^n)$, $i = 1, 2, 3$, such that

$$(1.18) \quad \text{supp } q_i \subset Q_i, \quad i = 1, 2, 3,$$

$$(1.19) \quad 0 \leq q_i \leq 1, \quad i = 1, 2, 3$$

$$(1.20) \quad q_1 + q_2 + q_3 = 1 \quad \text{for all } (y, x, \eta, \xi) \in [y_0 - \epsilon_1/2, y_0 + \epsilon_1/2] \times \overline{B}_2 \times S^n,$$

where B_2 is a neighborhood of x_0 in R^n and its closure $\overline{B}_2 \subset B_1$.

Next let $\tilde{q}_i \in C^\infty(R^{n+1} \times R^{n+1})$ be an extension of q_i , $i = 1, 2, 3$, such that

$$(1.21) \quad \text{supp } \tilde{q}_i \subset \Omega_1 \times R^{n+1},$$

$$(1.22) \quad \tilde{q}_i = q_i \quad \text{on } R^{n+1} \times S^n,$$

$$(1.23) \quad \tilde{q}_i \text{ is homogeneous in } (\eta, \xi) \text{ of degree zero for } \eta^2 + |\xi|^2 \geq 1.$$

Then, it follows that $\tilde{q}_i \in S_{1,0}^0(R^{n+1})$. We can also choose a function $\rho_1(y, x) \in C_0^\infty(R^{n+1})$ such that

$$(1.24) \quad \text{supp } \rho_1 \subset (y_0 - \epsilon_1/2, y_0 + \epsilon_1/2) \times B_2,$$

$$(1.25) \quad \rho_1(y, x) = 1 \quad \text{on } [y_0 - \epsilon_1/3, y_0 + \epsilon_1/3] \times \overline{B}_3,$$

where B_3 is a neighborhood of x_0 in R^n and its closure $\overline{B}_3 \subset B_2$. Let us define $\Lambda_i \in OPS^0(R^{n+1})$, $i = 1, 2, 3$, by

$$(1.26) \quad \Lambda_i(v) = \sigma_i(\rho_1 v) \quad \text{for each } v \in \mathcal{D}'(R^{n+1}),$$

where $\sigma_i \in OPS^0(R^{n+1})$ has the symbol \tilde{q}_i .

Then, we find that

$$(1.27) \quad \rho_1 v = (\Lambda_1 + \Lambda_2 + \Lambda_3)v \text{ mod } C^\infty(R^{n+1})$$

for each $v \in \mathcal{D}'(R^{n+1})$, since

$$(1.28) \quad ES(I - (\sigma_1 + \sigma_2 + \sigma_3)) \cap \{(y_0 - \epsilon_1/2, y_0 + \epsilon_1/2) \times B_2 \times S^n\} = \phi,$$

where I stands for the identity mapping.

1.1. Regularity of $\Lambda_2 u$ for $s \leq -\frac{1}{2}$. We first note that $\text{supp } q_2$ is not empty by virtue of the definition of Q_i 's and (1.20). Since $(y_0, x_0, \pm 1, 0)$ does not belong to the characteristic set of the differential operator $D_y^2 - P_2(y, x, D_x) - P_1(y, x, D_x, D_y)$, u is microlocally $H^{\mu+2}$ at $(y_0, x_0, \pm 1, 0)$. Hence, there are $0 < \delta_2 < \frac{1}{3} - \delta_1$, a neighborhood Ω_2 of (y_0, x_0) in R^{n+1} , $q_4 \in C_0^\infty(R^{n+1} \times S^n)$, and $\Lambda_4 \in OPS^0(R^{n+1})$ such that

$$(1.29) \quad \overline{\Omega}_2 \subset \Omega_1,$$

$$(1.30) \quad \text{supp } q_4 \subset Q_4 \stackrel{\text{def}}{=} \Omega_1 \times \{(\eta, \xi) : (\eta, \xi) \in S^n, |\eta| > 1 - 3\delta_2\},$$

$$(1.31) \quad q_4 = 1 \quad \text{on } \overline{\Omega}_2 \times \{(\eta, \xi) : (\eta, \xi) \in S^n, |\eta| \geq 1 - 2\delta_2\},$$

$$(1.32) \quad \Lambda_4 u \in H^{\mu+2}(R^{n+1})$$

where the symbol of Λ_4 is $\tilde{q}_4(y, x, \eta, \xi) \in C^\infty(R^{n+1} \times R^{n+1})$ such that

$$(1.33) \quad \text{supp } \tilde{q}_4 \subset \Omega_1 \times R^{n+1},$$

$$(1.34) \quad \tilde{q}_4 = q_4 \quad \text{on } R^{n+1} \times S^n,$$

$$(1.35) \quad \tilde{q}_4 \text{ is homogeneous in } (\eta, \xi) \text{ of degree zero for } \eta^2 + |\xi|^2 \geq 1.$$

Next we choose $q_5 \in C_0^\infty(R^{n+1} \times S^n)$ with support in Q_2 such that

$$(1.36) \quad 0 \leq q_5 \leq 1$$

$$(1.37) \quad q_5 = 1 \quad \text{on an open subset of } \Omega_1 \times S^n \text{ which contains the support of } q_2.$$

Let $\Lambda_5 \in OPS^0(R^{n+1})$ have the symbol $\tilde{q}_5(y, x, \eta, \xi) \in C^\infty(R^{n+1} \times R^{n+1})$ which is an extension of q_5 satisfying the conditions analogous to (1.33), (1.34), and (1.35). We also choose $\rho_2 \in C_0^\infty(R^{n+1})$ such that

$$(1.38) \quad \text{supp } \rho_2 \subset \Omega_2,$$

$$(1.39) \quad \rho_2 = 1 \quad \text{on } \overline{\Omega}_3 \subset \Omega_2,$$

where Ω_3 is a neighborhood of (y_0, x_0) . Then it follows that

$$(1.40) \quad (I - \Lambda_5)\rho_2\Lambda_2 \in OPS^{-\infty}(R^{n+1})$$

and consequently,

$$(1.41) \quad \left(D_y^2 + \sum_{i=1}^n D_{x_i}^2 \right) (I - \Lambda_5)\rho_2\Lambda_2 \in OPS^{-\infty}(R^{n+1}).$$

Let us define

$$(1.42) \quad \mathcal{L} = D_y^2\Lambda_5 - P_2(y, x, D_x)\Lambda_5 + \left(D_y^2 + \sum_{i=1}^n D_{x_i}^2 \right) (I - \Lambda_5).$$

Then, \mathcal{L} is elliptic and it follows from (1.13) that

$$(1.43) \quad \mathcal{L}\rho_2\Lambda_2u = h_1 \bmod C_0^\infty(R^{n+1}),$$

where

$$(1.44) \quad h_1 = \Lambda_5\rho_2\Lambda_2P_1(y, x, D_x, D_y)u + \Lambda_5\rho_2\Lambda_2f + [D_y^2 - P_2(y, x, D_x), \Lambda_5\rho_2\Lambda_2]u,$$

and we used $(I - \Lambda_5)\rho_2\Lambda_2u \in C_0^\infty(R^{n+1})$.

Hence, we have

$$(1.45) \quad \mathcal{L}\rho_2\Lambda_2(I - \Lambda_4)u = h_2 \bmod C_0^\infty(R^{n+1}),$$

$$(1.46) \quad h_2 = [\mathcal{L}\rho_2\Lambda_2, I - \Lambda_4]u + (I - \Lambda_4)h_1.$$

Now we observe that

$$(1.47) \quad h_1, h_2 \in H^{s-1}(R^{n+1}),$$

$$(1.48) \quad WF(h_1) \subset ES(\Lambda_2) \cap (\Omega_2 \times R^{n+1}),$$

$$(1.49) \quad \begin{aligned} WF(h_2) \subset & \{ES(I - \Lambda_4) \cap ES(\Lambda_2) \cap (\Omega_2 \times R^{n+1})\} \\ & \cup \{ES(I - \Lambda_4) \cap WF(h_1)\}, \end{aligned}$$

from which we can deduce that

$$(1.50) \quad WF(h_2) \cap [R^{n+1} \times \{(\eta, \xi) : (\eta, \xi) \in S^n, |\eta| < 2\delta_1 \text{ or } |\eta| > 1 - 2\delta_2\}] = \phi.$$

For (1.48) and (1.49), the reader may refer to [19, pp. 127–128]. Next let \mathcal{M} be a parametrix for \mathcal{L} . Then (1.45) yields

$$(1.51) \quad \rho_2\Lambda_2(I - \Lambda_4)u = \mathcal{M}h_2 \bmod C^\infty(R^{n+1}).$$

Finally we choose $q_6(\eta, \xi) \in C^\infty(S^n)$ such that

$$(1.52) \quad \text{supp } q_6 \subset \{(\eta, \xi) : (\eta, \xi) \in S^n, \delta_1 < |\eta| < 1 - \delta_2\}$$

$$(1.53) \quad q_6 = 1 \quad \text{for } \frac{3}{2}\delta_1 \leq |\eta| \leq 1 - \frac{3}{2}\delta_2, \quad (\eta, \xi) \in S^n.$$

Let $\Lambda_6 \in OPS^0(R^{n+1})$ have the symbol $\tilde{q}_6(\eta, \xi) \in C^\infty(R^{n+1})$ which coincides with q_6 on S^n and is homogeneous in (η, ξ) of degree zero for $\eta^2 + |\xi|^2 \geq 1$. Then, we find that

$$(1.54) \quad WF((I - \Lambda_6)\mathcal{M}h_2) \subset ES(I - \Lambda_6) \cap WF(h_2)$$

and this is empty by virtue of (1.50) and (1.53). Consequently,

$$(1.55) \quad \mathcal{M}h_2 = \Lambda_6\mathcal{M}h_2 \bmod C^\infty(R^{n+1}).$$

Let us set

$$(1.56) \quad h_3 = \mathcal{M}h_2.$$

Then, $h_3 \in H^{s+1}(R^{n+1})$ since $\mathcal{M} \in OPS^{-2}(R^{n+1})$. We also find that

$$(1.57) \quad \mathcal{F}(\Lambda_6 h_3)(\eta, \xi) = \tilde{q}_6(\eta, \xi) \mathcal{F}(h_3)(\eta, \xi)$$

where \mathcal{F} denotes the Fourier transform.

By virtue of (1.52), we see that for all (η, ξ) satisfying $\eta^2 + |\xi|^2 \geq 1$ and $k = 1, 2$,

$$(1.58) \quad \begin{aligned} & (1 + |\eta|)^k (1 + |\xi|)^{s+1-k} |\tilde{q}_6(\eta, \xi) \mathcal{F}(h_3)(\eta, \xi)| \\ & \leq c(1 + |\eta| + |\xi|)^{s+1} |\tilde{q}_6(\eta, \xi) \mathcal{F}(h_3)(\eta, \xi)| \end{aligned}$$

holds for some positive constant c . Since $h_3 \in H^{s+1}(R^{n+1})$, it follows from (1.58) that

$$(1.59) \quad \Lambda_6 h_3 \in C(R; H^s(R^n)) \cap C^1(R; H^{s-1}(R^n)).$$

By virtue of (1.51), (1.55), and (1.56), we find that

$$(1.60) \quad \rho_2 \Lambda_2 (I - \Lambda_4) u \in C(R; H_{\text{loc}}^s(R^n)) \cap C^1(R; H_{\text{loc}}^{s-1}(R^n)),$$

and thus, on account of (1.38),

$$(1.61) \quad \rho_2 \Lambda_2 (I - \Lambda_4) u \in C(R; H^s(R^n)) \cap C^1(R; H^{s-1}(R^n)).$$

Since $\Lambda_2 \in OPS^0(R^{n+1})$, (1.32) implies that

$$(1.62) \quad \Lambda_2 \Lambda_4 u \in C(R; H^{\mu+3/2}(R^n)) \quad \text{if } \mu > -\frac{3}{2}$$

and

$$(1.63) \quad \Lambda_2 \Lambda_4 u \in C(R; H^{\mu+3/2}(R^n)) \cap C^1(R; H^{\mu+1/2}(R^n)) \quad \text{if } \mu > -\frac{1}{2}.$$

Combining (1.61), (1.62), and (1.63), we conclude that

$$(1.64) \quad \rho_2 \Lambda_2 u \in C(R; H^s(R^n)) \quad \text{if } \mu > -\frac{3}{2},$$

$$(1.65) \quad \rho_2 \Lambda_2 u \in C(R; H^s(R^n)) \cap C^1(R; H^{s-1}(R^n)) \quad \text{if } \mu > -\frac{1}{2}.$$

1.2. Regularity of $\Lambda_2 u$ for $s > -\frac{1}{2}$. For $-\frac{1}{2} < s \leq \frac{1}{2}$, we take $\mu = s - 1$ to obtain (1.64), and obtain (1.65) under assumption (1.7). For $s > \frac{1}{2}$, we simply take $\mu = s - 1$ to have (1.65).

1.3. Regularity of $\Lambda_3 u$. If $\text{supp } q_3$ is empty, then Λ_3 is vacuous and we skip over this section. So we assume that $\text{supp } q_3$ is not empty in this section. We define

$$(1.66) \quad G_1 = \{(y, x, \xi) : (y, x) \in \Omega_1, \xi \in S^{n-1}, P_2(y, x, \xi) > \delta_1^2 / (1 - 4\delta_1^2)\},$$

$$(1.67) \quad \Omega_3 = \{(y, x) : (y, x) \in \Omega_1, q_3(y, x, \eta, \xi) \neq 0 \text{ for some } (\eta, \xi) \in S^n\},$$

$$(1.68) \quad G_2 = \{(y, x, \xi) : (y, x) \in \Omega_3, \xi \in S^{n-1}, P_2(y, x, \xi) > 4\delta_1^2 / 3(1 - 4\delta_1^2)\},$$

where Ω_1 and δ_1 were defined in the above section and S^{n-1} denotes the unit sphere in R^n . Since $\text{supp } q_3$ is not empty, Ω_3 is not empty. We note that if $(y, x, \eta, \xi) \in Q_3$, then $\xi \neq 0$, $\eta^2 + |\xi|^2 = 1$, $|\eta| > 2\delta_1$ and

$$(1.69) \quad P_2(y, x, \xi) > \frac{1}{3}\eta^2 > 4\delta_1^2 |\xi|^2 / 3(1 - 4\delta_1^2),$$

since $1 - 4\delta_1^2 > |\xi|^2$. Therefore, G_2 is not empty. On account of (1.18), $\overline{\Omega}_3 \subset \Omega_1$ and thus, $\overline{G}_2 \subset G_1$. Next we choose $\psi \in C_0^\infty(R^{n+1} \times S^{n-1})$ such that

$$(1.70) \quad \text{supp } \psi \subset G_1,$$

$$(1.71) \quad 0 \leq \psi \leq 1,$$

$$(1.72) \quad \psi = 1 \quad \text{on } \overline{G}_2.$$

Let $\tilde{\psi} \in C^\infty(R^{n+1} \times R^n)$ be an extension of ψ such that

$$(1.73) \quad \text{supp } \tilde{\psi} \subset \Omega_1 \times R^n,$$

$$(1.74) \quad \tilde{\psi} = \psi \quad \text{on } R^{n+1} \times S^{n-1},$$

$$(1.75) \quad \tilde{\psi} \text{ is homogeneous in } \xi \text{ of degree zero for } |\xi| \geq 1.$$

Let $\Psi \in OPS^0(R^n)$ have the symbol $\tilde{\psi}$ so that Ψ depends smoothly on $y \in R$.

LEMMA 1.3. *It holds that*

$$(1.76) \quad \Psi \Lambda_3 \in OPS^0(R^{n+1}),$$

$$(1.77) \quad \text{supp } \Psi \Lambda_3 v \subset \Omega_1 \quad \text{for every } v \in \mathcal{D}'(R^{n+1}),$$

$$(1.78) \quad (I - \Psi) \Lambda_3 \in OPS^{-\infty}(R^{n+1}).$$

Proof. Since $\text{supp } q_3 \subset Q_3$, there is a positive constant c such that

$$(1.79) \quad \tilde{q}_3(y, x, \eta, \xi) = 0 \quad \text{if } |\xi| \leq c|\eta| \quad \text{and} \quad \eta^2 + |\xi|^2 \geq 1.$$

Recalling that Λ_3 was defined by (1.26), we can use Theorem 18.1.35 of [6] with the help of (1.79) to derive (1.76). For (1.77), we choose any $v_1 \in C_0^\infty(R^{n+1})$ and set

$$(1.80) \quad v_2 = \Lambda_3 v_1.$$

Then, $v_2 \in C_0^\infty(R^{n+1})$ with support in Ω_1 and

$$(1.81) \quad \Psi v_2 = (2\pi)^{-n} \int_{R^n} \tilde{\psi}(y, x, \xi) \exp(ix \cdot \xi) \mathcal{F}_x(v_2)(y, \xi) d\xi,$$

where

$$(1.82) \quad \mathcal{F}_x(v_2)(y, \xi) = \int_{R^n} \exp(-ix \cdot \xi) v_2(y, x) dx.$$

It follows from (1.73) and (1.81) that

$$(1.83) \quad \text{supp } \Psi v_2 \subset \Omega_1.$$

This implies (1.77). For (1.78), we use (1.68), (1.69), (1.72), and (1.79) to see that

$$(1.84) \quad \begin{aligned} \text{supp } \tilde{q}_3 \cap \{ & (y, x, \eta, \xi) : (y, x) \in R^{n+1}, \eta^2 + |\xi|^2 \geq 1 \} \\ & \subset \{ (y, x, \eta, \xi) : (y, x) \in \Omega_1, |\xi| \geq 1, |\xi| \geq c|\eta| \text{ and } \tilde{\psi}(y, x, \xi) = 1 \} \\ & \cup \{ (y, x, \eta, \xi) : (y, x) \in \Omega_1, 1 \geq |\xi| \geq c|\eta| \}, \end{aligned}$$

where the positive constant c is the same size as in (1.79). Now (1.78) follows from (1.84). This ends the proof of the lemma.

Next we derive from (1.13) that

$$(1.85) \quad \begin{aligned} (D_y^2 - P_2(y, x, D_x))\Psi\Lambda_3 u &= \Psi\Lambda_3 P_1(y, x, D_x, D_y)u \\ &+ \Psi\Lambda_3 f + [D_y^2 - P_2(y, x, D_x), \Psi\Lambda_3]u, \end{aligned}$$

and define

$$(1.86) \quad A = P_2(y, x, D_x)\Psi + \sum_{i=1}^n D_{x_i}^2(I - \Psi).$$

Then, A is elliptic in R^n with y as a parameter. By virtue of (1.78), it is evident that

$$(1.87) \quad (D_y^2 - P_2(y, x, D_x))\Psi\Lambda_3 u = (D_y^2 - A)\Lambda_3 u \bmod C^\infty(R^{n+1}),$$

and consequently,

$$(1.88) \quad \begin{aligned} (D_y^2 - A)\Lambda_3 u &= \Psi\Lambda_3 P_1(y, x, D_x, D_y)u \\ &+ \Psi\Lambda_3 f + [D_y^2 - P_2(y, x, D_x), \Psi\Lambda_3]u \bmod C^\infty(R^{n+1}). \end{aligned}$$

We set

$$(1.89) \quad w = \Lambda_3 u$$

and note that

$$(1.90) \quad w \in H^s(R^{n+1}),$$

$$(1.91) \quad \text{supp } w \subset \Omega_1,$$

$$(1.92) \quad (D_y^2 - A)w = h_4 \bmod C^\infty(R^{n+1}),$$

where

$$(1.93) \quad \begin{aligned} h_4 &\stackrel{\text{def}}{=} \Psi\Lambda_3 P_1(y, x, D_x, D_y)u + \Psi\Lambda_3 f \\ &+ [D_y^2 - P_2(y, x, D_x), \Psi\Lambda_3]u. \end{aligned}$$

By means of (1.76) and (1.77), it is easy to see that

$$(1.94) \quad h_4 \in H^{s-1}(R^{n+1}),$$

$$(1.95) \quad \text{supp } h_4 \subset \Omega_1.$$

Since $WF(w) \subset ES(\Lambda_3)$ and $WF(h_4) \subset ES(\Lambda_3)$, it follows that

$$(1.96) \quad WF(w) \cap (R^{n+1} \times S^n) \subset Q_3,$$

$$(1.97) \quad WF(h_4) \cap (R^{n+1} \times S^n) \subset Q_3.$$

Next we choose positive constants c_1 and c_2 such that

$$(1.98) \quad Q_3 \subset \Omega_1 \times \{(\eta, \xi) : (\eta, \xi) \in S^n, c_1|\eta| \leq |\xi| \leq c_2|\eta|\},$$

and let $\Lambda_7 \in OPS^0(R^{n+1})$ have the symbol $q_7(\eta, \xi) \in C^\infty(R^{n+1})$ such that

$$(1.99) \quad \text{supp } q_7 \cap S^n \subset \{(\eta, \xi) : (\eta, \xi) \in S^n, \tfrac{1}{2}c_1|\eta| \leq |\xi| \leq 2c_2|\eta|\},$$

$$(1.100) \quad q_7 = 1 \quad \text{on } \{(\eta, \xi) : (\eta, \xi) \in S^n, c_1|\eta| \leq |\xi| \leq c_2|\eta|\}$$

$$(1.101) \quad q_7 \text{ is homogeneous in } (\eta, \xi) \text{ of degree zero for } \eta^2 + |\xi|^2 \geq 1.$$

Then, by means of (1.96)–(1.101), we can infer that

$$(1.102) \quad w = \Lambda_7 w \bmod C^\infty(R^{n+1})$$

$$(1.103) \quad h_4 = \Lambda_7 h_4 \bmod C^\infty(R^{n+1}).$$

Since the Fourier transform of $\Lambda_7 w$ is given by

$$(1.104) \quad \mathcal{F}(\Lambda_7 w)(\eta, \xi) = q_7(\eta, \xi) \mathcal{F}(w)(\eta, \xi),$$

we derive from (1.90), (1.99), and (1.101) that

$$(1.105) \quad \Lambda_7 w \in H^3(R; H^{s-3}(R^n))$$

which, together with (1.91) and (1.102), yields

$$(1.106) \quad w \in C^2(R; H^{s-3}(R^n)).$$

Similarly, by virtue of (1.94), (1.99), and (1.101), we find that

$$(1.107) \quad \Lambda_7 h_4 \in L^2(R; H^{s-1}(R^n))$$

and thus, by (1.95) and (1.103),

$$(1.108) \quad h_4 \in L^2(R; H^{s-1}(R^n)).$$

In the meantime, it follows from (1.77), (1.86), and (1.89) that

$$(1.109) \quad \text{supp } Aw \subset \Omega_1.$$

Consequently, we can rewrite (1.92), with the help of (1.95) and (1.109), as

$$(1.110) \quad (D_y^2 - A)w = h_4 + h_5,$$

where $h_5 \in C_0^\infty(R^{n+1})$.

According to Theorem 23.2.2 of [6], there is a unique solution

$$(1.111) \quad \tilde{w} \in C([y_0 - \epsilon_1, y_0 + \epsilon_1]; H^s(R^n)) \cap C^1([y_0 - \epsilon_1, y_0 + \epsilon_1]; H^{s-1}(R^n))$$

of

$$(1.112) \quad (D_y^2 - A)\tilde{w} = h_4 + h_5,$$

$$(1.113) \quad \tilde{w} = 0, \quad D_y \tilde{w} = 0 \quad \text{for } y = y_0 - \epsilon_1.$$

Again by Theorem 23.2.2 of [6], the uniqueness of solution is still valid for lower s . Thus, $w = \tilde{w}$ and

$$(1.114) \quad \Lambda_3 u \in C([y_0 - \epsilon_1, y_0 + \epsilon_1]; H^s(R^n)) \cap C^1([y_0 - \epsilon_1, y_0 + \epsilon_1]; H^{s-1}(R^n)).$$

1.4. Conclusion of the proof. We derive from (1.10), (1.15), and (1.21) that

$$(1.115) \quad \Lambda_1 u \in C_0^\infty(R^{n+1})$$

with support in Ω_1 .

We combine (1.27), (1.64), (1.65), (1.114), and (1.115) to arrive at (1.6) and (1.8).

2. Application to exact boundary control of a wave equation. As mentioned earlier, Russell [16], [17] obtained the exact boundary control of a wave equation via Huygen's Principle. This idea was further developed by Lagnese [8], [9] and Littman [14], [15]. Our purpose in this section is to improve the regularity of the boundary control obtained in [8] and [16]. We will discuss each method separately.

2.1. Russell's method. We consider a wave equation

$$(2.1) \quad \frac{\partial^2 u}{\partial t^2} - \Delta u = 0 \quad \text{in } \mathcal{O} \times (0, T),$$

$$(2.2) \quad u(z, 0) = u_0(z), \quad \frac{\partial u}{\partial t}(z, 0) = v_0(z) \quad \text{in } \mathcal{O},$$

$$(2.3) \quad \alpha u(z, t) + \beta \frac{\partial u}{\partial \nu}(z, t) = F(z, t) \quad \text{on } \partial \mathcal{O} \times (0, T).$$

Here, \mathcal{O} is a bounded domain in R^n with smooth boundary $\partial \mathcal{O}$, $\partial/\partial \nu$ denotes the outward normal derivative on $\partial \mathcal{O}$, and α, β are nonnegative constants such that $\alpha + \beta > 0$. The issue of exact boundary controllability is to find $F(z, t)$ for a given $u_0(z)$ and $v_0(z)$ such that the solution of (2.1), (2.2), and (2.3) satisfies

$$(2.4) \quad u(z, T) = 0, \quad \frac{\partial u}{\partial t}(z, T) = 0 \quad \text{in } \mathcal{O}.$$

We will sketch Russell's method when $n \geq 3$ is odd. Let \mathcal{O}_δ be an open bounded domain in R^n such that $\overline{\mathcal{O}} \subset \mathcal{O}_\delta$ and distance $(\partial \mathcal{O}, \partial \mathcal{O}_\delta) < \delta$. Let $(u_0, v_0) \in H^2(\mathcal{O}) \times H^1(\mathcal{O})$ be given. We can extend (u_0, v_0) to $(u_\delta, v_\delta) \in H^2(R^n) \times H^1(R^n)$ such that $u_\delta(z) = v_\delta(z) = 0$ for $z \notin \mathcal{O}_\delta$. Then, we solve the Cauchy problem for (2.1) in $R^n \times (0, \infty)$ with initial data (u_δ, v_δ) . Then, the solution w satisfies

$$(2.5) \quad w(z, t) = 0 \quad \text{for all } z \in \mathcal{O} \quad \text{and} \quad t > 2\delta + \text{diameter of } \mathcal{O},$$

which follows from Huygen's principle. We set

$$(2.6) \quad F(z, t) = \alpha w(z, t) + \beta \frac{\partial w}{\partial \nu}(z, t)$$

for $(z, t) \in \partial \mathcal{O} \times (0, T)$, where $T > 2\delta + \text{diameter of } \mathcal{O}$, and find the solution u of (2.1), (2.2), and (2.3). By the uniqueness of solution to the initial-boundary value problem (2.1), (2.2), and (2.3), $u = w$ in $\mathcal{O} \times (0, T)$ and consequently, $F(z, t)$ given by (2.6) is the desired control.

THEOREM 2.1. *If \mathcal{O} is convex and $(u_0, v_0) \in H^2(\mathcal{O}) \times H^1(\mathcal{O})$ has compact support in \mathcal{O} , then the above control given by (2.6) has the following regularity:*

$$(2.7) \quad F \in H^1(\partial \mathcal{O} \times (0, T)) \quad \text{if } \beta \neq 0,$$

$$(2.8) \quad F \in H^2(\partial \mathcal{O} \times (0, T)) \quad \text{if } \beta = 0.$$

This follows from the following discussion of a more general situation. For given $(u_0, v_0) \in H^s(R^n) \times H^{s-1}(R^n)$, $s \in R$, let $u \in C(R; H^s(R^n)) \cap C^1(R; H^{s-1}(R^n))$ be the unique solution of the following Cauchy problem:

$$(2.9) \quad \frac{\partial^2 u}{\partial t^2} - \Delta u = 0 \quad \text{in } R^n \times R,$$

$$(2.10) \quad u(z, 0) = u_0(z), \quad \frac{\partial u}{\partial t}(z, 0) = v_0(z) \quad \text{in } R^n.$$

and set

$$(2.11) \quad g(z, t) = \text{the restriction of } u(z, t) \quad \text{to } \partial\mathcal{O} \times R,$$

$$(2.12) \quad h(z, t) = \text{the restriction of } \frac{\partial u}{\partial \nu}(z, t) \quad \text{to } \partial\mathcal{O} \times R.$$

THEOREM 2.2. *Suppose that \mathcal{O} is convex and that $\text{supp } u_0 \cup \text{supp } v_0 \subset K$, for some compact subset $K \subset \mathcal{O}$. Then, for any $T > 0$, it holds that*

$$(2.13) \quad g \in H^s(\partial\mathcal{O} \times (-T, T)),$$

$$(2.14) \quad h \in H^{s-1}(\partial\mathcal{O} \times (-T, T)),$$

$$(2.15) \quad \|g\|_{H^s(\partial\mathcal{O} \times (-T, T))} + \|h\|_{H^{s-1}(\partial\mathcal{O} \times (-T, T))} \leq C(\|u_0\|_{H^s(R^n)} + \|v_0\|_{H^{s-1}(R^n)})$$

for some positive constant C which depends on K and T , but is independent of u_0 and v_0 .

Proof. Choose any $(z_0, t_0) \in \partial\mathcal{O} \times (-\infty, \infty)$. Each bicharacteristic strip of (2.9) is a straight line in $R^{n+1} \times R^{n+1}$. We call its projection onto the base space R^{n+1} a bicharacteristic curve. Since \mathcal{O} is convex and $\text{supp } u_0 \cup \text{supp } v_0 \subset K$, each bicharacteristic curve which passes through (z_0, t_0) and is tangent to the surface $\partial\mathcal{O} \times R$ at (z_0, t_0) does not meet $\text{supp } u_0 \cup \text{supp } v_0$ at $t = 0$. Since the waves propagate at finite speed, it is easily seen that $(z, 0, \zeta, \tau) \notin WF(u)$ for any $(\zeta, \tau) \in R^{n+1} \setminus \{0\}$ if $z \notin \text{supp } u_0 \cup \text{supp } v_0$. Thus, by virtue of Proposition 3.5.1 of [5], we find that

$$(2.16) \quad (z_0, t_0, \zeta, \tau) \notin WF(u)$$

if $(\zeta, \tau) \in R^{n+1} \setminus \{0\}$ is tangent to $\partial\mathcal{O} \times R$ at (z_0, t_0) . Furthermore, according to Corollary C.5.3 of [6], there is a local coordinate transformation from (z, t) to (y, x) such that:

- (i) (z_0, t_0) is mapped to (y_0, x_0) ;
- (ii) t variable is not affected and becomes one component of the x variables;
- (iii) the points of $\partial\mathcal{O} \times R$ near (z_0, t_0) are characterized by $y = y_0$;
- (iv) the points of $\mathcal{O} \times R$ near (z_0, t_0) are characterized by $y > y_0$;
- (v) equation (2.9) is transformed into (1.1) with $f = 0$, which is valid near (y_0, x_0) .

This coordinate transformation induces a local diffeomorphism of the cotangent bundle. Under this diffeomorphism, we find that (z_0, t_0, ζ, τ) is mapped to $(y_0, x_0, 0, \xi)$ for some $\xi \in R^n \setminus \{0\}$ if and only if $(\zeta, \tau) \in R^{n+1} \setminus \{0\}$ is tangent to the surface $\partial\mathcal{O} \times R$ at (z_0, t_0) .

In the meantime, the wave front set is invariant under the diffeomorphism of coordinates. Therefore, we conclude that

$$(2.17) \quad (y_0, x_0, 0, \xi) \notin WF(\tilde{u}),$$

for each $\xi \in R^n \setminus \{0\}$, where we write

$$(2.18) \quad \tilde{u}(y, x) = u(z(y, x), t(y, x)).$$

Now (2.13) and (2.14) follow from (1.6) and (1.8). It remains to prove (2.15). In the above setting, we let \mathcal{T} be a linear operator that maps $(u_0(z), v_0(z))$ to $\tilde{u}(y, x)$, which was defined by (2.18). Next we write

$$(2.19) \quad H_K^s(R^n) = \{w \in H^s(R^n) : \text{supp } w \subset K\}.$$

If $u(z, t)$ is a solution of (2.9) and (2.10) with $(u_0, v_0) \in H_K^s(R^n) \times H_K^{s-1}(R^n)$, then for each $(\zeta, \tau) \in R^{n+1} \setminus \{0\}$ which is tangent to $\partial\mathcal{O} \times R$ at (z_0, t_0) , we can find a conic neighborhood of (z_0, t_0, ζ, τ) in $R^{n+1} \times (R^{n+1} \setminus \{0\})$ which is disjoint from $WF(u)$. We can choose this conic neighborhood independently of (u_0, v_0) since K is fixed. Consequently, ϵ_1, B_1 , and δ_1 in (1.9) and (1.10) can be taken independently of (u_0, v_0) . Since f in (1.1) vanishes in this section, δ_2 in (1.30) and Λ_4 in (1.32) can be taken independently of (u_0, v_0) . Hence, ϵ and B in (1.6) and (1.8) are independent of (u_0, v_0) .

Now we conclude that \mathcal{T} is a linear mapping from $H_K^s(R^n) \times H_K^{s-1}(R^n)$ into $C((-\epsilon, \epsilon); H^s(B)) \cap C^1((-\epsilon, \epsilon); H^{s-1}(B))$. It is apparent that \mathcal{T} is a closed operator and thus, \mathcal{T} is continuous. It follows that there is a neighborhood Σ of (z_0, t_0) in $\partial\mathcal{O} \times R$ such that

$$(2.20) \quad \|g\|_{H^s(\Sigma)} + \|h\|_{H^{s-1}(\Sigma)} \leq C(\|u_0\|_{H_K^s(R^n)} + \|v_0\|_{H_K^{s-1}(R^n)})$$

for some constant C independent of u_0 and v_0 . Since $\partial\mathcal{O} \times [-T, T]$ can be covered by a finite number of such neighborhoods, we arrive at (2.15).

Next we will extend Theorem 2.1 to the case where (u_0, v_0) is less regular. We need to define a weak solution to the initial-boundary value problem. For this, we first define

$$(2.21) \quad \tilde{H}_\rho^s(\partial\mathcal{O} \times (0, T)) = \{g \in H^s(\partial\mathcal{O} \times (0, T)) : g \text{ vanishes for } 0 < t < \rho\},$$

which is a closed subspace of $H^s(\partial\mathcal{O} \times (0, T))$. As above, we assume that K is a compact subset of \mathcal{O} .

DEFINITION 2.3. Let $s \in R$. Suppose that $(u_0, v_0) \in H_K^s(R^n) \times H_K^{s-1}(R^n)$ and $g \in \tilde{H}_\rho^s(\partial\mathcal{O} \times (0, T))$. Then, a function $u(z, t) \in C([0, T]; H^s(\mathcal{O})) \cap C^1([0, T]; H^{s-1}(\mathcal{O}))$ is called a solution of the initial-boundary value problem (2.1), (2.2), and

$$(2.22) \quad u(z, t) = g(z, t) \quad \text{on } \partial\mathcal{O} \times (0, T)$$

if u satisfies

$$(2.23) \quad \int_0^T \langle u(z, t), \chi(z, t) \rangle_1 dt = \langle v_0(z), \theta(z, 0) \rangle_2 - \left\langle u_0(z), \frac{\partial \theta}{\partial t}(z, 0) \right\rangle_3 - \left\langle g(z, t), \frac{\partial \theta}{\partial \nu}(z, t) \right\rangle_4$$

for any $\chi \in C_0^\infty(\mathcal{O} \times (0, T))$, where $\theta(z, t) \in C^\infty(\overline{\mathcal{O}} \times [0, T])$ is the solution of

$$(2.24) \quad \frac{\partial^2 \theta}{\partial t^2} - \Delta \theta = \chi \quad \text{in } \mathcal{O} \times (0, T),$$

$$(2.25) \quad \theta(z, T) = 0, \quad \frac{\partial \theta}{\partial t}(z, T) = 0 \quad \text{in } \mathcal{O},$$

$$(2.26) \quad \theta(z, t) = 0 \quad \text{on } \partial \mathcal{O} \times (0, T),$$

and we use the following notation:

$$(2.27) \quad \langle \cdot, \cdot \rangle_1 = \text{the duality pairing between } H^s(\mathcal{O}) \text{ and its dual,}$$

$$(2.28) \quad \langle \cdot, \cdot \rangle_2 = \text{the duality pairing between } H_c^{s-1}(\mathcal{O}) \text{ and its dual } H_{\text{loc}}^{1-s}(\mathcal{O}),$$

$$(2.29) \quad \langle \cdot, \cdot \rangle_3 = \text{the duality pairing between } H_c^s(\mathcal{O}) \text{ and its dual } H_{\text{loc}}^{-s}(\mathcal{O}),$$

$$(2.30) \quad \langle \cdot, \cdot \rangle_4 = \text{the duality pairing between } \tilde{H}_\rho^s(\partial \mathcal{O} \times (0, T)) \text{ and its dual.}$$

Here ρ is a positive number such that $\rho < \frac{1}{2}$ distance $(\partial \mathcal{O}, K)$. Each bracket reduces to the L^2 inner product when both elements belong to L^2 . Since $\chi \in C_0^\infty(\mathcal{O} \times (0, T))$, (2.25) and (2.26) imply that θ vanishes near $t = T$. Hence, the last term of (2.23) is well defined.

PROPOSITION 2.4. *Let $u(z, t)$ be the solution of the Cauchy problem (2.9) and (2.10) with $(u_0, v_0) \in H_K^s(R^n) \times H_K^{s-1}(R^n)$. Let g be defined by (2.11). Then, for this (u_0, v_0) and g , $u(z, t)$ is a unique solution of the initial-boundary value problem (2.1), (2.2), and (2.22).*

Proof. Fix any $\chi(z, t) \in C_0^\infty(\mathcal{O} \times (0, T))$ and let θ be a solution of (2.24), (2.25), and (2.26). Choose a sequence $\{(u_0^k, v_0^k)\}_{k=1}^\infty$ in $C_0^\infty(R^n) \times C_0^\infty(R^n)$ with support in some compact subset K_1 such that (u_0^k, v_0^k) converges to (u_0, v_0) in $H_K^s(R^n) \times H_K^{s-1}(R^n)$ where $K \subset K_1 \subset \mathcal{O}$ and distance $(\partial \mathcal{O}, K_1) > \frac{1}{2}$ distance $(\partial \mathcal{O}, K)$. Let $u^k(z, t)$ be a solution of (2.9) with initial data (u_0^k, v_0^k) . Then, it is evident that u^k satisfies

$$(2.31) \quad \int_0^T \langle u^k(z, t), \chi(z, t) \rangle_1 dt = \langle v_0^k(z), \theta(z, 0) \rangle_2 - \left\langle u_0^k(z), \frac{\partial \theta}{\partial t}(z, 0) \right\rangle_3 \\ - \left\langle g^k(z, t), \frac{\partial \theta}{\partial \nu}(z, t) \right\rangle_4,$$

where g^k is the restriction of u^k to $\partial \mathcal{O} \times R$. We note that $g^k \in \tilde{H}_\rho^s(\partial \mathcal{O} \times (0, T))$ for each k since distance $(\partial \mathcal{O}, K_1) > \frac{1}{2}$ distance $(\partial \mathcal{O}, K) > \rho$. By virtue of (2.15), we pass $k \rightarrow \infty$ to see that u satisfies (2.23). The uniqueness is trivial.

Now we can assert the following theorem.

THEOREM 2.5. *Let $T > \text{diameter of } \mathcal{O}$. If \mathcal{O} is convex and $(u_0, v_0) \in H^s(\mathcal{O}) \times H^{s-1}(\mathcal{O})$, $s \in R$ has compact support in \mathcal{O} , then there is a control $F \in H^s(\partial \mathcal{O} \times (0, T))$ which drives the solution of (2.1), (2.2), and (2.3) with $\beta = 0$ to (2.4).*

By modifying Definition 2.3 in an obvious manner, we can also define a weak solution to the initial-boundary value problem with the Neumann boundary condition. By repeating the same procedure as above, we can assert the following theorem.

THEOREM 2.6. *Under the same assumption as in Theorem 2.5, there is a control $F \in H^{s-1}(\partial \mathcal{O} \times (0, T))$ which drives the solution of (2.1), (2.2), and (2.3) with $\alpha = 0$ to (2.4).*

2.2. Lagnese's method. Lagnese [8] discussed a more general equation than a wave equation. But we will consider only a wave equation when the space dimension is even. In order to obtain a more regular boundary control, we will slightly modify the procedure.

For a given open bounded domain \mathcal{O} with smooth boundary, we define open bounded domains \mathcal{O}_δ and $\mathcal{O}_{2\delta}$ with smooth boundary such that

$$(2.32) \quad \overline{\mathcal{O}} \subset \mathcal{O}_\delta \subset \overline{\mathcal{O}_\delta} \subset \mathcal{O}_{2\delta},$$

$$(2.33) \quad \text{distance}(\partial\mathcal{O}, \partial\mathcal{O}_\delta) < \delta,$$

$$(2.34) \quad \text{distance}(\partial\mathcal{O}_\delta, \partial\mathcal{O}_{2\delta}) < \delta,$$

where δ is a small positive number. We employ a total extension operator E for \mathcal{O}_δ which maps $H^m(\mathcal{O}_\delta)$ into $H^m(R^n)$ continuously for each $m \geq 0$ such that for $h \in H^m(\mathcal{O}_\delta)$,

$$(2.35) \quad (Eh)(x) = h(x) \quad \text{for } x \in \mathcal{O}_\delta,$$

$$(2.36) \quad (Eh)(x) = 0 \quad \text{for } x \notin \mathcal{O}_{2\delta}.$$

For details, see [1]. We note that this total extension operator was not necessary in [8]. We suppose that

$$(2.37) \quad s \geq 2,$$

$$(2.38) \quad T_0 > 2\delta + \text{diameter of } \mathcal{O}_\delta$$

and construct a linear operator Λ_T , for $T \geq T_0$ as follows. For given $(u_0, v_0) \in H^s(\mathcal{O}_\delta) \times H^{s-1}(\mathcal{O}_\delta)$, let $w \in C([0, \infty); H^s(R^n)) \cap C^1([0, \infty); H^{s-1}(R^n))$ be the solution of

$$(2.39) \quad \frac{\partial^2 w}{\partial t^2} - \Delta w = 0 \quad \text{in } R^n \times [0, \infty),$$

$$(2.40) \quad w(z, 0) = Eu_0, \quad \frac{\partial w}{\partial t}(z, 0) = Ev_0.$$

We next choose $\psi \in C_0^\infty(\mathcal{O}_{2\delta})$ such that

$$(2.41) \quad \psi(z) = 1 \quad \text{for } z \in \mathcal{O}_\delta.$$

By solving the backward and forward Cauchy problem, we can obtain a solution $\Xi(z, t)$ of (2.39) in $R^n \times [0, \infty)$ which satisfies

$$(2.42) \quad \Xi(z, T) = \psi(z)w(z, T), \quad \frac{\partial \Xi}{\partial t}(z, T) = \psi(z) \frac{\partial w}{\partial t}(z, T).$$

Since $T \geq T_0$, we have

$$(2.43) \quad \Xi(z, T) \in C_0^\infty(\mathcal{O}_{2\delta}), \quad \frac{\partial \Xi}{\partial t}(z, T) \in C_0^\infty(\mathcal{O}_{2\delta})$$

from which it follows that

$$(2.44) \quad \Xi \in C^\infty(R^n \times [0, \infty)) \cap C([0, \infty); H^s(R^n)) \cap C^1([0, \infty); H^{s-1}(R^n)).$$

Let (\hat{u}_0, \hat{v}_0) be the restriction of $(\Xi(z, 0), \partial\Xi/\partial t(z, 0))$ to \mathcal{O}_δ . Then, it is evident that

$$(2.45) \quad (\hat{u}_0, \hat{v}_0) \in C^\infty(\overline{\mathcal{O}_\delta}) \times C^\infty(\overline{\mathcal{O}_\delta}).$$

Let us define the operator Λ_T , for $T \geq T_0$, by

$$(2.46) \quad \Lambda_T(u_0, v_0) = (\hat{u}_0, \hat{v}_0).$$

Then, Λ_T is a bounded linear operator from $H^s(\mathcal{O}_\delta) \times H^{s-1}(\mathcal{O}_\delta)$ into itself.

Lagnese [8] showed that for all $T \geq T_0$, possibly except for a finite number of values, $(I - \Lambda_T)^{-1}$ exists. Therefore, for given $\tilde{T} > T_0$, we can find T such that

$$(2.47) \quad \max \left\{ T_0, \tilde{T} - \frac{1}{2} \text{distance}(\partial\mathcal{O}, \partial\mathcal{O}_\delta) \right\} < T < \tilde{T}$$

and

$$(2.48) \quad (I - \Lambda_T)^{-1} \text{ exists.}$$

Hence, for given $(u_0^*, v_0^*) \in H^s(\mathcal{O}_\delta) \times H^{s-1}(\mathcal{O}_\delta)$, there is $(u_0, v_0) \in H^s(\mathcal{O}_\delta) \times H^{s-1}(\mathcal{O}_\delta)$ such that

$$(2.49) \quad (u_0, v_0) - \Lambda_T(u_0, v_0) = (u_0^*, v_0^*).$$

We then set

$$(2.50) \quad u = w - \Xi$$

where w is the solution of (2.39) and (2.40), and Ξ is the solution of (2.39) and (2.42). Then, it follows that

$$(2.51) \quad u \in C([0, \infty); H^s(R^n)) \cap C^1([0, \infty); H^{s-1}(R^n)),$$

$$(2.52) \quad u(z, 0) = u_0^*(z), \quad \frac{\partial u}{\partial t}(z, 0) = v_0^*(z) \quad \text{for } z \in \mathcal{O}_\delta,$$

$$(2.53) \quad u(z, T) = 0, \quad \frac{\partial u}{\partial t}(z, T) = 0 \quad \text{for } z \in \mathcal{O}_\delta,$$

which combined with (2.47) yields

$$(2.54) \quad u(z, \tilde{T}) = 0, \quad \frac{\partial u}{\partial t}(z, \tilde{T}) = 0 \quad \text{for } z \in \mathcal{O},$$

since the wave speed is 1. Now we assume that \mathcal{O} is convex and that $\tilde{T} > \text{diameter of } \mathcal{O}$ is given. Then, there are positive numbers δ, T , and T_0 such that (2.32), (2.33), (2.34), (2.38), (2.47), and (2.48) hold. We also assume that $\Theta = \text{supp } u_0^* \cup \text{supp } v_0^*$ is a compact subset of \mathcal{O} . Recalling that E is a total extension operator for \mathcal{O}_δ , we use (2.45) and (2.49) to find that

$$(2.55) \quad (Eu_0, Ev_0) \in C^\infty(R^n \setminus \Theta) \times C^\infty(R^n \setminus \Theta).$$

We can now apply Theorem 1.1 to the trace regularity of w on $\partial\mathcal{O} \times (0, \tilde{T})$. The procedure is the same as in §2.1 and we will omit the details. The control is given by

$$(2.56) \quad F(z, t) = \alpha u(z, t) + \beta \frac{\partial u}{\partial \nu}(z, t) \quad \text{on } \partial\mathcal{O} \times (0, \tilde{T}),$$

where α, β are nonnegative constants such that $\alpha + \beta > 0$.

THEOREM 2.7. *If $s \geq 2$, \mathcal{O} is a convex bounded domain with smooth boundary and $(u_0^*, v_0^*) \in H^s(\mathcal{O}) \times H^{s-1}(\mathcal{O})$ has compact support in \mathcal{O} , then the control given by (2.56) has the following property:*

$$(2.57) \quad F \in H^{s-1}(\partial\mathcal{O} \times (0, \tilde{T})) \quad \text{if } \beta \neq 0,$$

$$(2.58) \quad F \in H^s(\partial\mathcal{O} \times (0, \tilde{T})) \quad \text{if } \beta = 0.$$

Next we will consider the case $s < 2$. This case was not mentioned in [8], but we can easily infer the following argument.

Let $(u_0, v_0) \in H^s(\mathcal{O}) \times H^{s-1}(\mathcal{O})$ be given with compact support in \mathcal{O} . We then extend (u_0, v_0) so that $(u_0, v_0) \in H^s(R^n) \times H^{s-1}(R^n)$ by setting $u_0(z) = 0, v_0(z) = 0$ for $z \notin \mathcal{O}$. Then, we find a solution w of (2.39) in $R^n \times [0, \infty)$ with initial data (u_0, v_0) at $t = 0$. Suppose that $T > \text{diameter of } \mathcal{O}$. Then, it follows that

$$(2.59) \quad w(z, T) \in C^\infty(\overline{\mathcal{O}}), \quad \frac{\partial w}{\partial t}(z, T) \in C^\infty(\overline{\mathcal{O}}).$$

Since the controllability for the case $s \geq 2$ has been already established in [8] without any assumption on the support of the initial data, we may assert that there is $h \in H^2(\partial\mathcal{O} \times (0, T))$ such that the solution of

$$(2.60) \quad \frac{\partial^2 \Xi}{\partial t^2} - \Delta \Xi = 0 \quad \text{in } \mathcal{O} \times (0, T),$$

$$(2.61) \quad \Xi(z, T) = w(z, T), \quad \frac{\partial \Xi}{\partial t}(z, T) = \frac{\partial w}{\partial t}(z, T) \quad \text{in } \mathcal{O},$$

$$(2.62) \quad \alpha \Xi + \beta \frac{\partial \Xi}{\partial \nu} = h \quad \text{on } \partial\mathcal{O} \times (0, T)$$

satisfies

$$(2.63) \quad \Xi(z, 0) = 0, \quad \frac{\partial \Xi}{\partial t}(z, 0) = 0 \quad \text{in } \mathcal{O}.$$

We set

$$(2.64) \quad u = w - \Xi$$

so that u satisfies

$$(2.65) \quad \frac{\partial^2 u}{\partial t^2} - \Delta u = 0 \quad \text{in } \mathcal{O} \times (0, T),$$

$$(2.66) \quad u(z, T) = 0, \quad \frac{\partial u}{\partial t}(z, T) = 0 \quad \text{in } \mathcal{O}$$

$$(2.67) \quad u(z, 0) = u_0(z), \quad \frac{\partial u}{\partial t}(z, 0) = v_0(z) \quad \text{in } \mathcal{O}.$$

Hence, a desired control F is given by

$$(2.68) \quad F = \alpha u + \beta \frac{\partial u}{\partial \nu} \quad \text{on } \partial \mathcal{O} \times (0, T).$$

For the regularity of F , we only need to consider the trace regularity of w since h in (2.62) is smooth enough. By the same argument as in the previous section, we can assert the following results under the assumptions:

- (i) \mathcal{O} is a convex bounded domain with smooth boundary;
 - (ii) $T > \text{diameter of } \mathcal{O}$;
 - (iii) $(u_0, v_0) \in H^s(\mathcal{O}) \times H^{s-1}(\mathcal{O})$ with compact support in \mathcal{O} .
- THEOREM 2.8. *If $1 \leq s < 2$, then the control F given by (2.68) satisfies*

$$(2.69) \quad F \in H^{s-1}(\partial \mathcal{O} \times (0, T)) \quad \text{if } \beta \neq 0,$$

$$(2.70) \quad F \in H^s(\partial \mathcal{O} \times (0, T)) \quad \text{if } \beta = 0.$$

If $s < 1$ and $\beta = 0$, then (2.70) holds, and if $s < 1$ and $\alpha = 0$, then (2.69) holds.

For $s < 1$, we used the following definition of weak solution, which is a slight variant of Definition 2.3.

DEFINITION 2.9. Suppose that K is a compact subset of \mathcal{O} and that ρ is a positive number such that $\rho < \frac{1}{2} \text{ distance } (\partial \mathcal{O}, K)$. Let $s \in \mathbb{R}$, $(u_0, v_0) \in H_K^s(\mathbb{R}^n) \times H_K^{s-1}(\mathbb{R}^n)$ and $g = g_1 + g_2$, where $g_1 \in \tilde{H}_\rho^s(\partial \mathcal{O} \times (0, T))$ and $g_2 \in L^2(\partial \mathcal{O} \times (0, T))$. Then, a function $u(z, t) \in C([0, T]; H^s(\mathcal{O})) \cap C^1([0, T]; H^{s-1}(\mathcal{O}))$ is called a solution of the initial-boundary value problem (2.1), (2.2), and (2.22) if u satisfies

$$(2.71) \quad \begin{aligned} \int_0^T \langle u(z, t), \chi(z, t) \rangle_1 dt &= \langle v_0(z), \theta(z, 0) \rangle_2 - \left\langle u_0(z), \frac{\partial \theta}{\partial t}(z, 0) \right\rangle_3 - \left\langle g_1(z, t), \frac{\partial \theta}{\partial \nu}(z, t) \right\rangle_4 \\ &\quad - \int_0^T \int_{\partial \mathcal{O}} g_2(z, t) \frac{\partial \theta}{\partial \nu}(z, t) dz dt, \end{aligned}$$

for each $\chi \in C_0^\infty(\mathcal{O} \times (0, T))$, where $\theta(z, t) \in C^\infty(\overline{\mathcal{O}} \times [0, T])$ is the solution of (2.24), (2.25), and (2.26), and we have used the notation (2.27)–(2.30).

In the above definition, it is necessary to split g into two parts because Ξ , which is the smoother part of u in (2.64), does not vanish near $t = 0$ and does not belong to $\tilde{H}_\rho^s(\partial \mathcal{O} \times (0, T))$. Next we observe that if $g = g_1 + g_2 = \tilde{g}_1 + \tilde{g}_2$ such that $g_1, \tilde{g}_1 \in \tilde{H}_\rho^s(\partial \mathcal{O} \times (0, T))$ and $g_2, \tilde{g}_2 \in L^2(\partial \mathcal{O} \times (0, T))$, then

$$(2.72) \quad \begin{aligned} \langle g_1 - \tilde{g}_1, \theta \rangle_4 &= \int_0^T \int_{\partial \mathcal{O}} (g_1 - \tilde{g}_1) \theta dz dt \\ &= \int_0^T \int_{\partial \mathcal{O}} (\tilde{g}_2 - g_2) \theta dz dt \end{aligned}$$

holds for each $\theta \in C^\infty(\partial \mathcal{O} \times (0, T))$ which vanishes near $t = T$, since $g_1 - \tilde{g}_1 \in L^2(\partial \mathcal{O} \times (0, T))$ and $\langle \cdot, \cdot \rangle_4$ reduces to the L^2 inner product.

Hence,

$$(2.73) \quad \langle g_1, \theta \rangle_4 + \int_0^T \int_{\partial \mathcal{O}} g_2 \theta dz dt = \langle \tilde{g}_1, \theta \rangle_4 + \int_0^T \int_{\partial \mathcal{O}} \tilde{g}_2 \theta dz dt$$

holds and (2.71) is independent of the decomposition of g .

3. Application to the Neumann boundary value problem. In this section, we will discuss the following initial-boundary value problem for a second-order hyperbolic equation.

$$(3.1) \quad \begin{aligned} c_0(x, y, t) \frac{\partial^2 u}{\partial t^2} &= \sum_{i,j=1}^{n-1} a_{ij}(x, y, t) \frac{\partial^2 u}{\partial x_i \partial x_j} + \frac{\partial^2 u}{\partial y^2} \\ &+ \sum_{i=1}^{n-1} b_i(x, y, t) \frac{\partial u}{\partial x_i} + b_0(x, y, t)u + c_1(x, y, t) \frac{\partial u}{\partial t} \\ &+ d(x, y, t) \frac{\partial u}{\partial y} + f(x, y, t), \quad \text{for } (x, y, t) \in R^{n-1} \times R^+ \times R^+, \end{aligned}$$

$$(3.2) \quad \frac{\partial u}{\partial y}(x, 0, t) = 0 \quad \text{for } (x, t) \in R^{n-1} \times R^+$$

$$(3.3) \quad u(x, y, 0) = u_0(x, y), \quad \frac{\partial u}{\partial t}(x, y, 0) = v_0(x, y) \quad \text{for } (x, y) \in R^{n-1} \times R^+,$$

where $R^+ = (0, \infty)$ and $n \geq 2$.

We assume that

$$(3.4) \quad a'_{ij}s, b'_is, c'_is \text{ and } d \text{ belong to } C^\infty(R^{n+1}) \text{ and these functions together with all their derivatives are bounded in } R^{n+1},$$

$$(3.5) \quad \begin{aligned} a_{ij} &= a_{ji} \quad \text{and} \quad \sum_{i,j=1}^{n-1} a_{ij}(x, y, t) \xi_i \xi_j \geq k_1 |\xi|^2 \quad \text{for all } \xi \in R^{n-1} \\ &\text{and all } (x, y, t) \in R^{n-1} \times R \times R, \end{aligned}$$

where k_1 is a positive constant,

$$(3.6) \quad c_0(x, y, t) \geq k_2 \quad \text{for all } (x, y, t) \in R^{n-1} \times R \times R,$$

where k_2 is positive constant,

$$(3.7) \quad \begin{aligned} a'_{ij}s, b'_is \text{ and } c'_is &\text{ are even functions with respect to the } y \text{ variable and } d \\ &\text{ is an odd function with respect to the } y \text{ variable.} \end{aligned}$$

THEOREM 3.1. Suppose that $u_0(x, y) \in H^1(R^{n-1} \times R^+)$ and $v_0(x, y) \in L^2(R^{n-1} \times R^+)$ have compact support in $R^{n-1} \times R^+$ and $f(x, y, t) \in L^2(R^{n-1} \times R^+ \times R^+)$ has compact support in $R^{n-1} \times R^+ \times \overline{R^+}$. Let $u \in C([0, \infty); H^1(R^{n-1} \times R^+)) \cap C^1([0, \infty); L^2(R^{n-1} \times R^+))$ be the unique solution of (3.1), (3.2), and (3.3). Then, for each $T > 0$, we have

$$(3.8) \quad u(x, 0, t) \in H^1(R^{n-1} \times (0, T)).$$

Proof. Since u_0 , v_0 , and f vanish near $y = 0$, we can easily extend u_0 , v_0 , and f so that

$$(3.9) \quad u_0, v_0, \text{ and } f \text{ are even functions with respect to the } y \text{ variable,}$$

$$(3.10) \quad f(x, y, t) = 0 \quad \text{for all } (x, y) \in R^{n-1} \times R \quad \text{if } t < 0.$$

It follows that

$$(3.11) \quad (u_0, v_0) \in H^1(R^n) \times L^2(R^n),$$

$$(3.12) \quad f \in L^2(R^{n+1}).$$

Let $u \in C(R; H^1(R^n)) \cap C^1(R; L^2(R^n))$ be the solution of the pure Cauchy problem for (3.1) in $R^n \times R$ satisfying (3.3) in R^n . By virtue of (3.7) and (3.9), u is an even function with respect to the y variable and consequently,

$$(3.13) \quad \frac{\partial u}{\partial y}(x, 0, t) = 0 \quad \text{for almost all } (x, t) \in R^{n-1} \times R.$$

By the uniqueness of solution to the initial-boundary value problem (3.1), (3.2), and (3.3), the restriction of u to $R^{n-1} \times R^+ \times R^+$ coincides with the solution of (3.1), (3.2), and (3.3). Furthermore, because of finite wave speed, it is enough to establish local trace regularity. Hence, the question of trace regularity is posed in the same format as in Theorem 1.1 with $s = 1$ and $y_0 = 0$.

It remains to verify the condition (1.4). The principal symbol of (3.1) is given by

$$(3.14) \quad P(x, y, t, \xi, \eta, \tau) = \eta^2 + \sum_{i,j=1}^{n-1} a_{ij}(x, y, t) \xi_i \xi_j - c_0(x, y, t) \tau^2$$

where $(\xi, \eta, \tau) \in R^{n-1} \times R \times R$ denotes the dual variables corresponding to $(x, y, t) \in R^{n-1} \times R \times R$. Let $(x(\alpha), y(\alpha), t(\alpha), \xi(\alpha), \eta(\alpha), \tau(\alpha))$ for $\alpha \in R$ be a bicharacteristic strip of (3.14) such that

$$(3.15) \quad \begin{aligned} x(0) &= x_0, & y(0) &= 0, & t(0) &= t_0 \\ \xi(0) &= \xi_0 \neq 0, & \eta(0) &= 0, & \tau(0) &= \tau_0 \neq 0. \end{aligned}$$

Then,

$$(3.16) \quad P(x_0, 0, t_0, \xi_0, 0, \tau_0) = 0$$

and

$$(3.17) \quad \frac{dx_i}{d\alpha} = \frac{\partial}{\partial \xi_i} P(x, y, t, \xi, \eta, \tau), \quad i = 1, \dots, n-1,$$

$$(3.18) \quad \frac{dy}{d\alpha} = \frac{\partial}{\partial \eta} P(x, y, t, \xi, \eta, \tau),$$

$$(3.19) \quad \frac{dt}{d\alpha} = \frac{\partial}{\partial \tau} P(x, y, t, \xi, \eta, \tau),$$

$$(3.20) \quad \frac{d\xi_i}{d\alpha} = -\frac{\partial}{\partial x_i} P(x, y, t, \xi, \eta, \tau), \quad i = 1, \dots, n-1$$

$$(3.21) \quad \frac{d\eta}{d\alpha} = -\frac{\partial}{\partial y} P(x, y, t, \xi, \eta, \tau),$$

$$(3.22) \quad \frac{d\tau}{d\alpha} = -\frac{\partial}{\partial t} P(x, y, t, \xi, \eta, \tau).$$

Since a'_{ij} s and c_0 are even functions with respect to the y variable, we have

$$(3.23) \quad \frac{\partial}{\partial y} P(x, 0, t, \xi, \eta, \tau) = 0 \quad \text{for every } x, t, \xi, \eta \text{ and } \tau.$$

Consequently, it follows from (3.15), (3.18), (3.21), and (3.23) that

$$(3.24) \quad y(\alpha) = 0, \quad \eta(\alpha) = 0 \quad \text{for all } \alpha$$

of the interval where the bicharacteristic strip is defined.

Next, we will observe the following fact.

LEMMA 3.2. *Let $t_0 \geq 0$. If $\tau_0 = \pm 1$, then there are positive constants α_0 and ϵ_0 independent of x_0, t_0 , and ξ_0 satisfying (3.16) such that the bicharacteristic strip is defined on $[-\alpha_0, \alpha_0]$ and such that $t(\alpha_0) \leq t_0 - \epsilon_0$ for $\tau_0 = 1$ and $t(-\alpha_0) \leq t_0 - \epsilon_0$ for $\tau_0 = -1$. Furthermore, if $\tau_0 = 1$, then $\tau(\alpha) > 0$ for all $\alpha \in [-\alpha_0, \alpha_0]$ and if $\tau_0 = -1$, then $\tau(\alpha) < 0$ for all $\alpha \in [-\alpha_0, \alpha_0]$.*

Proof. We first note that

$$(3.25) \quad P(x(\alpha), 0, t(\alpha), \xi(\alpha), 0, \tau(\alpha)) = 0$$

holds along the bicharacteristic strip, and rewrite (3.17), (3.19), (3.20), and (3.22) as

$$(3.26) \quad \frac{dx_i}{d\alpha} = 2 \sum_{j=1}^{n-1} a_{ij}(x, 0, t) \xi_j, \quad i = 1, \dots, n-1,$$

$$(3.27) \quad \frac{dt}{d\alpha} = -2c_0(x, 0, t)\tau,$$

$$(3.28) \quad \frac{d\xi_i}{d\alpha} = - \sum_{j,k=1}^{n-1} \frac{\partial}{\partial x_i} a_{jk}(x, 0, t) \xi_j \xi_k + \frac{\partial}{\partial x_i} c_0(x, 0, t) \tau^2, \quad i = 1, \dots, n-1,$$

$$(3.29) \quad \frac{d\tau}{d\alpha} = - \sum_{j,k=1}^{n-1} \frac{\partial}{\partial t} a_{jk}(x, 0, t) \xi_j \xi_k + \frac{\partial}{\partial t} c_0(x, 0, t) \tau^2.$$

Since ξ_0 satisfies (3.16), we infer from (3.4) and (3.5) that for $\tau_0 = \pm 1$,

$$(3.30) \quad |\xi_0| \leq M_1,$$

holds for some positive constant M_1 which is independent of x_0 and t_0 . Hence, by (3.4) and (3.30), there are positive constants α_1 and M_2 independent of x_0, t_0 , and ξ_0 such that the bicharacteristic strip is defined on $[-\alpha_1, \alpha_1]$ and

$$(3.31) \quad |\tau(\alpha)| + |\xi(\alpha)| \leq M_2$$

for all $\alpha \in [-\alpha_1, \alpha_1]$.

It follows from (3.4), (3.29), and (3.31) that

$$(3.32) \quad \left| \frac{d\tau}{d\alpha} \right| \leq M_3 \quad \text{for all } \alpha \in [-\alpha_1, \alpha_1]$$

for some positive constant M_3 independent of x_0, t_0 , and ξ_0 . Now we use (3.6), (3.27), and (3.32) to find $0 < \alpha_0 \leq \alpha_1$ and $\epsilon_0 > 0$ as in the assertion of the lemma. For the last statement of the lemma, we argue as follows. If $\tau(\alpha_2) = 0$, for some $\alpha_2 \in [-\alpha_1, \alpha_1]$, then

$\xi(\alpha_2) = 0$ by (3.25). As a result of the uniqueness of solution to the system (3.26)–(3.29), it is evident that $x(\alpha) = x(\alpha_2)$, $t(\alpha) = t(\alpha_2)$, $\tau(\alpha) = 0$, and $\xi(\alpha) = 0$ should hold for all $\alpha \in [-\alpha_1, \alpha_1]$. This contradicts $\tau(0) = \pm 1$. Now the proof of the lemma is complete.

We also need the following fact.

LEMMA 3.3. *There is a constant $\epsilon_1 > 0$ such that*

$$(3.33) \quad \{(x, y, t) : x \in R^{n-1}, y = 0, -\epsilon_1 < t < 0\} \\ \text{is disjoint from the singular support of } u.$$

Proof. We recall (3.10) and the assumption that

$$(3.34) \quad \{(x, y) : x \in R^{n-1}, y = 0\} \text{ is disjoint from } \text{supp } u_0 \cup \text{supp } v_0.$$

The assertion (3.33) is an immediate consequence of finite domain of dependence.

We now verify condition (1.4). Choose any $(x_0, t_0) \in R^{n-1} \times R^+$ and $\xi_0 \in R^{n-1}$ which satisfies (3.16) with $\tau_0 = 1$. Since $\{(x, y, t) : x \in R^{n-1}, y = 0, t \in R\}$ is disjoint from $\text{supp } f$, Proposition 3.5.1 of [5] implies that $(x_0, 0, t_0, \xi_0, 0, 1) \notin WF(u)$ if and only if $(x(\alpha), 0, t(\alpha), \xi(\alpha), 0, \tau(\alpha)) \notin WF(u)$ for some $\alpha \in [-\alpha_0, \alpha_0]$. Here α_0 is the same as in Lemma 3.2, which says that $t(\alpha_0) \leq t_0 - \epsilon_0$. Thus, if $t(\alpha_0) < 0$, then $(x_0, 0, t_0, \xi_0, 0, 1) \notin WF(u)$ according to Lemma 3.3. If $0 \leq t(\alpha_0) \leq t_0 - \epsilon_0$, we argue as follows. Since $\tau(\alpha_0) > 0$, it is evident that $(x(\alpha_0), 0, t(\alpha_0), \xi(\alpha_0), 0, \tau(\alpha_0)) \notin WF(u)$ if and only if $(x(\alpha_0), 0, t(\alpha_0), \xi(\alpha_0)/\tau(\alpha_0), 0, 1) \notin WF(u)$. By taking $(x(\alpha_0), 0, t(\alpha_0), \xi(\alpha_0)/\tau(\alpha_0), 0, 1)$ as the initial value of the bicharacteristic strip, we apply Lemma 3.2 so that the new terminal value of t satisfies

$$(3.35) \quad t \leq t_0 - 2\epsilon_0.$$

If $t_0 - 2\epsilon_0 < 0$, then obviously, $(x_0, 0, t_0, \xi_0, 0, 1) \notin WF(u)$. If not, we repeat the same procedure until we reach negative value of t . For $\tau_0 = -1$, we use the same argument to find $(x_0, 0, t_0, \xi_0, -1) \notin WF(u)$. Now condition (1.4) has been established, which completes the proof of Theorem 3.1.

Remark 3.4. When (3.1) reduces to a wave equation with constant coefficients, the above result was already obtained by Symes [18] and Lasiecka and Triggiani [10]. The method of geometric optics was used in [18] and the Fourier–Laplace transform was used in [10]. In [10], we can find a very enlightening example which shows that the H^1 regularity is not true, in general, when the support of f intersects the boundary. For the general second-order hyperbolic operator, the most up-to-date results on the trace regularity of solution to the Neumann boundary value problem can be found in [11] and [12], where it is not assumed that the data have compact support.

STATE SPACE REALIZATION OF 2-D FINITE-DIMENSIONAL BEHAVIOURS*

E. FORNASINI[†], P. ROCHA[‡], AND S. ZAMPIERI[†]

Abstract. This paper deals with the state space realization of autonomous autoregressive two-dimensional (2-D) systems in the context of the behavioural approach. An arbitrary autoregressive 2-D system Σ can be viewed as the sum of an externally controllable subsystem Σ^c with an autonomous one Σ^a , so that a state space realization of Σ can be obtained by separately realizing Σ^c and Σ^a . Since a procedure for realizing externally controllable systems in state/driving-variable form is already available in the literature, the general realization problem is easily reduced to the autonomous case. Here, some properties of finite-dimensional autonomous systems are discussed, allowing for a realization procedure that uses the Gröbner bases theory.

Key words. autonomous systems, (externally) controllable systems, Gröbner basis, state/driving-variable realization

AMS subject classifications. 93B20, 93B25

1. Introduction. In this paper we will present some results and algorithms involved in the construction of two-dimensional (2-D) state space models on the basis of external data. Following the behavioural approach to dynamical systems introduced in [1], [2], [3], external data are characterized by means of a family of laws telling us that certain signals can occur and others cannot. Moreover, all the components of the external data play completely symmetric roles, so that no input/output structure is a priori assumed.

Realization theory has been developed for the most part in the one-dimensional environment, where state space models have shown to be a very convenient framework for the mathematical analysis and synthesis of real time data processors and controllers. In this context the state is very naturally viewed as a set of latent variables which parametrize the content of system memory, and the realization problems are inextricably connected with the definitions of past and future that underlie the notion of memory.

When trying to formulate state concepts for 2-D systems, it is of central importance to realize that there is often no natural, intrinsic direction of the evolution for systems defined over a 2-D domain. In this case any choice of a preferred direction is artificial, and there are various possible definitions of past and future. Some of them are discussed in [1], where their connections with 2-D state representations available in the literature are illustrated in detail. Obviously, the most classical example is provided by the quarter plane causality structure. It underlies the so-called South West (SW)-state representation, which is the behavioural counterpart of the state space model of quarter plane impulse responses, introduced by Attasi [4], Roesser [5], and Fornasini and Marchesini [6] within the classical input/output framework.

Singular state space models have been analyzed to cope with more general causality structures in, e.g., Morf [7], Kaczorek [8], and Lewis [9]. In this paper an alternative approach to noncausal structures is considered, based on the introduction of a set of auxiliary free variables in SW-state representation. These act in some sense like an input driving the system dynamics and are therefore called the “driving variables.” State/driving-variable models allow us to compute recursively joint input-output trajectories from the values of the auxiliary free variables via the state. Although only the realization of 2-D “auto-regressive (AR)” equations is considered, we remark, however, that transfer functions can also be handled in this context, since they can be identified with (externally) controllable AR systems; see [1].

It is shown in [1] that every controllable AR 2-D system (and hence every 2-D rational transfer function) can be realized in SW-state/driving-variable form, independently of the

[‡] Faculty of Technical Mathematics and Informatics, Delft University of Technology, P.O. Box 5031, 2600 GA Delft, the Netherlands.

existence of a quarter plane causal structure between the system variables. This results from the possibility of generating the joint input-output trajectories $w = \text{col}(u, y)$ of a controllable AR system from (auxiliary) driving-variable trajectories v such that the relationship between w and v is quarter plane causal, even if u and y are not causally related. Viewing v as the new “input” and w as the new “output,” a 2-D state space model (for instance, of the Fornasini–Marchesini (FM) type [6]) can then be obtained by the classical realization procedures, yielding the desired state/driving-variable realization.

The realizability of arbitrary, i.e., not necessarily controllable, AR systems is still an open problem. Reducing this problem to the realization of autonomous systems is the first goal of our paper. Indeed, we show that every AR system Σ can be viewed as the sum of an externally controllable system Σ^c and an autonomous one Σ^a and, therefore, the realization of Σ can be obtained by realizing separately Σ^c and Σ^a . Since a procedure for realizing externally controllable systems is given in [1], it will be enough to derive a realization procedure for autonomous systems.

This contribution focuses on finite-dimensional autonomous AR systems with q (real-valued) variables defined over \mathbb{Z}^2 . It turns out that, in this case, the admissible system trajectories constitute a finite-dimensional vector space \mathcal{B} , given by $\mathcal{B} = \{w : \mathbb{Z}^2 \rightarrow \mathbb{R}^q | R(\sigma_1, \sigma_2, \sigma_1^{-1}, \sigma_2^{-1})w = 0\}$, with σ_1 and σ_2 the 2-D shifts and $R(z_1, z_2, z_1^{-1}, z_2^{-1})$ a factor right prime 2-D polynomial matrix.

The second goal we pursue in this paper is that of representing the autonomous behaviour via a state model, characterized by a pair of commuting matrices that describe the state evolution in the two directions of the grid. The realization algorithm exploits the algebraic duality between \mathcal{B} and a suitable quotient module over the space of 2-D polynomial rows, as well as the correspondence between the shift operators in \mathcal{B} and a pair of adjoint operators in the quotient module. These operators are represented by a pair of commutative invertible matrices and can be obtained by computer algebra techniques and linear manipulations.

2. Autonomous 2-D systems. Following the behavioural approach to dynamical systems introduced in [1] and [2], we characterize a 2-D system by means of its behaviour, which consists of the set of all the signals which are compatible with the system laws. Moreover, we do not start with a given input/output structure, i.e., the system signals are stacked together in a signal w instead of being divided into inputs u and outputs y . A 2-D system Σ with q real valued variables defined over \mathbb{Z}^2 and with behaviour $\mathcal{B} \subseteq \{w : \mathbb{Z}^2 \rightarrow \mathbb{R}^q\}$ will be denoted by $\Sigma = (\mathbb{Z}^2, \mathbb{R}^q, \mathcal{B})$.

In the sequel we will be interested in the class of autoregressive 2-D systems. $\Sigma = (\mathbb{Z}^2, \mathbb{R}^q, \mathcal{B})$ is said to be an AR system if there exists a 2-D Laurent polynomial matrix $R(z_1, z_2, z_1^{-1}, z_2^{-1})$ such that

$$\mathcal{B} = \{w : \mathbb{Z}^2 \rightarrow \mathbb{R}^q | R(\sigma_1, \sigma_2, \sigma_1^{-1}, \sigma_2^{-1})w = 0\} =: \ker R(\sigma_1, \sigma_2, \sigma_1^{-1}, \sigma_2^{-1}),$$

with σ_1 and σ_2 the 2-D shift operators. An AR 2-D system is said to be finite-dimensional if its behaviour \mathcal{B} is a finite-dimensional vector space; otherwise, Σ is said to be infinite-dimensional.

In order to define the notion of autonomy we introduce the following nomenclature. A subset of \mathbb{R}^2 is said to be 2-D unbounded if it contains a plane sector $\mathcal{S}(v, v_1, v_2) := \{v + \alpha v_1 + \beta v_2 | \alpha, \beta \geq 0\}$ with $v, v_1, v_2 \in \mathbb{R}^2$, and v_1, v_2 linearly independent. $U \subseteq \mathbb{Z}^2$ is a 2-D unbounded set if $U = \mathcal{U} \cap \mathbb{Z}^2$ for some 2-D unbounded set \mathcal{U} in \mathbb{R}^2 .

Definition 1. $\Sigma = (\mathbb{Z}^2, \mathbb{R}^q, \mathcal{B})$ is an autonomous 2-D system if there exists a subset $T \subseteq \mathbb{Z}^2$ such that $\mathbb{Z}^2 \setminus T$ is 2-D unbounded and satisfies the condition $\{w_1, w_2 \in \mathcal{B} \text{ and } w_1|_T = w_2|_T\} \Rightarrow \{w_1 = w_2\}$.

So, intuitively, a system is autonomous if the evolution of its trajectories in a sufficiently large portion $\mathbb{Z}^2 \setminus T$ of the discrete plane is completely specified by what occurs in the remaining portion T of the domain \mathbb{Z}^2 . As stated in Proposition 2.1, for autoregressive systems the autonomy is equivalent to the absence of free variables.

Notation. Let $\Sigma = (\mathbb{Z}^2, \mathbb{R}^q, \mathcal{B})$ be a system in the variables $(w_1, \dots, w_q)^T := w$. The variable $w_i, i \in \{1, \dots, q\}$, is a free variable if, for every $\alpha : \mathbb{Z}^2 \rightarrow \mathbb{R}$, there exists some $w \in \mathcal{B}$ such that $w_i = \alpha$. Similarly, a vector $(w_{i_1}, \dots, w_{i_l})^T$, with $i_j \in J \subseteq \{1, \dots, q\}$ and $i_j \neq i_k$ if $j \neq k$, is a vector of free variables if for every $\beta : \mathbb{Z}^2 \rightarrow \mathbb{R}^l$ there exists $w \in \mathcal{B}$ such that $(w_{i_1}, \dots, w_{i_l})^T = \beta$. The number of free variables in a system Σ is defined as the maximum dimension of a vector of free variables in Σ .

LEMMA 2.1. *Let $\Sigma = (\mathbb{Z}^2, \mathbb{R}^q, \mathcal{B})$ be an autoregressive 2-D system such that $\mathcal{B} = \{w : \mathbb{Z}^2 \rightarrow \mathbb{R}^q | R(\sigma_1, \sigma_2, \sigma_1^{-1}, \sigma_2^{-1})w = 0\}$. Then*

1. *The number l of free variables in Σ is $q - \text{rank } R$;*

2. *If $l > 0$, there exists a nonzero $q \times l$ polynomial matrix $M(z_1, z_2, z_1^{-1}, z_2^{-1})$ such that $\mathcal{B} \supseteq \text{im } M(\sigma_1, \sigma_2, \sigma_1^{-1}, \sigma_2^{-1})$, where $M(\sigma_1, \sigma_2, \sigma_1^{-1}, \sigma_2^{-1})$ is viewed as an operator from $\{v : \mathbb{Z}^2 \rightarrow \mathbb{R}^l\}$ into $\{w : \mathbb{Z}^2 \rightarrow \mathbb{R}^q\}$. Moreover, $\text{im } M$ has l free variables.*

Proof. In order to prove statement 1, we first consider the case where R has full row rank. In this case, there is a column permutation Π such that $R\Pi = [P|Q]$ with P square $r \times r$ and nonsingular. This means that the equation $Rw = 0$ is equivalent to

$$(2.1) \quad Pw_1 = -Qw_2,$$

with $\text{col}(w_1, w_2) = \Pi w$. Since P is full row rank, it can be shown that $P(\sigma_1, \sigma_2, \sigma_1^{-1}, \sigma_2^{-1})$ is a surjective operator, and w_2 is a $q - r$ -dimensional vector of free variables. So $l \geq q - r$. Now, it remains to see that none of the components of w_1 are free. Let $P^*(z_1, z_2, z_1^{-1}, z_2^{-1})$ be such that $P^*P = \text{diag}(p) =: D$, with $p := \det P$, and define $E := -P^*Q$. Premultiplying (2.1) by P^* yields

$$(2.2) \quad Dw_1 = Ew_2.$$

In particular, if $w_2 \equiv 0$, (2.2) implies that the components w_{1i} of w_1 must satisfy

$$(2.3) \quad p(\sigma_1, \sigma_2, \sigma_1^{-1}, \sigma_2^{-1})w_{1i} = 0 \quad i = 1, \dots, r$$

and are, hence, not free. This shows that the number l of free variables in $\mathcal{B} := \ker R$ is exactly $l = q - r$.

If R does not have full row rank, there exists a factorization

$$(2.4) \quad R = F\bar{R}$$

such that F has full column rank, \bar{R} has full row rank and $\text{rank } F = \text{rank } \bar{R} = \text{rank } R$. Let \bar{F} be an $r \times r$ submatrix of F obtained by selecting r linearly independent rows. It is not difficult to see that

$$\bar{R}w = 0 \Rightarrow F\bar{R}w = 0 \Rightarrow \bar{F}\bar{R}w = 0,$$

or, equivalently,

$$\mathcal{B}_1 := \ker \bar{R} \subseteq \mathcal{B} := \ker R \subseteq \ker \bar{F}\bar{R} =: \mathcal{B}_2.$$

Since \bar{R} and $\bar{F}\bar{R}$ are both matrices with full row rank r , it follows from the previous reasoning that both \mathcal{B}_1 and \mathcal{B}_2 have $l = q - r$ free variables, proving the first statement of the lemma.

As for statement 2, if $l = q - r$, without loss of generality, the matrix \bar{R} in the factorization (2.4) can be taken to be a full rank factor left prime 2-D polynomial matrix of size $r \times q$ (note that if \bar{R} is not left prime its nontrivial left factors can be extracted and included in F). In this case it follows from [1, Thm. 1] that there exists a $q \times l$ matrix $M(z_1, z_2, z_1^{-1}, z_2^{-1})$ such that $\ker \bar{R}(\sigma_1, \sigma_2, \sigma_1^{-1}, \sigma_2^{-1}) = \text{im } M(\sigma_1, \sigma_2, \sigma_1^{-1}, \sigma_2^{-1})$. So, $\mathcal{B} \supseteq \ker \bar{R} = \text{im } M$. Finally, we note that the number of free variables in $\ker \bar{R}$ is still l , and hence $\text{im } M = \ker \bar{R}$ has l free variables. \square

PROPOSITION 2.1. *An autoregressive system $\Sigma = (\mathbb{Z}^2, \mathbb{R}^q, \mathcal{B})$ is autonomous if and only if it has no free variables.*

Proof. (i) Suppose that Σ is a system without free variables. This means that $\mathcal{B} = \ker R$, for some full rank matrix $R(z_1, z_2, z_1^{-1}, z_2^{-1})$. Let P be a $q \times q$ matrix obtained by taking q rows of R , and define $P^* := DP^{-1}$ with $D := \text{diag}(p)$ and $p := \det P$ (note that P^* is a polynomial matrix). Clearly,

$$Rw = 0 \Rightarrow Pw = 0 \Rightarrow Dw = 0 \Leftrightarrow p(\sigma_1, \sigma_2, \sigma_1^{-1}, \sigma_2^{-1})w_i = 0 \quad i = 1, \dots, q,$$

where w_i denotes the i th component of w .

We next show that $\ker D$ is an autonomous behaviour. Since $\mathcal{B} \subseteq \ker D$, this implies that also \mathcal{B} (and hence Σ) is autonomous. Since the support of p is finite, then there exist integers l_1, L_1, l_2, L_2 such that such support is included in the set $T := \{(h_1, h_2) \in \mathbb{Z}^2 \mid l_1 \leq h_1 \leq L_1 \text{ or } l_2 \leq h_2 \leq L_2\}$. It can be shown that the solutions of the equation are completely determined by their values on T , i.e., if w_1, w_2 are elements of $\ker D$ and $w_1|_T = w_2|_T$, then $w_1 = w_2$. Since $\mathbb{Z}^2 \setminus T$ is 2-D unbounded, this means that $\ker D$ is autonomous.

(ii) Assume that Σ has $l > 0$ free variables and let M be as in Lemma 2.1. Denote, respectively, by \bar{m}_i and \underline{m}_i the maximum and the minimum of the exponents of z_i in the entries of M , and define the extent of M as $e(M) := \sqrt{2} \max\{\bar{m}_1 - \underline{m}_1, \bar{m}_2 - \underline{m}_2\}$. Further, denote the Euclidean distance by $d(\cdot, \cdot)$. Given any subset $T \subseteq \mathbb{Z}^2$ such that $\mathbb{Z}^2 \setminus T$ is 2-D unbounded, define two trajectories v' and $v'' \in \{v : \mathbb{Z}^2 \rightarrow \mathbb{R}^q\}$ in the following way. The trajectory v' is simply the zero trajectory. As for v'' , we require that $v''(t_1, t_2) = 0$ if $d((t_1, t_2), T) \leq e(M)$; for (t_1, t_2) with $d((t_1, t_2), T) > e(M)$, we define $v''(t_1, t_2)$ in such a way that $Mv'' \neq 0$. Note that this is possible since the value of Mv'' at a point $(t_1^*, t_2^*) \in \mathbb{Z}^2$ depends only on the values of v'' at the points (t_1, t_2) such that $d((t_1, t_2), (t_1^*, t_2^*)) \leq e(M)$. Now let $w' := Mv' = 0$ and $w'' := Mv''$. Clearly, $w', w'' \in \mathcal{B}$. Moreover $w'|_T = w''|_T = 0$, and $w'' \neq 0 = w'$. This shows that Σ is not autonomous. \square

Contrary to the one-dimensional case, where autonomous linear systems are necessarily finite-dimensional [2], autonomous 2-D systems may be infinite-dimensional. The following proposition characterizes the autonomy and the finite dimensionality properties of AR 2-D systems.

PROPOSITION 2.2. *Let $\Sigma = (\mathbb{Z}^2, \mathbb{R}^q, \mathcal{B})$ be an AR 2-D system with behaviour $\mathcal{B} = \{w : \mathbb{Z}^2 \rightarrow \mathbb{R}^q \mid R(\sigma_1, \sigma_2, \sigma_1^{-1}, \sigma_2^{-1})w = 0\}$, where $R(z_1, z_2, z_1^{-1}, z_2^{-1})$ is a 2-D polynomial matrix. Then Σ is autonomous if and only if R has full column rank. Moreover Σ is finite-dimensional if and only if R is right factor prime.*

Proof. The first part of the result is an immediate consequence of Lemma 2.1 and Proposition 2.1. To prove the second statement assume first that R is right factor prime. Without loss of generality, we can suppose that the entries of R are in $\mathbb{R}[z_1, z_2]$. Then there exist [7] matrices $X_i(z_1, z_2)$ such that

$$X_i(z_1, z_2)R(z_1, z_2) = \text{diag}(d(z_i), \dots, d(z_i)), \quad i = 1, 2.$$

So $Rw = 0$ implies $d(\sigma_i)w_j = 0, i = 1, 2$. Consequently the projection of \mathcal{B} into the j th signal component is finite-dimensional ($j = 1, \dots, q$). Therefore \mathcal{B} is finite-dimensional.

Conversely if \mathcal{B} is finite-dimensional, the same is true for its restriction to horizontal and vertical lines in \mathbb{Z}^2 . So there exist [3] full rank square matrices $R_i(z_i)$, $i = 1, 2$ such that $\ker R_i(\sigma_i) \supseteq \ker R(\sigma_1, \sigma_2)$. Hence

$$R_i(z_i) = X_i(z_1, z_2)R(z_1, z_2)$$

for some matrices X_i , $i = 1, 2$. By [7] this means that R is factor right prime. \square

An extreme example of nonautonomous systems is the class of (externally) controllable systems. For these systems, the evolution of the trajectories outside a restricted part T of the domain eventually becomes independent of what occurs in T . Formally, we define (external) controllability as follows.

Definition 2. A 2-D system $\Sigma = (\mathbb{Z}^2, \mathbb{R}^q, \mathcal{B})$ is (externally) controllable if the following condition holds. There exists a positive real number ρ such that, for all $T_1, T_2 \subseteq \mathbb{Z}^2$ with $d(T_1, T_2) > \rho$ and for all $w_1, w_2 \in \mathcal{B}$, there exists $w \in \mathcal{B}$ such that $w|_{T_i} = w_i|_{T_i}$, $i = 1, 2$. Here $d(T_1, T_2)$ denotes the Euclidean distance between the sets T_1 and T_2 .

Remark. We refer to the above notion of controllability as to external controllability in order to make a distinction from the classical notion, which applies to state space realization. Our definition is given at an external level, as it only refers to the (external) system variables $w \in \mathcal{B}$. However, when no possibility of confusion arises, we will simply refer to it as controllability.

An interesting feature of controllability and autonomy is the fact that these are complementary properties, in the sense that an arbitrary AR system can be viewed as the sum of a controllable system with an autonomous one.

Notation. Given two systems $\Sigma_i = (\mathbb{Z}^2, \mathbb{R}^q, \mathcal{B}_i)$, $i = 1, 2$, the sum $\Sigma_1 + \Sigma_2$ of Σ_1 and Σ_2 is defined as $\Sigma_1 + \Sigma_2 := (\mathbb{Z}^2, \mathbb{R}^q, \mathcal{B})$, where $\mathcal{B} := \mathcal{B}_1 + \mathcal{B}_2$.

PROPOSITION 2.3. *Let $\Sigma = (\mathbb{Z}^2, \mathbb{R}^q, \mathcal{B})$ be a 2-D system. Then there exist AR systems $\Sigma^c = (\mathbb{Z}^2, \mathbb{R}^q, \mathcal{B}^c)$ and $\Sigma^a = (\mathbb{Z}^2, \mathbb{R}^q, \mathcal{B}^a)$ such that*

1. Σ^c is controllable;
2. Σ^a is autonomous, and
3. $\Sigma = \Sigma^c + \Sigma^a$.

Proof. Let $R(z_1, z_2, z_1^{-1}, z_2^{-1})$ such that

$$\mathcal{B} = \{w : \mathbb{Z}^2 \rightarrow \mathbb{R}^q | R(\sigma_1, \sigma_2, \sigma_1^{-1}, \sigma_2^{-1})w = 0\},$$

Then there exist polynomial matrices $F(z_1, z_2, z_1^{-1}, z_2^{-1})$, with full column rank, and $P(z_1, z_2, z_1^{-1}, z_2^{-1})$, with full row rank and factor left prime, such that $R = FP$. Without loss of generality, we can assume that $P = [P_1 \ P_2]$ with P_1 a square and full rank matrix. Define

$$\mathcal{B}^c = \{w : \mathbb{Z}^2 \rightarrow \mathbb{R}^q | Pw = 0\},$$

$$\mathcal{B}^a = \{w : \mathbb{Z}^2 \rightarrow \mathbb{R}^q | w = \begin{bmatrix} w_1 \\ w_2 \end{bmatrix}, \quad w_2 = 0, \quad \text{and } FP_1w_1 = 0\},$$

$\Sigma^c = (\mathbb{Z}^2, \mathbb{R}^q, \mathcal{B}^c)$ and $\Sigma^a = (\mathbb{Z}^2, \mathbb{R}^q, \mathcal{B}^a)$. Since P is factor left prime, by [1] Σ^c is controllable. On the other hand, by Proposition 2.2, Σ^a is autonomous. We will show that $\Sigma = \Sigma^c + \Sigma^a$. Since both \mathcal{B}^c and \mathcal{B}^a are subspaces of \mathcal{B} ,

$$\mathcal{B}^c + \mathcal{B}^a \subseteq \mathcal{B}.$$

In order to prove the reciprocal inclusion, assume that $w \in \mathcal{B}$ is given. Let

$$w^a := \begin{bmatrix} w_1^a \\ w_2^a \end{bmatrix},$$

with $w_2^a := 0$ and w_1^a such that $P_1 w_1^a = Pw$ (note that $P_1(\sigma_1, \sigma_2, \sigma_1^{-1}, \sigma_2^{-1})$ is a surjective operator, as P_1 has full row rank). Further, define $w^c := w - w^a$. Now, since $FP_1 w_1^a = FFW = RW = 0$, it follows that $w^a \in \mathcal{B}^a$. Moreover,

$$Pw^c = Pw - Pw^a = Pw - [P_1 \ P_2] \begin{bmatrix} w_1^a \\ w_2^a \end{bmatrix} = Pw - P_1 w_1^a = 0,$$

and hence $w^c \in \mathcal{B}^c$. So, $w = w^c + w^a$ with $w^c \in \mathcal{B}^c$ and $w^a \in \mathcal{B}^a$, proving that $\mathcal{B} \subseteq \mathcal{B}^c + \mathcal{B}^a$. This yields the desired result. \square

Remark. Note that the above sum $\mathcal{B} = \mathcal{B}^c + \mathcal{B}^a$ (and hence $\Sigma = \Sigma^c + \Sigma^a$) is not necessarily a direct sum, i.e., we may have $\mathcal{B}^c \cap \mathcal{B}^a \neq \{0\}$. However, it can be shown that $\mathcal{B} = \mathcal{B}^c \oplus \mathcal{B}^a$ if and only if, in the decomposition $R = FP$, the matrix P is zero left prime. Moreover, it is not difficult to prove that $\Sigma = \Sigma_1^c + \Sigma_1^a = \Sigma_2^c + \Sigma_2^a$ imply $\Sigma_1^c = \Sigma_2^c$, i.e., in the decomposition $\Sigma = \Sigma^c + \Sigma^a$ the system Σ^c is unique. In fact, it turns out that Σ^c is the largest controllable subsystem of Σ . Curiously, this uniqueness does not necessarily hold for Σ^a . This is illustrated in the following example.

Example. Let $\Sigma = (\mathbb{Z}^2, \mathbb{R}^3, \mathcal{B})$ with

$$\mathcal{B} = \{w : \mathbb{Z}^2 \rightarrow \mathbb{R}^3 \mid R(\sigma_1, \sigma_2, \sigma_1^{-1}, \sigma_2^{-1})w = 0\}$$

where

$$R(z_1, z_2, z_1^{-1}, z_2^{-1}) := \begin{bmatrix} z_1 - 1 & 0 & (z_1 - 1)(z_1 + z_2) \\ 0 & z_2 - 1 & (z_2 - 1)(z_2 - z_1) \end{bmatrix}.$$

Then, clearly, R can be decomposed as $R = FP$ with

$$F(z_1, z_2, z_1^{-1}, z_2^{-1}) := \begin{bmatrix} z_1 - 1 & 0 \\ 0 & z_2 - 1 \end{bmatrix}$$

and

$$P(z_1, z_2, z_1^{-1}, z_2^{-1}) := \begin{bmatrix} 1 & 0 & z_1 + z_2 \\ 0 & 1 & z_2 - z_1 \end{bmatrix}.$$

Constructing Σ^c and Σ^a as in the proof of Proposition 2.4 yields $\Sigma^c = (\mathbb{Z}^2, \mathbb{R}^3, \mathcal{B}^c)$ with

$$\mathcal{B}^c := \{w : \mathbb{Z}^2 \rightarrow \mathbb{R}^3 \mid Pw = 0\},$$

and $\Sigma^a = (\mathbb{Z}^2, \mathbb{R}^3, \mathcal{B}^a)$ with

$$\mathcal{B}^a := \left\{ w : \mathbb{Z}^2 \rightarrow \mathbb{R}^3 \mid w = \begin{bmatrix} w_1 \\ w_2 \\ w_3 \end{bmatrix}, w_3 = 0, F \begin{bmatrix} w_1 \\ w_2 \end{bmatrix} = 0 \right\}.$$

So, $\Sigma = \Sigma^a + \Sigma^c$. Now let $\bar{\Sigma}^a = (\mathbb{Z}^2, \mathbb{R}^3, \bar{\mathcal{B}}^a)$, with

$$\bar{\mathcal{B}}^a := \left\{ w : \mathbb{Z}^2 \rightarrow \mathbb{R}^3 \mid w_2 = 0, F\bar{P} \begin{bmatrix} w_1 \\ w_3 \end{bmatrix} = 0 \right\}$$

and

$$\bar{P}(z_1, z_2, z_1^{-1}, z_2^{-1}) := \begin{bmatrix} 1 & z_1 + z_2 \\ 0 & z_1 - z_2 \end{bmatrix}.$$

Applying the same reasoning as in the proof of Proposition 2.3, it is easily shown that, also, $\bar{\Sigma}^a + \Sigma^c = \Sigma$. So, in the decomposition $\Sigma = \Sigma^a + \Sigma^c$ the autonomous subsystem is not unique.

The decomposition of an arbitrary AR 2-D system Σ into the sum of a controllable part Σ^c and an autonomous part Σ^a can be used to obtain state space realizations of Σ by separately realizing Σ^c and Σ^a .

As shown in [1], every controllable AR system admits a state/driving-variable realization of the form

$$\begin{aligned} (2.5) \quad & S(\sigma)\mathbf{x} = 0 \\ (2.6) \quad & \sigma_1\mathbf{x} = (A_1\sigma + A_0)x + (B_1\sigma + B_0)v \\ (2.7) \quad & w = C\mathbf{x} + Dv \end{aligned}$$

with $\sigma := \sigma_2^{-1}\sigma_1$ the diagonal shift, \mathbf{x} the state, and v an auxiliary free driving variable. Moreover, the matrices $S(z), A(z) := A_1z + A_0$ and $B(z) := B_1z + B_0$ are such that $A(\sigma) \ker S(\sigma) \subseteq \ker S(\sigma)$ and $\text{im } B(\sigma) \subseteq \ker S(\sigma)$.

This model can be interpreted as follows. On each diagonal line $\mathcal{L}_k := \{(i, k - i) | i \in \mathbb{Z}\}$, $k \in \mathbb{Z}$, the state trajectories must satisfy the constraint of (2.5). Equation (2.6) yields the state on \mathcal{L}_{k+1} once the state and the driving variable on \mathcal{L}_k are given. We remark that, due to the special structure of $S(z), A(z)$, and $B(z)$, if $\mathbf{x}|_{\mathcal{L}_k}$ satisfies (2.5), then the corresponding state $\mathbf{x}|_{\mathcal{L}_{k+1}}$ computed from (2.6) also satisfies this restriction. Therefore we can view equation (2.5) as a constraint on the admissible initial states along the diagonal line, say \mathcal{L}_0 , and use (2.6) and (2.7) to propagate the (\mathbf{x}, w) trajectories on the half plane $\mathcal{H}_0 := \cup_{k \geq 0} \mathcal{L}_k$. By means of (2.6) the state $\mathbf{x}(i + 1, j)$ is computed from the values of \mathbf{x} and v on the nearest neighbours (i, j) and $(i + 1, j - 1)$ of $(i + 1, j)$.

This updating structure is the same as for the 2-D input-state-output (i/s/o) model introduced in [6], known in the literature as the FM model. However, here the system dynamics are driven by the auxiliary variable v instead of being driven by the system inputs, and the model output is the system variable w , which includes both inputs and outputs. Another important distinction is that the FM i/s/o model does not include an explicit restriction on the admissible initial states as in (2.5). As it will later become clear, such a restriction is essential for the realization of autonomous systems in state/driving-variable form.

In view of foregoing considerations, it turns out that in order to study the realizability of an arbitrary 2-D system $\Sigma = \Sigma^c + \Sigma^a$ by state/driving-variable model as (2.5), (2.6), and (2.7), it is enough to focus on the realizability of the autonomous part Σ^a . This problem will be considered in the next section for the autonomous finite-dimensional case.

3. Autonomous finite-dimensional systems. We will assume throughout that R is a full column rank, factor right prime matrix, with elements in the Laurent polynomial ring $\mathbb{R}[z_1, z_2, z_1^{-1}, z_2^{-1}] := A_{\pm}$. Moreover, for sake of simplicity, we will first restrict to scalar behaviours, by assuming that $R = [r_1 \ r_2 \ \cdots \ r_t]^T$ is a column vector, and successively extend the results to the general case.

3.1. Scalar case. In the subsequent discussion a significant role will be played by some connections between the ideals in A_{\pm} and the ideals in $A_+ := \mathbb{R}[z_1, z_2]$ and by an abstract characterization of the system behaviour based on the algebraic properties of dual spaces. Let us first consider the following map:

$$|\cdot| : A_{\pm} \rightarrow A_+ : p \mapsto |p| := z_1^{-i} z_2^{-j} p,$$

where i and j are the minimum degrees of the monomials that appear in the nonzero Laurent polynomial p with respect to the variables z_1 and z_2 . More precisely, if

$$p = \sum_{h,k \in \mathbb{Z}} p_{hk} z_1^h z_2^k$$

then

$$\begin{aligned} i &:= \min\{h \in \mathbb{Z} \mid \exists k \in \mathbb{Z}, p_{hk} \neq 0\} \\ j &:= \min\{k \in \mathbb{Z} \mid \exists h \in \mathbb{Z}, p_{hk} \neq 0\}. \end{aligned}$$

In case $p = 0$, we define $|p| = 0$. Clearly, for every nonzero Laurent polynomial p , $|p|$ includes a monomial in z_1 and a monomial in z_2 with nonzero coefficients.

The operation just described, of shifting the support of a Laurent polynomial into the positive orthant of $\mathbb{Z} \times \mathbb{Z}$, associates with the ideal $\mathcal{I}_{\pm} := (r_1, r_2, \dots, r_t)_{\pm}$ generated in A_{\pm} by the elements of the matrix R an ideal $\mathcal{I}_+ := (|r_1|, |r_2|, \dots, |r_t|)_+$ generated in A_+ by $|r_1|, |r_2|, \dots, |r_t|$. Some relevant connections between \mathcal{I}_{\pm} and \mathcal{I}_+ are summarized in the following lemma.

LEMMA 3.1. (i) $p \in \mathcal{I}_{\pm}$ if and only if there exists a pair of integers (i, j) such that $z_1^i z_2^j p \in \mathcal{I}_+$.

(ii) The quotient space $A_{\pm}/\mathcal{I}_{\pm}$ is finite-dimensional if and only if the same holds for A_+/\mathcal{I}_+ .

Proof. Statement (i) is obvious. As far as (ii) is concerned, suppose first that A_+/\mathcal{I}_+ is a nonzero finite-dimensional space. This implies that \mathcal{I}_+ , and hence \mathcal{I}_{\pm} , include two nonzero polynomials $f(z_1)$ and $g(z_2)$, with $\deg f > 0$ and $\deg g > 0$. It is easily seen that the cosets

$$[z_1^i z_2^j] := z_1^i z_2^j + \mathcal{I}_{\pm}, \quad 0 \leq i < \deg f, \quad 0 \leq j < \deg g$$

constitute a finite set of generators for the quotient space $A_{\pm}/\mathcal{I}_{\pm}$.

Conversely suppose that $A_{\pm}/\mathcal{I}_{\pm}$ is finite-dimensional and let d be any common factor of $|r_1|, |r_2|, \dots, |r_t|$.

It is clear that $\mathcal{I}_{\pm} \subseteq (d)_{\pm}$, where $(d)_{\pm}$ is the principal ideal of A_{\pm} generated by d . We therefore have $\dim A_{\pm}/\mathcal{I}_{\pm} \geq \dim A_{\pm}/(d)_{\pm}$ and $A_{\pm}/(d)_{\pm}$ is finite-dimensional. This implies that the polynomial sets $\{z_1^i, i \in \mathbb{Z}\}$ and $\{z_2^j, j \in \mathbb{Z}\}$ are linearly dependent modulo $(d)_{\pm}$, and hence $(d)_{\pm}$ includes two nonzero polynomials $f(z_1)$ and $g(z_2)$. Since d must be the constant polynomial, r_1, \dots, r_t are coprime and $A_{\pm}/\mathcal{I}_{\pm}$ is finite-dimensional. \square

We introduce next a special nondegenerate bilinear function

$$\langle \cdot, \cdot \rangle : A_{\pm} \times \mathbb{R}^{\mathbb{Z} \times \mathbb{Z}} \rightarrow \mathbb{R},$$

by assuming

$$\langle p, w \rangle = \sum_{ij} p_{ij} w(i, j)$$

for all polynomials $p = \sum p_{ij} z_1^i z_2^j$ in A_{\pm} and all signals w in $\mathbb{R}^{\mathbb{Z} \times \mathbb{Z}}$.

For instance, if p is the Laurent polynomial $z_1 + z_2^2 - z_1^{-1} z_2 + 3 - z_2^{-3}$ and $w(i, j) = e^{i+j}$, then $\langle p, w \rangle = e^2 + e + 2 - e^{-3}$.

In this way, the “universe” $\mathbb{R}^{\mathbb{Z} \times \mathbb{Z}}$ of all signals with support in $\mathbb{Z} \times \mathbb{Z}$ is isomorphic to the algebraic dual of A_{\pm} , i.e., to the space of the linear functionals on A_{\pm} . Moreover, the

behaviour \mathcal{B} can be identified with the orthogonal complement of \mathcal{I}_\pm with respect to such bilinear function

$$(3.1) \quad \mathcal{B} = \mathcal{I}_\pm^\perp,$$

and, by duality,

$$\mathcal{B}^\perp = \mathcal{I}_\pm^{\perp\perp} = \mathcal{I}_\pm.$$

The proof of (3.1) is an easy consequence of the following identity:

$$p(\sigma_1, \sigma_2, \sigma_1^{-1}, \sigma_2^{-1})w(h, k) = \langle pz_1^h z_2^k, w \rangle.$$

In fact, $w \in \mathcal{B}$ implies $p(\sigma_1, \sigma_2, \sigma_1^{-1}, \sigma_2^{-1})w = 0$ and, therefore, $\langle p, w \rangle = 0, \forall p \in \mathcal{I}_\pm$. Vice versa, given $w \in \mathcal{I}_\pm^\perp$ and $p \in \mathcal{I}_\pm$, we have $\langle pz_1^h z_2^k, w \rangle = 0, \forall h, k \in \mathbb{Z}$, which implies $p(\sigma_1, \sigma_2, \sigma_1^{-1}, \sigma_2^{-1})w = 0$.

We now restrict our attention to the space \mathcal{B} and to the quotient space A_\pm/\mathcal{I}_\pm . Using standard techniques of linear algebra [13], it can be shown that $A_\pm/\mathcal{B}^\perp = A_\pm/\mathcal{I}_\pm$ and \mathcal{B} constitute a dual pair with respect to the bilinear function

$$\langle [p], w \rangle := \langle p, w \rangle.$$

Moreover, the canonical injection

$$i : \mathcal{B} \rightarrow \mathbb{R}^{\mathbb{Z} \times \mathbb{Z}}$$

is dual with respect to the canonical projection π of A_\pm onto A_\pm/\mathcal{I}_\pm

$$\pi : A_\pm/\mathcal{I}_\pm \leftarrow A_\pm.$$

For reasons that will be clear later on, we then wish to exhibit explicitly an isomorphism (for the vector space structure) of \mathcal{B} onto A_\pm/\mathcal{I}_\pm .

PROPOSITION 3.1. *If the matrix R is right factor prime, then \mathcal{B} and A_\pm/\mathcal{I}_\pm are finite-dimensional isomorphic vector spaces.*

Proof. Since R is right factor prime, A_+/\mathcal{I}_+ is finite-dimensional. Therefore, by Lemma 3.1, A_\pm/\mathcal{I}_\pm is finite-dimensional also. Now let $([p_1], [p_2], \dots, [p_n])$ be a basis of A_\pm/\mathcal{I}_\pm and consider the linear map

$$\psi : \mathcal{B} \rightarrow A_\pm/\mathcal{I}_\pm : w \mapsto \sum_{i=1}^n \langle p_i, w \rangle [p_i].$$

If $[\alpha_1 \ \alpha_2 \ \dots \ \alpha_n]^T \in \mathbb{R}^n$ is orthogonal to $[\langle p_1, w \rangle \langle p_2, w \rangle \dots \langle p_n, w \rangle]^T$ for all $w \in \mathcal{B}$, then $\langle \sum \alpha_i p_i, w \rangle = 0$, for all $w \in \mathcal{B}$ and

$$\sum_{i=1}^n \alpha_i p_i \in \mathcal{B}^\perp = \mathcal{I}_\pm.$$

This implies $\alpha_i = 0, i = 1, 2, \dots, n$ and, consequently, as w varies over \mathcal{B} , $[\langle p_1, w \rangle \langle p_2, w \rangle \dots \langle p_n, w \rangle]^T$ span \mathbb{R}^n . Therefore ψ is surjective.

Suppose now that $w \in \mathcal{B}$ satisfies $\psi(w) = 0$ or, equivalently, $\langle p_i, w \rangle = 0, i = 1, 2, \dots, n$. Since every p in A_\pm can be expressed as $p = \sum_{i=1}^n \alpha_i p_i + r, r \in \mathcal{I}_\pm$, for all $p \in A_\pm$ we have $\langle p, w \rangle = \langle r, w \rangle = 0$, which implies $w = 0$. Therefore ψ is injective. \square

From now on we suppose that a basis $([p_1], [p_2], \dots, [p_n])$ has been chosen in $A_{\pm}/\mathcal{I}_{\pm}$, and consider the corresponding dual basis (w_1, w_2, \dots, w_n) in \mathcal{B} .

The relations $\langle [p_i], w_j \rangle = \delta_{ij}$, $i, j = 1, 2, \dots, n$ imply $[p] = \sum_{i=1}^n \langle [p], w_i \rangle [p_i]$, for all $[p] \in A_{\pm}/\mathcal{I}_{\pm}$ and, on the other hand, $w = \sum_{i=1}^n \langle [p_i], w \rangle w_i$, for all $w \in \mathcal{B}$. Introduce the following invertible linear maps:

$$\begin{aligned}\mathcal{Z}_1 : A_{\pm}/\mathcal{I}_{\pm} &\rightarrow A_{\pm}/\mathcal{I}_{\pm} : [p] \mapsto [z_1 p], \\ \mathcal{Z}_2 : A_{\pm}/\mathcal{I}_{\pm} &\rightarrow A_{\pm}/\mathcal{I}_{\pm} : [p] \mapsto [z_2 p].\end{aligned}$$

Clearly, $\mathcal{Z}_1 \mathcal{Z}_2 = \mathcal{Z}_2 \mathcal{Z}_1$ and the adjoint maps of \mathcal{Z}_1 and \mathcal{Z}_2 in \mathcal{B} are σ_1 and σ_2 , respectively.

The matrices $N_l = [n_{hk}^{(l)}]$, $l = 1, 2$, representing the linear transformations \mathcal{Z}_l with respect to the basis $([p_1], [p_2], \dots, [p_n])$ are given by $n_{hk}^{(l)} = \langle [z_l p_k], w_h \rangle$. Hence, the matrices representing σ_1 and σ_2 with respect to the dual basis are N_1^T and N_2^T , respectively. In fact, letting $\sigma_l w_j = \sum_h t_{hj}^{(l)} w_h$, $l = 1, 2$, we have

$$(3.2) \quad \langle [p_k], \sigma_l w_j \rangle = \sum_h t_{hj}^{(l)} \langle [p_k], w_h \rangle = t_{kj}^{(l)}$$

and, using the duality,

$$(3.3) \quad \langle [p_k], \sigma_l w_j \rangle = \langle [z_l p_k], w_j \rangle = \sum_r n_{rk}^{(l)} \langle p_r, w_j \rangle = n_{jk}^{(l)}.$$

Comparing (3.2) and (3.3) gives the result.

We are now in a position to provide a state driving-variable realization of an autonomous finite-dimensional system Σ^a .

For any $w \in \mathcal{B}$, we introduce the following signal:

$$\mathbf{x} : \mathbb{Z} \times \mathbb{Z} \rightarrow \mathbb{R}^n : (h, k) \mapsto \begin{bmatrix} \langle [p_1], \sigma_1^h \sigma_2^k w \rangle \\ \langle [p_2], \sigma_1^h \sigma_2^k w \rangle \\ \vdots \\ \langle [p_n], \sigma_1^h \sigma_2^k w \rangle \end{bmatrix}.$$

The value of \mathbf{x} at (h, k) provides the components of $\sigma_1^h \sigma_2^k w$ with respect to the basis (w_1, w_2, \dots, w_n) . It is clear that, once $\mathbf{x}(0, 0)$ is known, $\mathbf{x}(h, k)$ is easily computed for all $(h, k) \in \mathbb{Z} \times \mathbb{Z}$

$$\mathbf{x}(h, k) = (N_1^T)^h (N_2^T)^k \mathbf{x}(0, 0).$$

Moreover, the value of w at (h, k) can be recovered from $\mathbf{x}(h, k)$ as follows:

$$\begin{aligned}w(h, k) &= (\sigma_1^h \sigma_2^k w)(0, 0) = \langle [1], \sigma_1^h \sigma_2^k w \rangle \\ &= \langle c_1 [p_1] + c_2 [p_2] + \dots + c_n [p_n], \sigma_1^h \sigma_2^k w \rangle = C \mathbf{x}(h, k).\end{aligned}$$

Here $C := [c_1 \ c_2 \ \dots \ c_n]$ denotes the row vector of the components of $[1]$ with respect to the basis $([p_1], [p_2], \dots, [p_n])$ in $A_{\pm}/\mathcal{I}_{\pm}$.

The above results are summarized in the following recursive model:

$$\begin{cases} \sigma_1 \mathbf{x} = N_1^T \mathbf{x} \\ \sigma_2 \mathbf{x} = N_2^T \mathbf{x} \\ w = C \mathbf{x}. \end{cases}$$

Every signal of the autonomous behaviour \mathcal{B} is uniquely determined by the corresponding value of the state \mathbf{x} at any point (h, k) and, conversely, different states at (h, k) induce different

signals in the autonomous system. Finally, letting $\sigma := \sigma_1 \sigma_2^{-1}$, $S(\sigma) := \sigma I - N_1^T (N_2^T)^{-1}$, and $A(\sigma) = N_1^T$, we end up with a state driving-variable realization of \mathcal{B} , as follows:

$$\begin{cases} S(\sigma)w = 0 \\ \sigma_1 \mathbf{x} = A(\sigma)\mathbf{x} \\ w = C\mathbf{x}. \end{cases}$$

When $p_j, j = 1, 2, \dots, n$ are monic monomials, i.e., $p_j = z_1^{\mu_j} z_2^{\nu_j}, j = 1, 2, \dots, n$, the structure of the corresponding dual basis is very appealing. In fact, the element w_j is the unique element of \mathcal{B} taking the values 1 at (μ_j, ν_j) and 0 at $(\mu_i, \nu_i), i = 1, 2, \dots, j-1, j+1, \dots, n$. Moreover, for every $(h, k) \in \mathbb{Z} \times \mathbb{Z}$, the components of the state vector $\mathbf{x}(h, k)$ are the values of w at $\{(\mu_1 + h, \nu_1 + k), (\mu_2 + h, \nu_2 + k), \dots, (\mu_n + h, \nu_n + k)\}$.

A further reason for using a monomial basis in $\mathcal{A}_\pm/\mathcal{I}_\pm$ will be made apparent in the following subsection, where an algorithm for the computation of the matrices N_1^T and N_2^T is outlined. Some concepts on computer algebra, and in particular on Gröbner basis theory, are required; for details see [10].

3.2. Computational methods. Let $\mathcal{G} = \{g_1, g_2, \dots, g_h\}, g_i \in A_+$, be a Gröbner basis of the ideal \mathcal{I}_+ , and denote by $\{q_1 = 1, q_2, \dots, q_m\}$ the set of monic monomials that are not multiple of the leading power products of any of the polynomials in \mathcal{G} . Then

$$(q_1 + \mathcal{I}_+, q_2 + \mathcal{I}_+, \dots, q_m + \mathcal{I}_+)$$

is a basis of A_+/\mathcal{I}_+ and the linear transformations

$$\phi_l : A_+/\mathcal{I}_+ \rightarrow A_+/\mathcal{I}_+ : q + \mathcal{I}_+ \mapsto z_l q + \mathcal{I}_+, \quad l = 1, 2$$

are represented by a pair of commuting matrices M_1 and M_2 .

Our purpose here is to supplement the algorithm discussed in [11] for obtaining M_1 and M_2 , so as to provide a constructive technique for obtaining the invertible matrices N_1 and N_2 introduced in the previous subsection. The procedure we are going to describe will also shed some light on the connections between the ideals \mathcal{I}_\pm and \mathcal{I}_+ .

Let μ be a positive integer with the property that the subspace of A_+/\mathcal{I}_+ spanned by $\{z_1^{\mu+h} z_2^{\mu+k} q_i + \mathcal{I}_+, i = 1, 2, \dots, m\}$ is independent of h and k , for all h and $k \geq 0$. Therefore $\mathcal{L} := \text{span}\{z_1^\mu z_2^\mu q_i + \mathcal{I}_+, i = 1, 2, \dots, m\}$ is a ϕ_1 - ϕ_2 -invariant subspace, satisfying $\phi_1 \mathcal{L} = \phi_2 \mathcal{L} = \mathcal{L}$ and the restrictions of ϕ_1 and ϕ_2 to \mathcal{L} constitute a couple of invertible commutative linear transformations.

Let S be the Boolean matrix that selects a basis of \mathcal{L} out of the ordered array $(z_1^\mu z_2^\mu q_1 + \mathcal{I}_+, z_1^\mu z_2^\mu q_2 + \mathcal{I}_+, \dots, z_1^\mu z_2^\mu q_m + \mathcal{I}_+)$

$$(3.4) \quad \begin{aligned} & (z_1^\mu z_2^\mu q_1 + \mathcal{I}_+, z_1^\mu z_2^\mu q_2 + \mathcal{I}_+, \dots, z_1^\mu z_2^\mu q_m + \mathcal{I}_+) S \\ & = (z_1^\mu z_2^\mu q_{i_1} + \mathcal{I}_+, z_1^\mu z_2^\mu q_{i_2} + \mathcal{I}_+, \dots, z_1^\mu z_2^\mu q_{i_\nu} + \mathcal{I}_+). \end{aligned}$$

So the restriction $\phi_1|_{\mathcal{L}}$ is associated with a $\nu \times \nu$ invertible matrix N_1 , and, recalling that M_1 and M_2 represent the linear transformations ϕ_1 and ϕ_2 with respect to the basis $(q_1 + \mathcal{I}_+, q_2 + \mathcal{I}_+, \dots, q_m + \mathcal{I}_+)$, we have

$$(3.5) \quad \begin{aligned} & (z_1^{\mu+1} z_2^\mu q_{i_1} + \mathcal{I}_+, z_1^{\mu+1} z_2^\mu q_{i_2} + \mathcal{I}_+, \dots, z_1^{\mu+1} z_2^\mu q_{i_\nu} + \mathcal{I}_+) \\ & = (q_1 + \mathcal{I}_+, q_2 + \mathcal{I}_+, \dots, q_m + \mathcal{I}_+) M_1^\mu M_2^\mu S N_1. \end{aligned}$$

On the other hand, the definitions of M_1 , M_2 , and S also imply

$$(3.6) \quad \begin{aligned} & (z_1^{\mu+1} z_2^\mu q_{i_1} + \mathcal{I}_+, z_1^{\mu+1} z_2^\mu q_{i_2} + \mathcal{I}_+, \dots, z_1^{\mu+1} z_2^\mu q_{i_\nu} + \mathcal{I}_+) \\ & = (q_1 + \mathcal{I}_+, q_2 + \mathcal{I}_+, \dots, q_m + \mathcal{I}_+) M_1^{\mu+1} M_2^\mu S. \end{aligned}$$

Comparing (3.5) and (3.6) gives $M_1^{\mu+1}M_2^\mu S = M_1^\mu M_2^\mu S N_1$. Since $M_1^\mu M_2^\mu S$ has full column rank, letting

$$H := (M_1^T)^\mu (M_2^T)^\mu M_1^\mu M_2^\mu,$$

we obtain

$$(3.7) \quad N_1 = (S^T H S)^{-1} (S^T H M_1 S).$$

Similarly,

$$(3.8) \quad N_2 = (S^T H S)^{-1} (S^T H M_2 S).$$

The next proposition shows that the monomials $q_{i_1}, q_{i_2}, \dots, q_{i_\nu}$ resulting from the previous procedure and associated, as shown, to a basis of the subspace $\mathcal{L} \subseteq A_+/\mathcal{I}_+$, also provide the basis of the quotient space A_\pm/\mathcal{I}_\pm we are looking for.

PROPOSITION 3.2. *The monomials $q_{i_1}, q_{i_2}, \dots, q_{i_\nu}$ constitute a basis of A_\pm , modulo \mathcal{I}_\pm .*

Proof. Suppose that $\sum_{h=1}^n \alpha_h q_{i_h}$ is in \mathcal{I}_\pm .

By Lemma 3.1 there exists a positive integer λ such that $\sum_{h=1}^\nu \alpha_h q_{i_h} z_1^\lambda z_2^\lambda$ and, a fortiori, $\sum_{h=1}^\nu \alpha_h q_{i_h} z_1^{\mu+\lambda} z_2^{\mu+\lambda}$ belong to \mathcal{I}_+ .

Since the monomials $q_{i_1} z_1^{\mu+\lambda} z_2^{\mu+\lambda}, q_{i_2} z_1^{\mu+\lambda} z_2^{\mu+\lambda}, \dots, q_{i_\nu} z_1^{\mu+\lambda} z_2^{\mu+\lambda}$ are linearly independent modulo \mathcal{I}_+ , we have $\alpha_h = 0, h = 1, 2, \dots, \nu$, and $q_{i_h}, h = 1, 2, \dots, \nu$ are linearly independent modulo \mathcal{I}_\pm .

It remains to show that they generate A_\pm modulo \mathcal{I}_\pm . To that purpose, consider any polynomial $p \in A_\pm$. Then there exists a positive integer λ such that $z_1^\lambda z_2^\lambda p \in A_+$. Therefore

$$\begin{aligned} (z_1^\lambda z_2^\lambda p) z_1^\mu z_2^\mu &= \sum_{h=1}^\nu \alpha_h q_{i_h} z_1^\mu z_2^\mu = \sum_{h=1}^\nu \beta_h q_{i_h} z_1^{\mu+\lambda} z_2^{\mu+\lambda} \bmod \mathcal{I}_+ \\ &= \sum_{h=1}^\nu \beta_h q_{i_h} z_1^{\mu+\lambda} z_2^{\mu+\lambda} \bmod \mathcal{I}_\pm. \end{aligned}$$

Upon multiplying on both sides by $z_1^{-\mu-\lambda} z_2^{-\mu-\lambda}$, we have $p = \sum_{h=1}^\nu \beta_h q_{i_h} \bmod \mathcal{I}_\pm$, showing that the monomials q_{i_h} generate A_\pm modulo \mathcal{I}_\pm . \square

As a consequence of Proposition 3.2, the matrices N_1 and N_2 associated with the restrictions to \mathcal{L} of ϕ_1 and ϕ_2 , with respect to the basis (3.4), represent \mathcal{Z}_1 and \mathcal{Z}_2 with respect to the basis

$$(3.9) \quad ([q_{i_1}], [q_{i_2}], \dots, [q_{i_\nu}])$$

in A_\pm/\mathcal{I}_\pm . This result is almost obvious. Upon introducing the following isomorphism $\psi : \mathcal{L} \rightarrow A_\pm/\mathcal{I}_\pm : \sum_{h=1}^\nu \alpha_h (z_1^\mu z_2^\mu q_{i_h}) + \mathcal{I}_+ \mapsto \sum_{h=1}^\nu \alpha_h [q_{i_h}]$, we check that the following diagram

$$\begin{array}{ccc} \mathcal{L} & \xrightarrow{\psi} & A_\pm/\mathcal{I}_\pm \\ \downarrow \phi_1 & & \downarrow \mathcal{Z}_1 \\ \mathcal{L} & \xrightarrow{\psi} & A_\pm/\mathcal{I}_\pm \end{array}$$

commutes. With respect to the bases (3.4) and (3.9), ψ is represented by the identity matrix and therefore the same matrix N_1 represents both ϕ_1 and \mathcal{Z}_1 . Similarly ϕ_2 and \mathcal{Z}_2 are both represented by N_2 .

Remark. In [11] it has been shown that the annihilating polynomials of M_1 and M_2 are exactly the polynomials of the ideal \mathcal{I}_+ , i.e.,

$$p(M_1, M_2) = 0 \Leftrightarrow p \in \mathcal{I}_+.$$

It is quite natural to ask whether the Laurent polynomials in \mathcal{I}_\pm do exhibit the characteristic property of annihilating the commutative invertible matrices N_1 and N_2 . Actually this is true and we have

$$(3.10) \quad p(N_1, N_2) = 0 \Leftrightarrow p \in \mathcal{I}_\pm.$$

To prove (3.10), we note first that, by Lemma 3.1, $p \in \mathcal{I}_\pm$ if and only if there exists a pair of nonnegative integers i and j , such that $q(z_1, z_2) := z_1^i z_2^j p(z_1, z_2) \in \mathcal{I}_+$. This in turn is equivalent to assuming that $0 = q(M_1, M_2) = q(\phi_1, \phi_2)$ and therefore (3.10) can be restated as follows:

$$(3.11) \quad p(N_1, N_2) = 0 \Leftrightarrow q(M_1, M_2) = 0$$

for some $q = z_1^i z_2^j p \in A_\pm$. To prove (3.11), assume first $q(M_1, M_2) = 0$. Then $q(\phi_1, \phi_2) = 0$ implies $q(\phi_1|_{\mathcal{L}}, \phi_2|_{\mathcal{L}}) = 0$ and, consequently, $0 = q(N_1, N_2) = N_1^i N_2^j p(N_1, N_2) = p(N_1, N_2)$, because of the invertibility of N_1 and N_2 .

Vice versa, consider any polynomial $p \in A_\pm$ that annihilates the commutative pair N_1, N_2 , i.e.,

$$(3.12) \quad p(N_1, N_2) = 0.$$

Select a pair of nonnegative integers h, k such that $p' = z_1^h z_2^k p$ is a polynomial in A_+ . Rewrite p' as follows:

$$p' = \sum_{j=1}^m \beta_j q_j + r, \quad r \in \mathcal{I}_+$$

and let

$$q := z_1^\mu z_2^\mu p' = \sum_{j=1}^m \beta_j z_1^\mu z_2^\mu q_j + z_1^\mu z_2^\mu r.$$

Note that (3.12) implies $p'(N_1, N_2) = q(N_1, N_2) = 0$ and $r \in \mathcal{I}_+$ implies $r(M_1, M_2) = 0$. Restricting ϕ_1 and ϕ_2 to \mathcal{L} gives $r(N_1, N_2) = 0$ and hence $\sum_{j=1}^m \beta_j q_j(N_1, N_2) = 0$. To prove that $q(M_1, M_2)$ is the zero matrix, we will show that $q(\phi_1, \phi_2)$ annihilates $q_i + \mathcal{I}_\pm$, $i = 1, 2, \dots, m$. Actually we have

$$\begin{aligned} q(\phi_1, \phi_2)(q_i + \mathcal{I}_+) &= \sum_{j=1}^m \beta_j \phi_1^\mu \phi_2^\mu q_j(\phi_1, \phi_2)(q_i + \mathcal{I}_+) + \phi_1^\mu \phi_2^\mu r(\phi_1, \phi_2)(q_i + \mathcal{I}_+) \\ &= \sum_{j=1}^m \beta_j q_j(\phi_1, \phi_2)(z_1^\mu z_2^\mu q_i + \mathcal{I}_+). \end{aligned}$$

Since $z_1^\mu z_2^\mu q_i + \mathcal{I}_+$, $i = 1, 2, \dots, m$ belong to \mathcal{L} and $\sum_j \beta_j q_j(\phi_1, \phi_2)$ acts on \mathcal{L} as the zero transformation, we are done.

Remark. An alternative way for computing the matrices N_1 and N_2 can be derived from the scheme presented in [3]. Actually, when \mathcal{B} is finite-dimensional that scheme gives a finite set of initial conditions that can be viewed as the state vector of a state space realization. The updating matrices in that case are obtained from the canonical computational form proposed there.

3.3. Extension to the vector case. Suppose now that R is a $t \times q$ full column rank right prime matrix, describing a q variables behaviour \mathcal{B} . All concepts previously introduced for the scalar case have an immediate extension to the vector case. Let

$$A_+^q := \mathbb{R}^{1 \times q}[z_1, z_2]$$

$$A_\pm^q := \mathbb{R}^{1 \times q}[z_1, z_2, z_1^{-1}, z_2^{-1}]$$

and define the map

$$|\cdot| : A_\pm^q \rightarrow A_+^q : r \mapsto |r| := z_1^i z_2^j r,$$

where i and j are the minimum degrees of r with respect to the indeterminates z_1 and z_2 . In case $p = 0$, we define $|p| = 0$.

Let $\mathcal{M}_\pm := (r_1, \dots, r_t)_\pm$ be the submodule in A_\pm^q generated by the rows of R and $\mathcal{M}_+ := (|r_1|, \dots, |r_t|)_+$ the submodule in A_+^q generated by the rows of the matrix

$$\overline{R} := \begin{bmatrix} |r_1| \\ \vdots \\ |r_t| \end{bmatrix} = \Lambda R$$

where $\Lambda := \text{diag} \{z_1^{\nu_1} z_2^{\mu_1}, \dots, z_1^{\nu_t} z_2^{\mu_t}\}$ and ν_i and μ_i satisfy $z_1^{\nu_i} z_2^{\mu_i} r_i = |r_i|$, $i = 1, \dots, t$.

LEMMA 3.2. (i) A row r belongs to \mathcal{M}_\pm if and only if there exists a pair of integers (i, j) such that $z_1^i z_2^j r$ is in \mathcal{M}_+ .

(ii) $A_\pm^q / \mathcal{M}_\pm$ is finite-dimensional if and only if A_+^q / \mathcal{M}_+ is finite-dimensional.

Proof. (i) The proof is obvious.

(ii) Suppose that A_+^q / \mathcal{M}_+ is finite-dimensional. This implies that there exist polynomials $f_i(z_1)$ and $g_i(z_2)$, $i = 1, \dots, q$, such that

$$f_i(z_1)e_i^T \in \mathcal{M}_+$$

$$g_i(z_2)e_i^T \in \mathcal{M}_+$$

where e_i is the element of the canonical basis of \mathbb{R}^q with one in position i . It is easily seen that

$$\bigcup_{i=1}^q \{z_1^h z_2^k e_i^T + \mathcal{M}_+, 0 \leq h < \deg f_i, 0 \leq k < \deg g_i\}$$

constitutes a set of generators for $A_\pm^q / \mathcal{M}_\pm$.

Conversely, suppose that $A_\pm^q / \mathcal{M}_\pm$ is finite dimensional and let D be any right factor of \overline{R} ,

$$\overline{R} = \hat{R}D.$$

It follows that $R = \Lambda^{-1} \overline{R} = \Lambda^{-1} \hat{R}D$, where Λ^{-1} is still a polynomial matrix with elements in A_\pm . Since the submodule $\mathcal{M}_\pm(D)$ generated by the rows of D , satisfies $\mathcal{M}_\pm \subseteq \mathcal{M}_\pm(D)$, we have $\dim A_\pm^q / \mathcal{M}_\pm \geq \dim A_\pm^q / \mathcal{M}_\pm(D)$ and $A_\pm^q / \mathcal{M}_\pm(D)$ is finite-dimensional. Therefore there exist polynomials $f_i(z_1)$ and $g_i(z_2)$, $i = 1, \dots, q$, such that

$$f_i(z_1)e_i^T \in \mathcal{M}_\pm(D)$$

$$g_i(z_2)e_i^T \in \mathcal{M}_\pm(D)$$

and, consequently, there exist polynomial matrices H and K such that

$$(3.13) \quad HD = \text{diag}\{f_1(z_1), \dots, f_q(z_1)\}$$

$$(3.14) \quad KD = \text{diag}\{g_1(z_2), \dots, g_q(z_2)\}.$$

Equation (3.13) implies that $\det D$ is a polynomial in z_1 and (3.14) implies that $\det D$ is a polynomial in z_2 . Therefore D is unimodular, \bar{R} is right factor prime and A_+^q/\mathcal{M}_+ is finite dimensional. \square

Introduce a nondegenerate bilinear function

$$\langle \cdot, \cdot \rangle : A_{\pm}^q \times (\mathbb{R}^q)^{\mathbb{Z} \times \mathbb{Z}} \rightarrow \mathbb{R},$$

such that $\langle r, w \rangle = \sum r_{ij}w(i, j)$, where $r = \sum r_{ij}z_1^i z_2^j$ is a polynomial row in A_{\pm}^q and $w \in (\mathbb{R}^q)^{\mathbb{Z} \times \mathbb{Z}}$.

Then $(\mathbb{R}^q)^{\mathbb{Z} \times \mathbb{Z}}$ is isomorphic to the algebraic dual of A_{\pm}^q and we still have $\mathcal{B} = \mathcal{M}_{\pm}^{\perp}$ and $\mathcal{B}^{\perp} = \mathcal{M}_{\pm}^{\perp\perp} = \mathcal{M}_{\pm}$. Moreover \mathcal{B} and $A_{\pm}^q/\mathcal{M}_{\pm}$ are finite-dimensional isomorphic vector spaces.

As in the scalar case, let N_1 and N_2 be the matrices of the linear transformations

$$\begin{aligned} \mathcal{Z}_1 : A_{\pm}^q/\mathcal{M}_{\pm} &\rightarrow A_{\pm}^q/\mathcal{M}_{\pm} : [r] \mapsto [z_1 r] \\ \mathcal{Z}_2 : A_{\pm}^q/\mathcal{M}_{\pm} &\rightarrow A_{\pm}^q/\mathcal{M}_{\pm} : [r] \mapsto [z_2 r] \end{aligned}$$

with respect to the basis $([r_1], \dots, [r_n])$ of $A_{\pm}^q/\mathcal{M}_{\pm}$. If the state vector relative to a signal $w \in \mathcal{B}$ is defined as

$$\mathbf{x}(h, k) := \begin{bmatrix} \langle \mathcal{Z}_1^h \mathcal{Z}_2^k [r_1], w \rangle \\ \vdots \\ \langle \mathcal{Z}_1^h \mathcal{Z}_2^k [r_n], w \rangle \end{bmatrix},$$

and C is a $q \times n$ constant matrix such that

$$\begin{bmatrix} [e_1^T] \\ \vdots \\ [e_q^T] \end{bmatrix} = C \begin{bmatrix} [r_1] \\ \vdots \\ [r_n] \end{bmatrix},$$

then we have

$$\mathbf{x}(h, k) := (N_1^T)^h (N_2^T)^k \mathbf{x}(0, 0)$$

and

$$w(h, k) = C\mathbf{x}(h, k).$$

By applying the theory of Gröbner basis over the polynomial modules [12], a basis in A_+^q/\mathcal{M}_+ with elements of the type $z_1^h z_2^k e_i^T + \mathcal{M}_+$ is easily obtained. After computing the matrices M_1 and M_2 that represent the transformations

$$\phi_l : A_+^q/\mathcal{M}_+ \rightarrow A_+^q/\mathcal{M}_+ : r + \mathcal{M}_+ \mapsto z_l r + \mathcal{M}_+, \quad l = 1, 2$$

with respect to that basis, the procedure for extracting N_1 and N_2 from M_1 and M_2 is the same introduced in the scalar case.

ROBUST STABILITY OF FEEDBACK SYSTEMS: A GEOMETRIC APPROACH USING THE GAP METRIC*

CIPRIAN FOIAS[†], TRYPHON T. GEORGIU[‡], AND MALCOLM C. SMITH[§]

Abstract. A geometric framework for robust stabilization of infinite-dimensional time-varying linear systems is presented. The uncertainty of a system is described by perturbations of its graph and is measured in the gap metric. Necessary and sufficient conditions for robust stability are generalized from the time-invariant case. An example is given to highlight an important difference between the obstructions, which limit the size of a stabilizable gap ball, in the time-varying and time-invariant cases. Several results on the gap metric and the gap topology are established that are central in a geometric treatment of the robust stabilizability problem in the gap. In particular, the concept of a “graphable” subspace is introduced in the paper. Subspaces that fail to be graphable are characterized by an index condition on a certain semi-Fredholm operator.

Key words. Robust stabilization, gap metric, graph topology, graphability, stabilizability

1. Introduction. In this paper we develop a geometric framework for robust stabilization of feedback systems using operator-theoretic methods. The theory is based on a description of the uncertainty of a system as a perturbation of its graph and is measured by the gap metric.

The gap metric has its origin in functional analysis [20], [13], where it was used in perturbation theory of linear operators. It was introduced into control theory in [25], [1] as being appropriate for the study of uncertainty in feedback systems. For shift-invariant systems it was shown in [5] that the gap metric was computable exactly in terms of two standard “2-block” H_∞ optimization problems. Building on this result and the work of [23], [24], [26], and [7], it was shown in [6] that robust stabilization in the gap metric is equivalent to robust stabilization for perturbations of the normalized coprime factors of the transfer function.

The simplicity of the robustness bounds obtained in [6] for the time-invariant case, which were expressed solely in terms of the plant and controller system operators, strongly suggests potential generalization. However, the techniques used in [6] are mostly function theoretic, relying on a specific representation for the graph of a time-invariant dynamical system as a shift-invariant subspace of $L_2[0, \infty]$, and do not admit immediate generalization to the shift-varying case. This motivated the search for a different approach, which does not rely on representations for the subspaces involved, and which elucidates the apparent geometric structure underlying the robust stabilization problem. It became apparent that substantially new techniques were needed, beyond those developed in [6], to meet this objective. The present paper is a continuation of work begun in [3], [4]. We note that some independent work on a geometric approach to robust stability in the gap metric has been presented in [15], [16], [19]. A generalization of the results of [5] has been presented in [2].

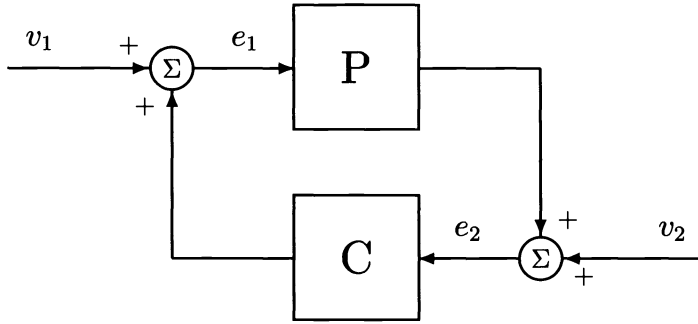

This paper is organized as follows. In §2 we present some basic material on

FIG. 1. *Standard feedback configuration*

graphs and stabilizability for linear systems. In §3 we establish several results on the gap metric that are used in the later development. Section 4 introduces the concept of graphability and proves a necessary and sufficient condition for a subspace to be graphable. Section 5 presents and proves the main robustness theorem for plant uncertainty in the gap metric. In §6 an example is presented to clarify the need for the uniform boundedness condition in the main robustness theorem. Section 7 uses the machinery of the previous sections to generalize an elegant result of Qiu and Davison [16] on combined plant-controller uncertainty to the time-varying case.

2. Graphs and stabilizability of linear systems. We consider a linear system to be a (possibly unbounded) linear operator $\mathbf{P} : \mathcal{D}_{\mathbf{P}} \subset \mathcal{U} \rightarrow \mathcal{Y}$, where \mathcal{U}, \mathcal{Y} are Hilbert spaces and $\mathcal{D}_{\mathbf{P}}$ is the *domain* of \mathbf{P} . We denote by $\mathcal{P}_{\mathcal{U}, \mathcal{Y}}$ the class of all linear systems from \mathcal{U} to \mathcal{Y} . A typical choice for the input and output spaces is $\mathcal{U} = \ell_2^m[0, \infty)$ and $\mathcal{Y} = \ell_2^p[0, \infty)$, or the corresponding continuous-time Lebesgue spaces. (Note: This paper does not impose the constraints of causality or time-invariance on the systems considered.)

Consider the feedback configuration of Fig. 1, where the *plant* $\mathbf{P} \in \mathcal{P}_{\mathcal{U}, \mathcal{Y}}$ and the *controller* $\mathbf{C} \in \mathcal{P}_{\mathcal{Y}, \mathcal{U}}$. This configuration, denoted by $[\mathbf{P}, \mathbf{C}]$, provides a pictorial representation of the following set of equations:

$$\begin{aligned} e_1 &= v_1 + Ce_2, \\ e_2 &= Pe_1 + v_2. \end{aligned}$$

Define the *graph* of a system $\mathbf{P} \in \mathcal{P}_{\mathcal{U}, \mathcal{Y}}$ as the linear manifold of bounded input-output pairs of \mathbf{P}

$$\mathcal{G}_{\mathbf{P}} := \begin{pmatrix} \mathbf{I}_{\mathcal{U}} \\ \mathbf{P} \end{pmatrix} \mathcal{D}_{\mathbf{P}} \subset \mathcal{L} := \mathcal{U} \oplus \mathcal{Y},$$

where $\mathbf{I}_{\mathcal{U}}$ denotes the identity operator on \mathcal{U} . Similarly, define the *inverse graph* of the controller \mathbf{C} by

$$\mathcal{G}'_{\mathbf{C}} := \begin{pmatrix} \mathbf{C} \\ \mathbf{I}_{\mathcal{Y}} \end{pmatrix} \mathcal{D}_{\mathbf{C}} \subset \mathcal{L}.$$

The feedback configuration $[\mathbf{P}, \mathbf{C}]$ is said to be *stable* if the operators mapping $v_i \rightarrow e_j$ for $i, j = 1, 2$ are bounded. This is equivalent to the operator

$$\mathbf{F}_{\mathbf{P}, \mathbf{C}} := \begin{pmatrix} \mathbf{I}_{\mathcal{U}} & \mathbf{C} \\ \mathbf{P} & \mathbf{I}_{\mathcal{Y}} \end{pmatrix} : \mathcal{D}_{\mathbf{P}} \times \mathcal{D}_{\mathbf{C}} \rightarrow \mathcal{G}_{\mathbf{P}} + \mathcal{G}'_{\mathbf{C}} : \begin{pmatrix} e_1 \\ -e_2 \end{pmatrix} \rightarrow \begin{pmatrix} v_1 \\ -v_2 \end{pmatrix}$$

having a bounded inverse defined on \mathcal{L} . In case an inverse exists it is denoted by $\mathbf{H}_{\mathbf{P}, \mathbf{C}} := \mathbf{F}_{\mathbf{P}, \mathbf{C}}^{-1}$.

A system \mathbf{P} is said to be *stabilizable* if and only if there exists a controller \mathbf{C} such that $[\mathbf{P}, \mathbf{C}]$ is stable.

PROPOSITION 1. *If $\mathbf{P} \in \mathcal{P}_{\mathcal{U}, \mathcal{Y}}$ is stabilizable then the graph of \mathbf{P} is closed.*

Proof. Let $\begin{pmatrix} u_i \\ y_i \end{pmatrix} \in \mathcal{G}_{\mathbf{P}}$ for $i = 1, 2, \dots$ be a Cauchy sequence with limit point $\begin{pmatrix} u \\ y \end{pmatrix}$, and let \mathbf{C} be such that $[\mathbf{P}, \mathbf{C}]$ is stable. Since

$$\begin{pmatrix} u_i \\ 0 \end{pmatrix} := \mathbf{H}_{\mathbf{P}, \mathbf{C}} \begin{pmatrix} u_i \\ y_i \end{pmatrix},$$

then

$$\begin{pmatrix} u \\ 0 \end{pmatrix} := \lim_{i \rightarrow \infty} \mathbf{H}_{\mathbf{P}, \mathbf{C}} \begin{pmatrix} u_i \\ y_i \end{pmatrix} = \mathbf{H}_{\mathbf{P}, \mathbf{C}} \begin{pmatrix} u \\ y \end{pmatrix},$$

which means that $u \in \mathcal{D}_{\mathbf{P}}$ and $\begin{pmatrix} u \\ y \end{pmatrix} = (\mathbf{I}_{\mathbf{P}})u \in \mathcal{G}_{\mathbf{P}}$. \square

Thus, a necessary condition for $[\mathbf{P}, \mathbf{C}]$ to be stable is that both \mathbf{P} and \mathbf{C} have closed graphs. A similar statement has been made in [27] for quotients of bounded operators. The idea in [27] gives Proposition 1 in the following way: Closed-loop stability ensures that $\mathbf{P}(\mathbf{I} + \mathbf{C}\mathbf{P})^{-1}$ is bounded and that $(\mathbf{I} + \mathbf{C}\mathbf{P})$ has closed graph and domain equal to $\mathcal{D}_{\mathbf{P}}$. This gives that $\mathbf{P} = \mathbf{P}(\mathbf{I} + \mathbf{C}\mathbf{P})^{-1}(\mathbf{I} + \mathbf{C}\mathbf{P})$ has closed graph.

The following proposition presents a geometric characterization of stability of $[\mathbf{P}, \mathbf{C}]$.

PROPOSITION 2. *Let $\mathbf{P} \in \mathcal{P}_{\mathcal{U}, \mathcal{Y}}$ and $\mathbf{C} \in \mathcal{P}_{\mathcal{Y}, \mathcal{U}}$. Then the following are equivalent:*

- (a) $[\mathbf{P}, \mathbf{C}]$ is stable,
- (b) $\mathcal{G}_{\mathbf{P}}, \mathcal{G}'_{\mathbf{C}}$ are closed,

$$(1) \quad \mathcal{G}_{\mathbf{P}} \cap \mathcal{G}'_{\mathbf{C}} = \{0\}$$

and

$$(2) \quad \mathcal{G}_{\mathbf{P}} + \mathcal{G}'_{\mathbf{C}} = \mathcal{L}.$$

Proof. (a) \Rightarrow (b). If $[\mathbf{P}, \mathbf{C}]$ is stable then, by Proposition 1, $\mathcal{G}_{\mathbf{P}}, \mathcal{G}'_{\mathbf{C}}$ are closed. Moreover, both (1) and (2) are necessary for $\mathbf{F}_{\mathbf{P}, \mathbf{C}}$ to be a one-to-one mapping onto \mathcal{L} .

(b) \Rightarrow (a). First note that (1) and (2) are sufficient to guarantee the existence of a set-theoretic inverse for $\mathbf{F}_{\mathbf{P}, \mathbf{C}}$ defined on \mathcal{L} . We need to show that the inverse is also bounded. We first observe that the graph of $\mathbf{F}_{\mathbf{P}, \mathbf{C}}$ is closed. To see this note that

$$\begin{aligned} \mathcal{G}_{\mathbf{F}} &= \left\{ \begin{pmatrix} e_1 \\ -e_2 \\ e_1 - \mathbf{C}e_2 \\ \mathbf{P}e_1 - e_2 \end{pmatrix} : \begin{pmatrix} e_1 \\ e_2 \end{pmatrix} \in \mathcal{D}_{\mathbf{P}} \times \mathcal{D}_{\mathbf{C}} \right\} \\ &= \left\{ \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 \\ 1 & 0 & -1 & 0 \\ 0 & 1 & 0 & -1 \end{pmatrix} \begin{pmatrix} e_1 \\ \mathbf{P}e_1 \\ \mathbf{C}e_2 \\ e_2 \end{pmatrix} : \begin{pmatrix} e_1 \\ e_2 \end{pmatrix} \in \mathcal{D}_{\mathbf{P}} \times \mathcal{D}_{\mathbf{C}} \right\} \\ &\cong \left\{ \begin{pmatrix} e_1 \\ \mathbf{P}e_1 \\ \mathbf{C}e_2 \\ e_2 \end{pmatrix} : \begin{pmatrix} e_1 \\ e_2 \end{pmatrix} \in \mathcal{D}_{\mathbf{P}} \times \mathcal{D}_{\mathbf{C}} \right\} = \begin{pmatrix} \mathcal{G}_{\mathbf{P}} \\ \mathcal{G}'_{\mathbf{C}} \end{pmatrix}, \end{aligned}$$

where \cong denotes a Hilbert space isomorphism. Consequently, the graph of $\mathbf{H}_{\mathbf{P},\mathbf{C}}$ ($= \mathbf{F}_{\mathbf{P},\mathbf{C}}^{-1}$) is also closed. The result now follows from the closed graph theorem. \square

Similar geometric concepts for expressing stability have been employed in earlier studies, notably in the context of nonlinear control systems [18], [22], and in the recent works [3], [14], [16], [19].

3. Preliminaries on the gap metric. In light of Proposition 2 we will restrict our attention in the rest of the paper to linear systems that have closed graphs. We will identify \mathbf{P} (through its graph) and \mathbf{C} (through its inverse graph) with elements of

$$S_{\mathcal{L}} := \{\mathcal{K} : \mathcal{K} \text{ is a closed subspace of } \mathcal{L}\}.$$

For $\mathcal{K} \in S_{\mathcal{L}}$ denote by $\Pi_{\mathcal{K}}$ the orthogonal projection with range \mathcal{K} . The *gap* between $\mathcal{K}_1, \mathcal{K}_2 \in S_{\mathcal{L}}$ is the metric defined as

$$\delta(\mathcal{K}_1, \mathcal{K}_2) := \|\Pi_{\mathcal{K}_1} - \Pi_{\mathcal{K}_2}\|$$

(see [11] and [12]), and $S_{\mathcal{L}}$ is equipped with the natural topology induced by the gap metric. Thus the *gap* between two systems \mathbf{P}_i , $i = 1, 2$, is defined to be the gap between their respective graphs $\mathcal{G}_{\mathbf{P}_i}$, $i = 1, 2$ ([25]).

Let $\mathcal{B}(\mathcal{K}_1, \mathcal{K}_2)$ denote the space of bounded operators between two Hilbert spaces \mathcal{K}_1 and \mathcal{K}_2 . For $\mathbf{X} \in \mathcal{B}(\mathcal{K}_1, \mathcal{K}_2)$ define $\tau(\mathbf{X}) := \inf_{x \in \mathcal{K}_1, \|x\|=1} \|\mathbf{X}x\|$.

PROPOSITION 3. *Let $\mathcal{K}_0 \in S_{\mathcal{L}}$. The following are equivalent:*

- (a) $\mathcal{K} \in S_{\mathcal{L}}$ and $\delta(\mathcal{K}_0, \mathcal{K}) < 1$;
- (b) $\Pi_{\mathcal{K}_0}|_{\mathcal{K}}$ is invertible;
- (c) There exists an $\mathbf{X} \in \mathcal{B}(\mathcal{K}_0, \mathcal{K}_0^\perp)$ such that $\mathcal{K} = (\mathbf{I}_{\mathcal{K}_0} + \mathbf{X})\mathcal{K}_0$.

Furthermore, if $\mathcal{K} \in S_{\mathcal{L}}$ and $\delta(\mathcal{K}_0, \mathcal{K}) < 1$, then

$$\begin{aligned} (3) \quad \delta(\mathcal{K}_0, \mathcal{K}) &= \sqrt{1 - \tau^2(\Pi_{\mathcal{K}_0}|_{\mathcal{K}})} = \sqrt{1 - \tau^2(\Pi_{\mathcal{K}}|_{\mathcal{K}_0})} \\ (4) \quad &= \|\mathbf{X}(\mathbf{I} + \mathbf{X}^*\mathbf{X})^{-1/2}\| = \frac{\|\mathbf{X}\|}{\sqrt{1 + \|\mathbf{X}\|^2}}. \end{aligned}$$

Proof. The equivalence (a) \Leftrightarrow (b), as well as a proof of (3), can be found in [12, Lemma 15.1].

(b) \Rightarrow (c). Since $\delta(\mathcal{K}_0, \mathcal{K}) = \delta(\mathcal{K}, \mathcal{K}_0)$ both $\Pi_{\mathcal{K}_0}|_{\mathcal{K}}$ and $\Pi_{\mathcal{K}}|_{\mathcal{K}_0}$ are invertible. Hence

$$\begin{aligned} \mathcal{K} &= \Pi_{\mathcal{K}}|_{\mathcal{K}_0}\mathcal{K}_0 = \left(\Pi_{\mathcal{K}_0}\Pi_{\mathcal{K}} + \Pi_{\mathcal{K}_0^\perp}\Pi_{\mathcal{K}}\right)\mathcal{K}_0 \\ &= \left(\mathbf{I}_{\mathcal{K}_0} + \Pi_{\mathcal{K}_0^\perp}\Pi_{\mathcal{K}}(\Pi_{\mathcal{K}_0}|_{\mathcal{K}})^{-1}\right)\mathcal{K}_0. \end{aligned}$$

Thus, (c) holds for $\mathbf{X} = \Pi_{\mathcal{K}_0^\perp}(\Pi_{\mathcal{K}_0}|_{\mathcal{K}})^{-1}$.

(c) \Rightarrow (b). From the equality $k_0 = \Pi_{\mathcal{K}_0}|_{\mathcal{K}}(\mathbf{I} + \mathbf{X})k_0$, for $k_0 \in \mathcal{K}_0$, we see that $\Pi_{\mathcal{K}_0}|_{\mathcal{K}}$ is onto and from $\mathcal{K} = (\mathbf{I}_{\mathcal{K}_0} + \mathbf{X})\mathcal{K}_0$ that it is one-to-one.

We defer the derivation of (4) to Proposition 4 below, where we prove a slightly more general statement. \square

From the definition of the gap metric it follows that

$$\begin{aligned} \delta(\mathcal{K}_1, \mathcal{K}_2) &= \left\| \begin{pmatrix} \Pi_{\mathcal{K}_1} \\ \Pi_{\mathcal{K}_1^\perp} \end{pmatrix} (\Pi_{\mathcal{K}_1} - \Pi_{\mathcal{K}_2}) (\Pi_{\mathcal{K}_2^\perp}, \Pi_{\mathcal{K}_2}) \right\| \\ &= \left\| \begin{pmatrix} \Pi_{\mathcal{K}_1}\Pi_{\mathcal{K}_2^\perp} & \mathbf{0} \\ \mathbf{0} & -\Pi_{\mathcal{K}_1^\perp}\Pi_{\mathcal{K}_2} \end{pmatrix} \right\| \\ &= \max\{\|\Pi_{\mathcal{K}_1^\perp}\Pi_{\mathcal{K}_2}\|, \|\Pi_{\mathcal{K}_2^\perp}\Pi_{\mathcal{K}_1}\|\} \end{aligned}$$

(see [12]). Note that

$$\|\Pi_{\mathcal{K}_1^\perp} \Pi_{\mathcal{K}_2}\| = \sup_{x \in \mathcal{K}_2, \|x\|=1} \text{dist}(x, \mathcal{K}_1),$$

where $\text{dist}(x, \mathcal{K}_1) := \inf_{y \in \mathcal{K}_1} \|x - y\|$.

PROPOSITION 4. Let $\mathbf{X}_i \in \mathcal{B}(\mathcal{K}_0, \mathcal{K}_0^\perp)$, for $i = 1, 2$, and $\mathcal{K}_i = (\mathbf{I}_{\mathcal{K}_0} + \mathbf{X}_i)\mathcal{K}_0$. Then

$$\delta(\mathcal{K}_1, \mathcal{K}_2) = \max \left\{ \left\| (\mathbf{I} + \mathbf{X}_1 \mathbf{X}_1^*)^{-1/2} (\mathbf{X}_2 - \mathbf{X}_1) (\mathbf{I} + \mathbf{X}_2^* \mathbf{X}_2)^{-1/2} \right\|, \right. \\ \left. \left\| (\mathbf{I} + \mathbf{X}_2 \mathbf{X}_2^*)^{-1/2} (\mathbf{X}_2 - \mathbf{X}_1) (\mathbf{I} + \mathbf{X}_1^* \mathbf{X}_1)^{-1/2} \right\| \right\} \quad (5)$$

$$= \sqrt{1 - \rho^2}, \quad (6)$$

where

$$\rho = \min \left\{ \tau \left((\mathbf{I} + \mathbf{X}_1^* \mathbf{X}_1)^{-1/2} (\mathbf{I} + \mathbf{X}_1^* \mathbf{X}_2) (\mathbf{I} + \mathbf{X}_2^* \mathbf{X}_2)^{-1/2} \right), \right. \\ \left. \tau \left((\mathbf{I} + \mathbf{X}_1 \mathbf{X}_1^*)^{-1/2} (\mathbf{I} + \mathbf{X}_1 \mathbf{X}_2^*) (\mathbf{I} + \mathbf{X}_2 \mathbf{X}_2^*)^{-1/2} \right) \right\}.$$

Proof. We compute

$$\|\Pi_{\mathcal{K}_1^\perp} \Pi_{\mathcal{K}_2}\| = \left\| \begin{pmatrix} -\mathbf{X}_1^* \\ \mathbf{I} \end{pmatrix} (\mathbf{I} + \mathbf{X}_1 \mathbf{X}_1^*)^{-1} (-\mathbf{X}_1, \mathbf{I}) \begin{pmatrix} \mathbf{I} \\ \mathbf{X}_2 \end{pmatrix} (\mathbf{I} + \mathbf{X}_2^* \mathbf{X}_2)^{-1} (\mathbf{I}, \mathbf{X}_2^*) \right\| \\ = \|(\mathbf{I} + \mathbf{X}_1 \mathbf{X}_1^*)^{-1/2} (\mathbf{X}_2 - \mathbf{X}_1) (\mathbf{I} + \mathbf{X}_2^* \mathbf{X}_2)^{-1/2}\| \quad (7)$$

since

$$\begin{pmatrix} -\mathbf{X}_1^* \\ \mathbf{I} \end{pmatrix} (\mathbf{I} + \mathbf{X}_1 \mathbf{X}_1^*)^{-1/2}$$

is an isometry and $(\mathbf{I} + \mathbf{X}_2^* \mathbf{X}_2)^{-1/2} (\mathbf{I}, \mathbf{X}_2^*)$ is a co-isometry. By symmetry $\|\Pi_{\mathcal{K}_2^\perp} \Pi_{\mathcal{K}_1}\|$ is given by the dual expression. This completes the proof of (5).

To prove (6) consider the unitary operators

$$\mathbf{Y}_i := \begin{pmatrix} (\mathbf{I} + \mathbf{X}_i^* \mathbf{X}_i)^{-1/2} & -\mathbf{X}_i^* (\mathbf{I} + \mathbf{X}_i \mathbf{X}_i^*)^{-1/2} \\ \mathbf{X}_i (\mathbf{I} + \mathbf{X}_i^* \mathbf{X}_i)^{-1/2} & (\mathbf{I} + \mathbf{X}_i \mathbf{X}_i^*)^{-1/2} \end{pmatrix},$$

for $i = 1, 2$, and define

$$\mathbf{Y} := \mathbf{Y}_1^* \mathbf{Y}_2 = \begin{pmatrix} (\mathbf{Y})_{1,1} & (\mathbf{Y})_{1,2} \\ (\mathbf{Y})_{2,1} & (\mathbf{Y})_{2,2} \end{pmatrix}, \quad (8)$$

where $(\mathbf{Y})_{i,j}$ denotes the (i, j) -block entry of \mathbf{Y} . Since

$$\begin{pmatrix} (\mathbf{Y})_{1,1} \\ (\mathbf{Y})_{2,1} \end{pmatrix}$$

is an isometry, it follows that $\|(\mathbf{Y})_{2,1}\|^2 + \tau^2((\mathbf{Y})_{1,1}) = 1$. Using (7) it follows that

$$\|\Pi_{\mathcal{K}_1^\perp} \Pi_{\mathcal{K}_2}\| = \|(\mathbf{Y})_{2,1}\| \\ = \sqrt{1 - \tau^2((\mathbf{Y})_{1,1})},$$

where $(\mathbf{Y})_{1,1} = (\mathbf{I} + \mathbf{X}_1^* \mathbf{X}_1)^{-1/2} (\mathbf{I} + \mathbf{X}_1^* \mathbf{X}_2) (\mathbf{I} + \mathbf{X}_2^* \mathbf{X}_2)^{-1/2}$. Similarly, $\|\Pi_{\mathcal{K}_1^\perp} \Pi_{\mathcal{K}_2}\| = \sqrt{1 - \tau^2((\mathbf{Y})_{2,2})}$, where $(\mathbf{Y})_{2,2} = (\mathbf{I} + \mathbf{X}_1 \mathbf{X}_1^*)^{-1/2} (\mathbf{I} + \mathbf{X}_1 \mathbf{X}_2^*) (\mathbf{I} + \mathbf{X}_2 \mathbf{X}_2^*)^{-1/2}$. This completes the proof. \square

Consider two subspaces \mathcal{K}_0 and \mathcal{K}_1 at a distance $\delta(\mathcal{K}_0, \mathcal{K}_1) < 1$, where $\mathcal{K}_1 = (\mathbf{I} + \mathbf{X})\mathcal{K}$ and $\mathbf{X} \in \mathcal{B}(\mathcal{K}_0, \mathcal{K}_0^\perp)$. Define

$$(9) \quad \mathcal{K}_\lambda = (\mathbf{I} + \lambda \mathbf{X})\mathcal{K}_0$$

for $\lambda \in \mathbb{R}$.

COROLLARY 1. *The family \mathcal{K}_λ , $\lambda \in [0, 1]$, defines a path, continuous in the gap metric, between \mathcal{K}_0 and \mathcal{K}_1 . Moreover, for $\lambda \in \mathbb{R}$,*

$$(10) \quad \delta(\mathcal{K}_0, \mathcal{K}_\lambda) = |\lambda| \|\mathbf{X}\| (1 + \lambda^2 \|\mathbf{X}\|^2)^{-1/2},$$

$$(11) \quad \delta(\mathcal{K}_1, \mathcal{K}_\lambda) = \|1 - \lambda\| \|\mathbf{X}^* \mathbf{X} (1 + \mathbf{X}^* \mathbf{X})^{-1} (1 + \lambda^2 \mathbf{X}^* \mathbf{X})^{-1}\|^{1/2}$$

$$(12) \quad \leq \frac{|1 - \lambda|}{|1 + \lambda|}.$$

Proof. To establish that the family \mathcal{K}_λ , $\lambda \in [0, 1]$, defines a path it suffices to prove (10)–(12). Equation (10) follows from Proposition 4 by identifying $\mathcal{K}_0, \mathcal{K}_1, \mathcal{K}_2$ with $\mathcal{K}_0, \mathcal{K}_0, \mathcal{K}_\lambda$, respectively, and $\mathbf{X}_1, \mathbf{X}_2$ with $\mathbf{0}, \lambda \mathbf{X}$. If, in Proposition 4, we identify $\mathcal{K}_0, \mathcal{K}_1, \mathcal{K}_2$ with $\mathcal{K}_0, \mathcal{K}_1, \mathcal{K}_\lambda$ and $\mathbf{X}_1, \mathbf{X}_2$ with $\mathbf{X}, \lambda \mathbf{X}$, then we obtain

$$(13) \quad \delta(\mathcal{K}_1, \mathcal{K}_\lambda) = \max \left\{ \|1 - \lambda\| \|(1 + \mathbf{X} \mathbf{X}^*)^{-1/2} \mathbf{X} (1 + \lambda^2 \mathbf{X}^* \mathbf{X})^{-1/2}\|, \right. \\ \left. \|1 - \lambda\| \|(1 + \mathbf{X} \mathbf{X}^*)^{-1/2} \mathbf{X} (1 + \lambda^2 \mathbf{X}^* \mathbf{X})^{-1/2}\| \right\}.$$

Both expressions are equal and can be seen to equal the right-hand side of (11). Since $\mathbf{X}^* \mathbf{X}$ is a positive, bounded, selfadjoint operator, by invoking the spectral mapping theorem, it follows that

$$\delta(\mathcal{K}_1, \mathcal{K}_\lambda) = \sup \left\{ \frac{|1 - \lambda| \sqrt{x}}{\sqrt{(1 + x)(1 + \lambda^2 x)}} : x \in \text{Spectrum}(\mathbf{X}^* \mathbf{X}) \right\}.$$

The supremum of the function in the interval $[0, \infty)$ occurs at $x = 1/\lambda$ and equals $|1 - \lambda|/|1 + \lambda|$. (Note that $\text{Spectrum}(\mathbf{X}^* \mathbf{X}) \subset [0, \infty)$.) \square

COROLLARY 2. *Let $\mathcal{K}_0, \mathcal{K}_1, \mathcal{K}_2 \in \mathcal{S}_{\mathcal{L}}$ be such that $\delta^2(\mathcal{K}_0, \mathcal{K}_1) + \delta^2(\mathcal{K}_0, \mathcal{K}_2) < 1$. Then*

$$(14) \quad \delta(\mathcal{K}_1, \mathcal{K}_2) \leq \delta(\mathcal{K}_0, \mathcal{K}_1) \sqrt{1 - \delta^2(\mathcal{K}_0, \mathcal{K}_2)} + \delta(\mathcal{K}_0, \mathcal{K}_2) \sqrt{1 - \delta^2(\mathcal{K}_0, \mathcal{K}_1)}.$$

Proof. Since $\delta(\mathcal{K}_0, \mathcal{K}_1) < 1$ and $\delta(\mathcal{K}_0, \mathcal{K}_2) < 1$, by Proposition 3 there exist bounded operators $\mathbf{X}_i : \mathcal{K}_0 \rightarrow \mathcal{K}_0^\perp$ such that $\mathcal{K}_i = (\mathbf{I}_{\mathcal{K}_0} + \mathbf{X}_i)\mathcal{K}_0$, for $i = 1, 2$. We observe that

$$\delta^2(\mathcal{K}_0, \mathcal{K}_1) + \delta^2(\mathcal{K}_0, \mathcal{K}_2) < 1 \Rightarrow \frac{\|\mathbf{X}_1\|^2}{1 + \|\mathbf{X}_1\|^2} + \frac{\|\mathbf{X}_2\|^2}{1 + \|\mathbf{X}_2\|^2} < 1 \\ \Rightarrow \|\mathbf{X}_1\| \|\mathbf{X}_2\| < 1.$$

Since $\|\mathbf{X}_1^*\mathbf{X}_2\| \leq \|\mathbf{X}_1\|\|\mathbf{X}_2\| < 1$, it follows that $\tau(\mathbf{I} + \mathbf{X}_1^*\mathbf{X}_2) = \tau(\mathbf{I} + \mathbf{X}_2^*\mathbf{X}_1) > 0$. Consequently $\delta(\mathcal{K}_1, \mathcal{K}_2) = \sqrt{1 - \rho^2} < 1$, where

$$\begin{aligned} \rho &= \tau \left((\mathbf{I} + \mathbf{X}_1^*\mathbf{X}_1)^{-1/2} (\mathbf{I} + \mathbf{X}_1^*\mathbf{X}_2) (\mathbf{I} + \mathbf{X}_2^*\mathbf{X}_2)^{-1/2} \right) \\ &\geq \tau \left((\mathbf{I} + \mathbf{X}_1^*\mathbf{X}_1)^{-1/2} \right) \tau(\mathbf{I} + \mathbf{X}_1^*\mathbf{X}_2) \tau \left((\mathbf{I} + \mathbf{X}_2^*\mathbf{X}_2)^{-1/2} \right) \\ &\geq \frac{1 - \|\mathbf{X}_1\|\|\mathbf{X}_2\|}{\sqrt{1 + \|\mathbf{X}_1\|^2} \sqrt{1 + \|\mathbf{X}_2\|^2}}. \end{aligned}$$

Thus,

$$\begin{aligned} \delta(\mathcal{K}_1, \mathcal{K}_2) &\leq \sqrt{1 - \frac{(1 - \|\mathbf{X}_1\|\|\mathbf{X}_2\|)^2}{(1 + \|\mathbf{X}_1\|^2)(1 + \|\mathbf{X}_2\|^2)}} \\ &= \frac{\|\mathbf{X}_1\|}{\sqrt{1 + \|\mathbf{X}_1\|^2}} \frac{1}{\sqrt{1 + \|\mathbf{X}_2\|^2}} + \frac{\|\mathbf{X}_2\|}{\sqrt{1 + \|\mathbf{X}_2\|^2}} \frac{1}{\sqrt{1 + \|\mathbf{X}_1\|^2}}. \end{aligned}$$

This completes the proof. \square

The arcsine of the gap metric can be thought of as the *maximal angle* between two subspaces, denoted by $\theta_{\max}(\mathcal{K}_1, \mathcal{K}_2) := \arcsin \delta(\mathcal{K}_1, \mathcal{K}_2)$. Corollary 2 is given in [16]. It was also observed in [16] that (14) can be rewritten in the form

$$(15) \quad \theta_{\max}(\mathcal{K}_1, \mathcal{K}_2) \leq \theta_{\max}(\mathcal{K}_1, \mathcal{K}) + \theta_{\max}(\mathcal{K}, \mathcal{K}_2)$$

so that θ_{\max} defines a metric in $S_{\mathcal{L}}$.

Given any subspace $\mathcal{K}_0 \in S_{\mathcal{L}}$ and a positive number b let

$$\text{Ball}(\mathcal{K}_0, b) := \{\mathcal{K} : \delta(\mathcal{K}_0, \mathcal{K}) < b\}$$

denote the gap-ball about \mathcal{K}_0 of radius b , and let $\overline{\text{Ball}}(\mathcal{K}_0, b)$ denote the closure of $\text{Ball}(\mathcal{K}_0, b)$.

PROPOSITION 5. *If $b < 1$, then $\overline{\text{Ball}}(\mathcal{K}_0, b) = \{\mathcal{K} : \delta(\mathcal{K}_0, \mathcal{K}) \leq b\}$.*

Proof. Let \mathcal{K}_1 be such that $\delta(\mathcal{K}_0, \mathcal{K}_1) = b$ and consider \mathcal{K}_λ , $\lambda \in \mathbb{R}$, constructed as in Corollary 1. It follows that

$$\{\mathcal{K}_\lambda : \lambda \in [0, 1)\} \subset \text{Ball}(\mathcal{K}_0, b).$$

Thus, any neighbourhood of \mathcal{K}_1 contains a subspace \mathcal{K}_λ for some $\lambda \in [0, 1)$. Hence, $\mathcal{K}_1 \in \overline{\text{Ball}}(\mathcal{K}_0, b)$. Conversely, take \mathcal{K}_1 such that for all $\epsilon > 0$, $\text{Ball}(\mathcal{K}_0, b) \cap \text{Ball}(\mathcal{K}_1, \epsilon) \neq \emptyset$. Then take $\mathcal{K} \in \text{Ball}(\mathcal{K}_0, b) \cap \text{Ball}(\mathcal{K}_1, \epsilon)$. Using the triangular inequality it follows that $\delta(\mathcal{K}_0, \mathcal{K}_1) \leq \delta(\mathcal{K}_0, \mathcal{K}) + \delta(\mathcal{K}, \mathcal{K}_1) < b + \epsilon$. Since this is valid for any $\epsilon > 0$, $\delta(\mathcal{K}_0, \mathcal{K}_1) \leq b$. \square

It should be noted that when $b = 1$, then $\overline{\text{Ball}}(\mathcal{K}_0, b) \neq \{\mathcal{K} : \delta(\mathcal{K}_0, \mathcal{K}) \leq b\}$.

THEOREM 1. *Let $b, \zeta \in \mathbb{R}$, with $0 < b < 1$ and $0 < \zeta < 1$. There exists $\epsilon > 0$ such that*

$$(16) \quad \text{Ball}(\mathcal{K}_0, b + \epsilon) \subseteq \bigcup_{\mathcal{K} \in \overline{\text{Ball}}(\mathcal{K}_0, b)} \text{Ball}(\mathcal{K}, \zeta).$$

Proof. Consider any \mathcal{K}_a such that $1 > \delta(\mathcal{K}_0, \mathcal{K}_a) = a > b$. We will construct a \mathcal{K}_b with $\delta(\mathcal{K}_0, \mathcal{K}_b) = b$ and $\delta(\mathcal{K}_b, \mathcal{K}_a) = a\sqrt{1 - b^2} - b\sqrt{1 - a^2}$. This establishes (16) for any ϵ such that $(b + \epsilon)\sqrt{1 - b^2} - b\sqrt{1 - (b + \epsilon)^2} < \zeta$.

Write $\mathcal{K}_a = (\mathbf{I} + \mathbf{X})\mathcal{K}_0$ with $\mathbf{X} \in \mathcal{B}(\mathcal{K}_0, \mathcal{K}_0^\perp)$. Let $\mathbf{X} = \mathbf{U}\mathbf{R}$ be a polar decomposition for \mathbf{X} (i.e., with $\mathbf{R} = (\mathbf{X}^*\mathbf{X})^{1/2}$ a positive selfadjoint operator and $\mathbf{U} : \text{range}\mathbf{R} \rightarrow \text{range}\mathbf{X}$ a partial isometry), denote by \mathbf{E}_λ the spectral family of projections corresponding to \mathbf{R} , define

$$\mathbf{\Lambda} := \int_{0-}^{\infty} g(\lambda) d\mathbf{E}_\lambda,$$

where

$$g(\lambda) = \begin{cases} 1 & \text{if } 0 \leq \lambda < \frac{b}{\sqrt{1-b^2}} \\ \frac{1}{\lambda} \frac{b}{\sqrt{1-b^2}} & \text{if } \frac{b}{\sqrt{1-b^2}} \leq \lambda \end{cases},$$

and define

$$(17) \quad \mathcal{K}_b := (\mathbf{I} + \mathbf{X}\mathbf{\Lambda})\mathcal{K}_0.$$

In the rest of the proof we verify that $\delta(\mathcal{K}_0, \mathcal{K}_b) = b$ and $\delta(\mathcal{K}_b, \mathcal{K}_a) = a\sqrt{1-b^2} - b\sqrt{1-a^2}$.

From Proposition 3, $\|\mathbf{X}\| = a/\sqrt{1-a^2}$. Also,

$$\begin{aligned} \|\mathbf{X}\mathbf{\Lambda}\| &= \|\mathbf{R}\mathbf{\Lambda}\| \\ &= \left\| \int_{0-}^{\infty} \lambda g(\lambda) d\mathbf{E}_\lambda \right\| \\ &= \sup\{\lambda g(\lambda) : \lambda \in \text{Spectrum}(\mathbf{R})\} \\ &= \lambda g(\lambda) \Big|_{\frac{a}{\sqrt{1-a^2}}} \\ &= \frac{b}{\sqrt{1-b^2}} \end{aligned}$$

since $\lambda g(\lambda)$ is nondecreasing on $[0, \infty)$, $\text{Spectrum}(\mathbf{R}) \subseteq [0, \|\mathbf{R}\|]$, and $(b/\sqrt{1-b^2}) < (a/\sqrt{1-a^2}) = \|\mathbf{R}\|$. From Proposition 3, we conclude that

$$\delta(\mathcal{K}_0, \mathcal{K}_b) = \frac{\|\mathbf{X}\mathbf{\Lambda}\|}{\sqrt{1 + \|\mathbf{X}\mathbf{\Lambda}\|^2}} = b.$$

From Proposition 4, we have that

$$\delta(\mathcal{K}_a, \mathcal{K}_b) = \max\{\delta_1, \delta_2\},$$

where the two expressions δ_1, δ_2 are computed below. First,

$$\begin{aligned} \delta_1 &:= \|(\mathbf{I} + \mathbf{X}\mathbf{X}^*)^{-1/2}(\mathbf{X}\mathbf{\Lambda} - \mathbf{X})(\mathbf{I} + \mathbf{\Lambda}\mathbf{X}^*\mathbf{X}\mathbf{\Lambda})^{-1/2}\| \\ &= \|\mathbf{U}\mathbf{R}(\mathbf{I} + \mathbf{R}^2)^{-1/2}(\mathbf{\Lambda} - \mathbf{I})(\mathbf{I} + \mathbf{\Lambda}\mathbf{R}^2\mathbf{\Lambda})^{-1/2}\| \\ &= \|\mathbf{R}(\mathbf{I} + \mathbf{R}^2)^{-1/2}(\mathbf{\Lambda} - \mathbf{I})(\mathbf{I} + \mathbf{\Lambda}\mathbf{R}^2\mathbf{\Lambda})^{-1/2}\| \\ (18) \quad &= \sup\left\{ \frac{\lambda|g(\lambda) - 1|}{\sqrt{1 + \lambda^2}\sqrt{1 + \lambda^2g(\lambda)^2}} : \lambda \in \text{Spectrum}(\mathbf{R}) \right\} \end{aligned}$$

$$\begin{aligned} (19) \quad &= \frac{\lambda|g(\lambda) - 1|}{\sqrt{1 + \lambda^2}\sqrt{1 + \lambda^2g(\lambda)^2}} \text{ evaluated at } \lambda = \frac{a}{\sqrt{1-a^2}} \\ &= a\sqrt{1-b^2} - b\sqrt{1-a^2}. \end{aligned}$$

The step (18) \Rightarrow (19) follows because $\lambda|g(\lambda) - 1|/\sqrt{1+\lambda^2}\sqrt{1+\lambda^2g(\lambda)^2}$ is monotonically nondecreasing in $\text{Spectrum}(\mathbf{R}) \subseteq [0, a/\sqrt{1-a^2}]$, while $\|\mathbf{R}\| = a/\sqrt{1-a^2}$. Next,

$$\begin{aligned} \delta_2 &:= \|(\mathbf{I} + \mathbf{X}\mathbf{\Lambda}^2\mathbf{X}^*)^{-1/2}(\mathbf{X}\mathbf{\Lambda} - \mathbf{X})(\mathbf{I} + \mathbf{X}^*\mathbf{X})^{-1/2}\| \\ (20) \quad &= \|(\mathbf{I} + \mathbf{U}\mathbf{R}\mathbf{\Lambda}^2\mathbf{R}\mathbf{U}^*)^{-1/2}\mathbf{U}\mathbf{R}(\mathbf{\Lambda} - \mathbf{I})(\mathbf{I} + \mathbf{R}^2)^{-1/2}\| \\ (21) \quad &= \|\mathbf{U}(\mathbf{I} + \mathbf{R}\mathbf{\Lambda}^2\mathbf{R})^{-1/2}\mathbf{R}(\mathbf{\Lambda} - \mathbf{I})(\mathbf{I} + \mathbf{R}^2)^{-1/2}\| \\ &= \delta_1 \end{aligned}$$

since \mathbf{R} and $\mathbf{\Lambda}$ commute. The step (20) \Rightarrow (21) is based on the fact that $\mathbf{R}\mathbf{U}^*\mathbf{U} = \mathbf{R}$ and $\mathbf{U}^*\mathbf{U}\mathbf{R} = \mathbf{R}$. \square

It is interesting to note that for arbitrary $\mathcal{K}_0, \mathcal{K}_a \in S_{\mathcal{L}}$ with $0 < b < a = \delta(\mathcal{K}_0, \mathcal{K}_a) < 1$ and \mathcal{K}_b as in (17), we have $\delta(\mathcal{K}_0, \mathcal{K}_b) = b$ and $\theta_{\max}(\mathcal{K}_0, \mathcal{K}_b) + \theta_{\max}(\mathcal{K}_b, \mathcal{K}_a) = \theta_{\max}(\mathcal{K}_0, \mathcal{K}_a)$.

4. Graphability. Let $\mathcal{K}, \mathcal{W} \in S_{\mathcal{L}}$. We say that \mathcal{K} is a *graph with respect to* \mathcal{W} if $\mathcal{K} \cap \mathcal{W}^\perp = \{0\}$. For any such \mathcal{K} we can define a linear operator \mathbf{K} by the relation $\mathbf{K}(\Pi_{\mathcal{W}}k) = \Pi_{\mathcal{W}^\perp}k$ for all $k \in \mathcal{K}$. For convenience we will identify each $u \in \mathcal{U}$ with $\begin{pmatrix} u \\ 0 \end{pmatrix} \in \mathcal{L}$ and, similarly, every $y \in \mathcal{Y}$ with $\begin{pmatrix} 0 \\ y \end{pmatrix} \in \mathcal{L}$, i.e., \mathcal{U} is identified with the subspace $\mathcal{U} \oplus \{0\}$ of \mathcal{L} and \mathcal{Y} with $\{0\} \oplus \mathcal{Y}$. We say \mathcal{K} is a *graph* if \mathcal{K} is a graph with respect to \mathcal{U} . Similarly, we say \mathcal{K} is an *inverse graph* if \mathcal{K} is a graph with respect to \mathcal{Y} . Denote

$$\text{Graph}_{\mathcal{W}} := \{\mathcal{K} \in S_{\mathcal{L}} : \mathcal{K} \cap \mathcal{W}^\perp = \{0\}\}.$$

For $\mathcal{K}, \mathcal{W} \in S_{\mathcal{L}}$ let $\mathbf{X}_{\mathcal{K}} := \Pi_{\mathcal{W}}|_{\mathcal{K}}$ and define S_{npi} to be the *complement* in $S_{\mathcal{L}}$ of the set

$$S_{\text{pi}} := \{\mathcal{K} \in S_{\mathcal{L}} : \mathbf{X}_{\mathcal{K}} \text{ is semi-Fredholm and } \text{ind } \mathbf{X}_{\mathcal{K}} > 0\}.$$

An operator \mathbf{X} is said to be *semi-Fredholm* if its range is closed and if at least one of $\dim \ker \mathbf{X}$, $\dim \ker \mathbf{X}^*$ is finite. In this case the *Fredholm index* is defined as $\text{ind } \mathbf{X} := \dim \ker \mathbf{X} - \dim \ker \mathbf{X}^*$.

LEMMA 1. S_{npi} is closed in $S_{\mathcal{L}}$.

Proof. Let $\mathcal{K} \in S_{\text{pi}}$ and let $\mathcal{K}_i \in S_{\mathcal{L}}$ satisfy $\delta(\mathcal{K}, \mathcal{K}_i) \rightarrow 0$ for $i = 1, 2, \dots$. We have

$$\begin{aligned} \|\mathbf{X}_{\mathcal{K}}^* - \Pi_{\mathcal{K}}\mathbf{X}_{\mathcal{K}_i}^*\| &= \|(\Pi_{\mathcal{K}} - \Pi_{\mathcal{K}}\Pi_{\mathcal{K}_i})|_{\mathcal{W}}\| \\ &\leq \|\Pi_{\mathcal{K}} - \Pi_{\mathcal{K}_i}\| = \delta(\mathcal{K}, \mathcal{K}_i) \rightarrow 0. \end{aligned}$$

Since the set of semi-Fredholm operators from \mathcal{W} to \mathcal{K} with a given index is open in the space of all bounded operators from \mathcal{W} to \mathcal{K} (see [11, Thm. 5.17]), it follows that there exists an N such that for $i \geq N$, $\Pi_{\mathcal{K}}\mathbf{X}_{\mathcal{K}_i}^*$ is semi-Fredholm and

$$\text{ind } \Pi_{\mathcal{K}}\mathbf{X}_{\mathcal{K}_i}^* = \text{ind } \mathbf{X}_{\mathcal{K}}^* = -\text{ind } \mathbf{X}_{\mathcal{K}}.$$

On the other hand, if $\delta(\mathcal{K}, \mathcal{K}_i) < 1$ then $\mathbf{Y} := \Pi_{\mathcal{K}}|_{\mathcal{K}_i}$ is an invertible operator from \mathcal{K}_i to \mathcal{K} and therefore $\mathbf{X}_{\mathcal{K}_i}^* = \mathbf{Y}^{-1}\Pi_{\mathcal{K}}\mathbf{X}_{\mathcal{K}_i}^*$ is semi-Fredholm and $\text{ind } \mathbf{X}_{\mathcal{K}_i}^* = \text{ind } \Pi_{\mathcal{K}}\mathbf{X}_{\mathcal{K}_i}^*$ for $i \geq N$. It follows that for i large enough $\mathbf{X}_{\mathcal{K}_i}^*$ is also semi-Fredholm and

$$\text{ind } \mathbf{X}_{\mathcal{K}_i} = -\text{ind } \mathbf{X}_{\mathcal{K}_i}^* = \text{ind } \mathbf{X}_{\mathcal{K}} > 0.$$

Thus S_{pi} is open and hence S_{npi} is closed in $S_{\mathcal{L}}$. \square

The following result characterizes the closure of $\text{Graph}_{\mathcal{W}}$ in $S_{\mathcal{L}}$. Any $\mathcal{K} \in \overline{\text{Graph}_{\mathcal{W}}}$ is said to be *graphable* with respect to \mathcal{W} .

THEOREM 2. $\overline{\text{Graph}}_{\mathcal{W}} = S_{\text{npi}}$.

Before we proceed with the proof of the theorem we provide a characterization of S_{npi} . By \mathbf{E}_λ (respectively, $\mathbf{E}_{*,\lambda}$), $\lambda \in \mathbb{R}$, we denote the spectral family associated with $\mathbf{X}_K^* \mathbf{X}_K$ (respectively, $\mathbf{X}_K \mathbf{X}_K^*$). Then

$$\mathbf{X}_K^* \mathbf{X}_K = \int_{0-}^{\infty} \lambda d\mathbf{E}_\lambda, \text{ and } \mathbf{X}_K \mathbf{X}_K^* = \int_{0-}^{\infty} \lambda d\mathbf{E}_{*,\lambda}$$

and the projections are chosen (strongly) continuous from the right (see [17]).

LEMMA 2. $S_{\text{npi}} = \{K : \dim \mathbf{E}_\lambda K \leq \dim \mathbf{E}_{*,\lambda} \mathcal{W}, \text{ for all } \lambda > 0 \text{ and } \lambda \text{ small enough}\}$.

Proof. (Inclusion \supset). It is a standard fact that $\mathbf{E}_0 K = \ker \mathbf{X}_K$, $\mathbf{E}_{*,0} \mathcal{W} = \ker \mathbf{X}_K^*$. If $K \in S_{\text{pi}}$ then we must have $\dim \mathbf{E}_0 K > \dim \mathbf{E}_{*,0} \mathcal{W}$. Since \mathbf{X}_K is semi-Fredholm then $\dim \mathbf{E}_\lambda K \rightarrow \dim \mathbf{E}_0 K$ and $\dim \mathbf{E}_{*,\lambda} \mathcal{W} \rightarrow \dim \mathbf{E}_{*,0} \mathcal{W}$ as $\lambda \rightarrow 0$. Hence, $\dim \mathbf{E}_\lambda K > \dim \mathbf{E}_{*,\lambda} \mathcal{W}$ for sufficiently small $\lambda > 0$.

(Inclusion \subset). Assume $K \in S_{\text{npi}}$ and that there exists a sequence $\lambda_i > 0$, $i = 1, 2, \dots$, $\lambda_i \rightarrow 0$, for which $\dim \mathbf{E}_{\lambda_i} K > \dim \mathbf{E}_{*,\lambda_i} \mathcal{W}$. Since $\dim \mathbf{E}_\lambda K$, $\dim \mathbf{E}_{*,\lambda} \mathcal{W}$ are nondecreasing in λ , $\dim \mathbf{E}_{*,\lambda_i} \mathcal{W}$ must be constant and finite—say equal to d —for i large enough. Thus 0 is isolated in the spectrum of $\mathbf{X}_K \mathbf{X}_K^*$ and $\dim \ker \mathbf{X}_K^* = \dim \ker \mathbf{X}_K \mathbf{X}_K^* = d$. It follows that \mathbf{X}_K is semi-Fredholm and that for λ_i small enough $\text{ind } \mathbf{X}_K = \dim \ker \mathbf{X}_K - \dim \ker \mathbf{X}_K^* = \dim \mathbf{E}_{\lambda_i} K - d > 0$. Thus $K \in S_{\text{pi}}$, which is a contradiction. \square

Proof of Theorem 2. We first show that $\overline{\text{Graph}}_{\mathcal{W}} \subseteq S_{\text{npi}}$. Let $K \notin S_{\text{npi}}$. Then

$$\begin{aligned} \text{ind } \mathbf{X}_K > 0 &\Rightarrow \dim \ker \mathbf{X}_K > 0 \\ &\Rightarrow K \cap \mathcal{W}^\perp \neq \{0\} \\ &\Rightarrow K \notin \text{Graph}_{\mathcal{W}}. \end{aligned}$$

Thus $\text{Graph}_{\mathcal{W}} \subseteq S_{\text{npi}}$ and, since S_{npi} is closed in $S_{\mathcal{L}}$ in the topology induced by the gap metric by Lemma 1, this implies that $K \notin \overline{\text{Graph}}_{\mathcal{W}}$ and completes the proof of the first part.

We now show that $\overline{\text{Graph}}_{\mathcal{W}} \supseteq S_{\text{npi}}$. Let $K \in S_{\text{npi}}$. For $\epsilon > 0$ small enough $\dim \mathbf{E}_\epsilon K \leq \dim \mathbf{E}_{*,\epsilon} \mathcal{W}$ and therefore there exists an isometry $\mathbf{V}_\epsilon : \mathbf{E}_\epsilon K \rightarrow \mathbf{E}_{*,\epsilon} \mathcal{W}$. Set $\mathcal{H}_\epsilon := \mathbf{E}_\epsilon K$, $\mathcal{K}_\epsilon := (K \ominus \mathcal{H}_\epsilon) + (\mathbf{I} + \sqrt{2\epsilon} \mathbf{V}_\epsilon) \mathcal{H}_\epsilon$ and note that

$$\begin{aligned} \delta(K, \mathcal{K}_\epsilon) &= \delta \left((K \ominus \mathcal{H}_\epsilon) \oplus \mathcal{H}_\epsilon, (K \ominus \mathcal{H}_\epsilon) + (\mathbf{I} + \sqrt{2\epsilon} \mathbf{V}_\epsilon) \mathcal{H}_\epsilon \right) \\ &= \delta \left(\mathcal{H}_\epsilon, (\mathbf{I} + \sqrt{2\epsilon} \Pi_{(K \ominus \mathcal{H}_\epsilon)^\perp} \mathbf{V}_\epsilon) \mathcal{H}_\epsilon \right). \end{aligned}$$

Therefore, $\lim_{\epsilon \rightarrow 0} \delta(K, \mathcal{K}_\epsilon) = 0$ by Proposition 3. We will now show that $\mathcal{K}_\epsilon \in \text{Graph}_{\mathcal{W}}$. Let $y \in \mathcal{K}_\epsilon \cap \mathcal{W}^\perp$. Then $y = k + h + \sqrt{2\epsilon} \mathbf{V}_\epsilon h$ with $k \in K \ominus \mathcal{H}_\epsilon$, $h \in \mathcal{H}_\epsilon$. It follows that

$$\begin{aligned} 0 &= \Pi_{\mathcal{W}} y = \Pi_{\mathcal{W}} k + \Pi_{\mathcal{W}} h + \sqrt{2\epsilon} \mathbf{V}_\epsilon h \\ &= \mathbf{X}_K k + \mathbf{X}_K h + \sqrt{2\epsilon} \mathbf{V}_\epsilon h, \end{aligned}$$

and thus

$$-\mathbf{X}_K^* \mathbf{X}_K k = \mathbf{X}_K^* \mathbf{X}_K h + \sqrt{2\epsilon} \mathbf{X}_K^* \mathbf{V}_\epsilon h.$$

Since $\mathbf{E}_\epsilon \mathbf{X}_K^* \mathbf{X}_K = \mathbf{X}_K^* \mathbf{X}_K \mathbf{E}_\epsilon$, $\mathbf{E}_\epsilon \mathbf{X}_K^* = \mathbf{X}_K^* \mathbf{E}_{*,\epsilon}$ and $\mathbf{E}_{*,\epsilon} \mathbf{V}_\epsilon = \mathbf{V}_\epsilon$, we see that

$$0 = -\mathbf{E}_\epsilon \mathbf{X}_K^* \mathbf{X}_K k$$

$$\begin{aligned}
&= \mathbf{E}_\epsilon(\mathbf{X}_\mathcal{K}^* \mathbf{X}_\mathcal{K} h + \sqrt{2\epsilon} \mathbf{X}_\mathcal{K}^* \mathbf{V}_\epsilon h) \\
&= \mathbf{X}_\mathcal{K}^* \mathbf{X}_\mathcal{K} h + \sqrt{2\epsilon} \mathbf{X}_\mathcal{K}^* \mathbf{V}_\epsilon h \\
&= -\mathbf{X}_\mathcal{K}^* \mathbf{X}_\mathcal{K} k.
\end{aligned}$$

Since $\|\mathbf{X}_\mathcal{K}^* \mathbf{X}_\mathcal{K} k\| \geq \epsilon \|k\|$, it follows that $k = 0$. Thus $y = h + \sqrt{2\epsilon} \mathbf{V}_\epsilon h$ and therefore

$$2\epsilon \|h\|^2 = \|\sqrt{2\epsilon} \mathbf{V}_\epsilon h\|^2 = \|\mathbf{X}_\mathcal{K} h\|^2 \leq \epsilon \|h\|^2$$

because $h \in \mathcal{H}_\epsilon$. This implies that $h = 0$, that is $y = 0$. \square

Remark. It is easy to see that the complement of $\overline{\text{Graph}}_\mathcal{W}$ can be characterized in the following way: $\mathcal{K} \notin \overline{\text{Graph}}_\mathcal{W} \Leftrightarrow$ there exists $\epsilon > 0$ such that $\mathcal{K}' \cap \mathcal{W}^\perp \neq \{0\}$ for all $\mathcal{K}' \in \text{Ball}(\mathcal{K}, \epsilon)$. From Theorem 2 the complement of $\overline{\text{Graph}}_\mathcal{W}$ is the set S_{pi} . A geometric characterization of S_{pi} is as follows:

$$\text{S}_{\text{pi}} = \{\mathcal{K} \in \mathcal{S}_\mathcal{L} : \mathcal{K} + \mathcal{W}^\perp \text{ is closed, } \dim(\mathcal{K} \cap \mathcal{W}^\perp) > \dim(\mathcal{L} \ominus (\mathcal{K} + \mathcal{W}^\perp))\}.$$

To see the equality, note that $\mathcal{K} + \mathcal{W}^\perp = \Pi_\mathcal{W} \mathcal{K} + \mathcal{W}^\perp$. Hence $\mathcal{K} + \mathcal{W}^\perp$ is closed $\Leftrightarrow \Pi_\mathcal{W} \mathcal{K}$ is closed. Also $\ker(\Pi_\mathcal{W}|_\mathcal{K}) = \mathcal{K} \cap \mathcal{W}^\perp$ and $\ker(\Pi_\mathcal{K}|_\mathcal{W}) = \mathcal{W} \cap \mathcal{K}^\perp = \mathcal{L} \ominus (\mathcal{K} + \mathcal{W}^\perp)$.

5. Robust stabilization. Consider the feedback interconnection $[\mathbf{P}, \mathbf{C}]$ and let $\mathcal{M} = \mathcal{G}_\mathbf{P}$, $\mathcal{N} = \mathcal{G}'_\mathbf{C} \in \mathcal{S}_\mathcal{L}$. Define $\mathbf{A}_{\mathcal{M}, \mathcal{N}} := \Pi_{\mathcal{N}^\perp}|_\mathcal{M}$. The following is a standard result in operator theory.

PROPOSITION 6. *Let $\mathcal{M}, \mathcal{N} \in \mathcal{S}_\mathcal{L}$. The following are equivalent:*

- (a) $\mathcal{M} \cap \mathcal{N} = \{0\}$ and $\mathcal{M} + \mathcal{N} = \mathcal{L}$;
- (b) $\mathbf{A}_{\mathcal{M}, \mathcal{N}}$ is invertible.

Proof. (a) \Rightarrow (b). Note that

$$\begin{aligned}
\Pi_{\mathcal{N}^\perp} \mathcal{M} &= \Pi_{\mathcal{N}^\perp} (\mathcal{M} + \mathcal{N}) \\
&= \Pi_{\mathcal{N}^\perp} \mathcal{L} \\
&= \mathcal{N}^\perp.
\end{aligned}$$

Thus $\mathbf{A}_{\mathcal{M}, \mathcal{N}}$ maps \mathcal{M} onto \mathcal{N}^\perp . Since $\mathcal{M} \cap \mathcal{N} = \{0\}$ then $\mathbf{A}_{\mathcal{M}, \mathcal{N}}$ is one-to-one. Thus $\mathbf{A}_{\mathcal{M}, \mathcal{N}}$ is invertible (see [9, Prob. 52]).

(b) \Rightarrow (a). For any $x \in \mathcal{M} \cap \mathcal{N}$ it clearly holds that $\mathbf{A}_{\mathcal{M}, \mathcal{N}} x = 0$. Since $\mathbf{A}_{\mathcal{M}, \mathcal{N}}$ is invertible, then $\mathcal{M} \cap \mathcal{N} = \{0\}$. Also, for any $x \in \mathcal{L}$ we can write

$$(22) \quad x = \mathbf{A}_{\mathcal{M}, \mathcal{N}}^{-1} \Pi_{\mathcal{N}^\perp} x + (\mathbf{I}_\mathcal{L} - \mathbf{A}_{\mathcal{M}, \mathcal{N}}^{-1} \Pi_{\mathcal{N}^\perp}) x =: m + n.$$

Clearly $m = \mathbf{A}_{\mathcal{M}, \mathcal{N}}^{-1} \Pi_{\mathcal{N}^\perp} x \in \mathcal{M}$. We claim that $n \in \mathcal{N}$. To see this note that $\Pi_{\mathcal{N}^\perp} n = \Pi_{\mathcal{N}^\perp} x - \Pi_{\mathcal{N}^\perp} \mathbf{A}_{\mathcal{M}, \mathcal{N}}^{-1} \Pi_{\mathcal{N}^\perp} x = 0$. Thus, $\mathcal{L} = \mathcal{M} + \mathcal{N}$. \square

It follows from Proposition 2 that $[\mathbf{P}, \mathbf{C}]$ is a stable feedback configuration if and only if $\mathbf{A}_{\mathcal{M}, \mathcal{N}}$ is invertible. When $[\mathbf{P}, \mathbf{C}]$ is stable we define the operator

$$\mathbf{Q}_{\mathcal{M}, \mathcal{N}} := \mathbf{A}_{\mathcal{M}, \mathcal{N}}^{-1} \Pi_{\mathcal{N}^\perp}.$$

This is the *parallel projection onto \mathcal{M} along \mathcal{N}* . Note that $\mathbf{Q}_{\mathcal{M}, \mathcal{N}}$ can be expressed directly in terms of \mathbf{P} and \mathbf{C} as follows:

$$(23) \quad \mathbf{Q}_{\mathcal{M}, \mathcal{N}} = \begin{pmatrix} \mathbf{I}_\mathcal{U} \\ \mathbf{P} \end{pmatrix} ((\mathbf{I}_\mathcal{U} - \mathbf{C}\mathbf{P})^{-1}, -\mathbf{C}(\mathbf{I}_\mathcal{Y} - \mathbf{P}\mathbf{C})^{-1})$$

and in terms of the input-to-error operator $\mathbf{H}_{\mathbf{P}, \mathbf{C}}$:

$$(24) \quad \mathbf{Q}_{\mathcal{M}, \mathcal{N}} = \begin{pmatrix} \mathbf{I}_{\mathcal{U}} & \mathbf{0} \\ \mathbf{0} & -\mathbf{I}_{\mathcal{Y}} \end{pmatrix} \mathbf{H}_{\mathbf{P}, \mathbf{C}} + \begin{pmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{I}_{\mathcal{Y}} \end{pmatrix}.$$

When $[\mathbf{P}, \mathbf{C}]$ is stable we also define

$$(25) \quad \begin{aligned} b_{\mathcal{M}, \mathcal{N}} &:= \|\mathbf{Q}_{\mathcal{M}, \mathcal{N}}\|^{-1} \\ &= \tau(\Pi_{\mathcal{N}^\perp} |_{\mathcal{M}}) = \sqrt{1 - \delta(\mathcal{M}, \mathcal{N}^\perp)^2} \\ &= \inf\{\|\mathbf{A}_{\mathcal{M}, \mathcal{N}}x\| : x \in \mathcal{M} \text{ and } \|x\| = 1\} \\ &= \inf\{\text{dist}(x, \mathcal{N}) : x \in \mathcal{M} \text{ and } \|x\| = 1\} \\ &= \inf\{\sin \theta(x, y) : 0 \neq x \in \mathcal{M}, 0 \neq y \in \mathcal{N}\}, \end{aligned}$$

where

$$\theta(x, y) := \arccos \frac{|\langle x, y \rangle|}{\|x\| \|y\|}$$

denotes the *angle* between two nonzero vectors $x, y \in \mathcal{L}$. When $[\mathbf{P}, \mathbf{C}]$ is not stable we set $b_{\mathcal{M}, \mathcal{N}} := 0$. Equation (25) follows from (3). The quantity $b_{\mathcal{M}, \mathcal{N}}$ is the sine of the *minimal angle*

$$\begin{aligned} \theta_{\min}(\mathcal{M}, \mathcal{N}) &:= \inf\{\theta(x, y) : 0 \neq x \in \mathcal{M}, 0 \neq y \in \mathcal{N}\} \\ &= \arcsin b_{\mathcal{M}, \mathcal{N}} \\ &= \arccos \delta(\mathcal{M}, \mathcal{N}^\perp) \end{aligned}$$

(e.g., see [8]). Since

$$\begin{aligned} \delta(\mathcal{M}, \mathcal{N}^\perp) &= \delta(\mathcal{M}^\perp, \mathcal{N}) \\ &= \delta(\mathcal{N}, \mathcal{M}^\perp) \\ &= \delta(\mathcal{N}^\perp, \mathcal{M}), \end{aligned}$$

it follows that

$$(26) \quad \begin{aligned} b_{\mathcal{M}, \mathcal{N}} &= b_{\mathcal{M}^\perp, \mathcal{N}^\perp} \\ &= b_{\mathcal{N}, \mathcal{M}} \\ &= b_{\mathcal{N}^\perp, \mathcal{M}^\perp}. \end{aligned}$$

Equation (26) was shown in [3] (cf. [21, Lemma 1.1, p. 341]), [6]. It also follows from [10, Lemma 4] after noting that $b_{\mathcal{M}, \mathcal{N}}$ is the inverse of the norm of a parallel projection.

Conditions for stability of a feedback configuration can be expressed in a number of equivalent ways (cf. [3], [14]).

COROLLARY 3. *The following are equivalent:*

- (a) $[\mathbf{P}, \mathbf{C}]$ is stable;
- (b) $\mathbf{A}_{\mathcal{M}, \mathcal{N}}$ is invertible;
- (b) $\delta(\mathcal{M}, \mathcal{N}^\perp) < 1$;
- (c) $\theta_{\max}(\mathcal{M}, \mathcal{N}^\perp) < \pi/2$;
- (d) $\theta_{\min}(\mathcal{M}, \mathcal{N}) > 0$.

Proof. The proof follows from Propositions 3 and 6. \square

THEOREM 3. *The following are equivalent:*

- (a) $[\mathbf{P}, \mathbf{C}]$ is stable and $b < b_{\mathcal{M}, \mathcal{N}}$;
- (b) $[\mathbf{P}', \mathbf{C}]$ is stable and $\mathbf{Q}_{\mathcal{M}', \mathcal{N}}$ is uniformly bounded for all \mathbf{P}' so that, with $\mathcal{M}' := \mathcal{G}_{\mathbf{P}'}$, $\delta(\mathcal{M}, \mathcal{M}') \leq b$.

Before presenting the proof of the theorem we will establish the following lemma. For any $0 \neq h \in \mathcal{L}$ we denote $\hat{h} := h/\|h\|$.

LEMMA 3. *Let $\mathcal{K}, \mathcal{W} \in \mathcal{S}_{\mathcal{L}}$. Take any $0 \neq h \in \mathcal{K}$ and $0 \neq h_1 \notin \mathcal{K}$. Define $\mathcal{K}_- = \mathcal{K} \ominus \mathbb{C}h$ and $\mathcal{K}_1 = \mathcal{K}_- + \mathbb{C}h_1$. Then*

$$(a) \quad \delta(\mathcal{K}, \mathcal{K}_1) = \sqrt{1 - |\langle \hat{h}, \hat{h}_2 \rangle|^2}, \text{ where } h_2 = \Pi_{\mathcal{K}_-^\perp} h_1;$$

$$(b) \quad \text{if } \mathcal{K} \in \text{Graph}_{\mathcal{W}} \text{ then } \mathcal{K}_1 \in \overline{\text{Graph}_{\mathcal{W}}}.$$

Proof. (a) Since $\mathcal{K}_1 = \mathcal{K}_- \oplus \mathbb{C}h_2$ and $\mathcal{K}^\perp = \mathcal{K}_-^\perp \ominus \mathbb{C}h$ we obtain

$$\begin{aligned} \|\Pi_{\mathcal{K}^\perp} \Pi_{\mathcal{K}_1}\| &= \|(\Pi_{\mathcal{K}_-^\perp} - \Pi_{\mathbb{C}h})(\Pi_{\mathcal{K}_-} + \Pi_{\mathbb{C}h_2})\| \\ &= \|(\Pi_{\mathbb{C}h_2} - \Pi_{\mathbb{C}h}) \Pi_{\mathbb{C}h_2}\| \\ &= \sqrt{1 - |\langle \hat{h}, \hat{h}_2 \rangle|^2}. \end{aligned}$$

Similarly, $\|\Pi_{\mathcal{K}_1^\perp} \Pi_{\mathcal{K}}\| = \|(\Pi_{\mathbb{C}h_2} - \Pi_{\mathbb{C}h}) \Pi_{\mathbb{C}h}\| = \sqrt{1 - |\langle \hat{h}, \hat{h}_2 \rangle|^2}$. Therefore, $\delta(\mathcal{K}, \mathcal{K}_1) = \sqrt{1 - |\langle \hat{h}, \hat{h}_2 \rangle|^2}$.

(b) Define $\mathbf{X} := \Pi_{\mathcal{W}}|_{\mathcal{K}}$, $\mathbf{X}_1 := \Pi_{\mathcal{W}}|_{\mathcal{K}_1}$, $\hat{\mathbf{X}} := \mathbf{X} \Pi_{\mathcal{K}}|_{(\mathcal{K} + \mathcal{K}_1)}$, and $\hat{\mathbf{X}}_1 := \mathbf{X}_1 \Pi_{\mathcal{K}_1}|_{(\mathcal{K} + \mathcal{K}_1)}$. If $\mathcal{K}_1 \notin \overline{\text{Graph}_{\mathcal{W}}} = \mathcal{S}_{\text{npi}}$, then \mathbf{X}_1 is semi-Fredholm and then it is obvious that $\mathbf{X}, \hat{\mathbf{X}}, \hat{\mathbf{X}}_1$ are also semi-Fredholm. Since $\mathcal{K} \in \text{Graph}_{\mathcal{W}}$, $\ker \mathbf{X} = 0$ and $\text{ind } \mathbf{X} \leq 0$. Because $h_1 \notin \mathcal{K}$, it can be seen that $\dim \ker \hat{\mathbf{X}} = \dim \ker \mathbf{X} + 1$ and similarly that $\dim \ker \hat{\mathbf{X}}_1 = \dim \ker \mathbf{X}_1 + 1$. It follows that $\text{ind } \hat{\mathbf{X}} = \text{ind } \mathbf{X} + 1$ and $\text{ind } \hat{\mathbf{X}}_1 = \text{ind } \mathbf{X}_1 + 1$. However,

$$\hat{\mathbf{X}}_1 = \Pi_{\mathcal{W}} \Pi_{\mathcal{K}}|_{(\mathcal{K} + \mathcal{K}_1)} + \Pi_{\mathcal{W}}(\Pi_{\mathbb{C}h_2} - \Pi_{\mathbb{C}h})|_{(\mathcal{K} + \mathcal{K}_1)} = \hat{\mathbf{X}} + \text{finite-rank operator}.$$

Therefore, $\text{ind } \hat{\mathbf{X}}_1 = \text{ind } \hat{\mathbf{X}}$ and hence $\text{ind } \mathbf{X}_1 = \text{ind } \mathbf{X}$. Thus, $\text{ind } \mathbf{X}_1 \leq 0$, and consequently, $\mathcal{K}_1 \notin \mathcal{S}_{\text{pi}}$; that is, $\mathcal{K}_1 \in \mathcal{S}_{\text{npi}}$, a contradiction. This proves that $\mathcal{K}_1 \in \overline{\text{Graph}_{\mathcal{W}}}$. \square

Proof of Theorem 3. (a) \Rightarrow (b). Assume (b) fails. We will show that, if $[\mathbf{P}, \mathbf{C}]$ is stable, then $b \geq b_{\mathcal{M}, \mathcal{N}}$. Since (b) fails then, either $\|(\Pi_{\mathcal{N}^\perp}|_{\mathcal{M}'})^{-1}\|$ is not bounded above in $\overline{\text{Ball}}(\mathcal{M}, b) \cap \text{Graph}_{\mathcal{U}}$ or $\Pi_{\mathcal{N}^\perp}|_{\mathcal{M}'}$ is not invertible for some $\mathcal{M}' \in \overline{\text{Ball}}(\mathcal{M}, b) \cap \text{Graph}_{\mathcal{U}}$. This means that one of the following two possibilities holds:

- (i) $\tau(\Pi_{\mathcal{N}^\perp}|_{\mathcal{M}'})$ is not bounded below in $\overline{\text{Ball}}(\mathcal{M}, b) \cap \text{Graph}_{\mathcal{U}}$;
- (ii) there exists $\mathcal{M}' \in \overline{\text{Ball}}(\mathcal{M}, b) \cap \text{Graph}_{\mathcal{U}}$ and $0 \neq y \in \mathcal{N}^\perp$ such that $\Pi_{\mathcal{M}'} y = 0$.

In case (i), for all $\epsilon > 0$ there exists \mathcal{M}' and $x \in \mathcal{M}'$ of unit norm such that $\|\Pi_{\mathcal{N}^\perp} x\| = \text{dist}(x, \mathcal{N}) < \epsilon$. Note that $b \geq \delta(\mathcal{M}, \mathcal{M}') \geq \sup_{\xi \in \mathcal{M}', \|\xi\|=1} \text{dist}(\xi, \mathcal{M}) \geq \text{dist}(x, \mathcal{M}) = \|\Pi_{\mathcal{M}^\perp} x\|$. Also

$$\begin{aligned} b_{\mathcal{M}, \mathcal{N}} &= b_{\mathcal{N}, \mathcal{M}} \leq \left\| \Pi_{\mathcal{M}^\perp} \frac{\Pi_{\mathcal{N}} x}{\|\Pi_{\mathcal{N}} x\|} \right\| \\ (27) \quad &\leq \frac{\|\Pi_{\mathcal{M}^\perp} x\| + \|\Pi_{\mathcal{M}^\perp} \Pi_{\mathcal{N}^\perp} x\|}{\|\Pi_{\mathcal{N}} x\|} \leq \frac{b + \epsilon}{\sqrt{1 - \epsilon^2}}. \end{aligned}$$

Since (27) holds for all ϵ then $b_{\mathcal{M},\mathcal{N}} \leq b$. In case (ii), note that $y \in \mathcal{M}'^\perp$. Thus $b \geq \delta(\mathcal{M}, \mathcal{M}') = \delta(\mathcal{M}^\perp, \mathcal{M}'^\perp) \geq \text{dist}(y, \mathcal{M}^\perp) = \|\Pi_{\mathcal{M}} y\|$. Also $b_{\mathcal{M},\mathcal{N}} = b_{\mathcal{M}^\perp, \mathcal{N}^\perp} \leq \|\Pi_{\mathcal{M}} y\|$ since $y \in \mathcal{N}^\perp$. Therefore $b_{\mathcal{M},\mathcal{N}} \leq b$.

(b) \Rightarrow (a). Suppose that (b) holds for some $b \geq b_{\mathcal{M},\mathcal{N}}$. Then the same is true for some $b > b_{\mathcal{M},\mathcal{N}}$. To see this, first note that $b < 1$ necessarily, otherwise $[\mathbf{P}', \mathbf{C}]$ is stable for *any* system \mathbf{P}' , and there is an easy contradiction. By assumption, there exists a c such that $\|\mathbf{Q}_{\mathcal{M}',\mathcal{N}}\| \leq c$ for all \mathbf{P}' with $\delta(\mathcal{M}, \mathcal{M}') \leq b$. From the identity $\mathbf{A}_{\mathcal{M}'',\mathcal{N}} = \mathbf{A}_{\mathcal{M}',\mathcal{N}}(\mathbf{I}_{\mathcal{M}'} + \mathbf{Q}_{\mathcal{M}',\mathcal{N}}(\Pi_{\mathcal{M}''} - \Pi_{\mathcal{M}'})|_{\mathcal{M}'})(\Pi_{\mathcal{M}''}|_{\mathcal{M}'})^{-1}|_{\mathcal{M}''}$ (cf. [3]) we can see that $\mathbf{A}_{\mathcal{M}'',\mathcal{N}}$ is invertible for all \mathbf{P}'' with $\delta(\mathcal{M}', \mathcal{M}'') \leq 1/2c$ for some \mathbf{P}' with $\delta(\mathcal{M}, \mathcal{M}') \leq b$. Moreover

$$\begin{aligned} \|\mathbf{Q}_{\mathcal{M}'',\mathcal{N}}\| &= \|\Pi_{\mathcal{M}''}|_{\mathcal{M}'}(\mathbf{I}_{\mathcal{M}'} + \mathbf{Q}_{\mathcal{M}',\mathcal{N}}(\Pi_{\mathcal{M}''} - \Pi_{\mathcal{M}'})|_{\mathcal{M}'})^{-1}\mathbf{Q}_{\mathcal{M}',\mathcal{N}}\| \\ &\leq 2c. \end{aligned}$$

From Theorem 1 the union of open balls, of radius $1/2c$, about all \mathcal{M}' with $\delta(\mathcal{M}, \mathcal{M}') \leq b$ includes an open ball about \mathcal{M} of radius $b + \epsilon$ for some $\epsilon > 0$. It now follows that (b) holds for \mathbf{P}'' in a ball about \mathbf{P} and radius strictly greater than $b_{\mathcal{M},\mathcal{N}}$. So from now on we assume that $b_{\mathcal{M},\mathcal{N}} < b < 1$.

Next we prove that there exists a subspace $\mathcal{M}' \in \overline{\text{Graph}}_{\mathcal{U}}$ with $\delta(\mathcal{M}, \mathcal{M}') < b$ such that $\Pi_{\mathcal{N}^\perp}|_{\mathcal{M}'}$ is not invertible. Let $\mathbf{A} := \mathbf{A}_{\mathcal{M},\mathcal{N}}$, \mathbf{E}_λ be the spectral family of $\mathbf{A}^* \mathbf{A}$, and $h \in \mathbf{E}_{\tau(\mathbf{A})+\epsilon} \mathcal{M}$ of unit norm, for some arbitrary $\epsilon > 0$. Then $\|(\mathbf{A}^* \mathbf{A} - b_{\mathcal{M},\mathcal{N}})h\| \leq \epsilon$. Define $\mathcal{M}_- := \mathcal{M} \ominus \mathbb{C}h$, $p_0 := \Pi_{\mathcal{N}} h \in \mathcal{N}$, $q_0 := \Pi_{\mathcal{M}_-} p_0$, and $\mathcal{M}' = \mathcal{M}_- + \mathbb{C}p_0$. Since $\mathcal{M}' \cap \mathcal{N} \neq \{0\}$ then $\Pi_{\mathcal{M}'}|_{\mathcal{N}^\perp}$ is not invertible. From Lemma 3 we have

$$(28) \quad \delta(\mathcal{M}, \mathcal{M}') = \sqrt{1 - |\langle h, \hat{q}_0 \rangle|^2}$$

and $\mathcal{M}' \in \overline{\text{Graph}}_{\mathcal{U}}$. To evaluate (28) we first note that

$$(29) \quad \begin{aligned} \langle h, q_0 \rangle &= \langle h, p_0 \rangle = \|p_0\|^2 \\ &= 1 - \|\mathbf{A}h\|^2. \end{aligned}$$

We also have

$$(30) \quad \begin{aligned} \|q_0\|^2 &= \|p_0\|^2 - \|\Pi_{\mathcal{M}_-} \Pi_{\mathcal{N}} h\|^2 \\ &= \|p_0\|^2 - \|\Pi_{\mathcal{M}_-} \Pi_{\mathcal{N}^\perp} h\|^2 \\ &= \|p_0\|^2 - \langle \Pi_{\mathcal{N}^\perp} h, (\Pi_{\mathcal{M}} - \Pi_{\mathbb{C}h}) \Pi_{\mathcal{N}^\perp} h \rangle \\ &= \|p_0\|^2 - \langle \Pi_{\mathcal{M}} \Pi_{\mathcal{N}^\perp} h, \Pi_{\mathcal{M}} \Pi_{\mathcal{N}^\perp} h \rangle + |\langle \Pi_{\mathcal{N}^\perp} h, h \rangle|^2 \\ &= 1 - \|\mathbf{A}h\|^2 - \|\mathbf{A}^* \mathbf{A} h\|^2 + \|\mathbf{A}h\|^4 \\ &= 1 - \|\mathbf{A}h\|^2 + O(\epsilon). \end{aligned}$$

From (28)–(30), we obtain $\delta(\mathcal{M}, \mathcal{M}') = \|\mathbf{A}h\| + O(\epsilon)$. In particular, for sufficiently small ϵ we have $\delta(\mathcal{M}, \mathcal{M}') < b$.

In case $\mathcal{M}' \in \overline{\text{Graph}}_{\mathcal{U}}$ then the hypothesis is violated and the proof is complete. If not, consider a sequence $\mathcal{M}'_i \in \text{Graph}_{\mathcal{U}}$, $i = 1, 2, \dots$, converging to \mathcal{M}' . If there is a subsequence such that $\Pi_{\mathcal{M}'_i}|_{\mathcal{N}^\perp}$ is not invertible then, again, there is a contradiction. Otherwise, since $\lim_{i \rightarrow \infty} \|\Pi_{\mathcal{M}'_i}|_{\mathcal{N}^\perp} - \Pi_{\mathcal{M}'}|_{\mathcal{N}^\perp}\| = 0$, we can find a subsequence such that $\lim_{i \rightarrow \infty} \|(\Pi_{\mathcal{M}'_i}|_{\mathcal{N}^\perp})^{-1}\| = \infty$. This also violates the hypothesis. \square

Remark 1. A similar result was established in [6, Thm. 5] for linear time-invariant causal systems. However, the result in [6] differs from the one above in that the $<$

and \leq signs are interchanged, and the “uniform boundedness” is absent. We will show that the exact statement of [6, Thm. 5] is not valid in the case of time-varying systems so that the uniformity condition is in fact necessary. More precisely, in the next section we will present an example where $[\mathbf{P}_1, \mathbf{C}]$ is stable for all \mathbf{P}_1 such that $\delta(\mathcal{M}, \mathcal{M}_1) < 1$ while $b_{\mathcal{M}, \mathcal{N}} = 1/\sqrt{2} < 1$.

Remark 2. The basic geometric ideas behind the proof of Theorem 3 can be simply expressed. The essence of the sufficiency part of Theorem 3 ((a) \Rightarrow (b)) can be seen from the identity $\mathbf{A}_{\mathcal{M}', \mathcal{N}} = \mathbf{A}_{\mathcal{M}, \mathcal{N}}(\mathbf{I}_{\mathcal{M}} + \mathbf{Q}_{\mathcal{M}, \mathcal{N}}(\Pi_{\mathcal{M}'} - \Pi_{\mathcal{M}})|_{\mathcal{M}})(\Pi_{\mathcal{M}'}|_{\mathcal{M}})^{-1}|_{\mathcal{M}'}$, which implies that $\mathbf{A}_{\mathcal{M}', \mathcal{N}}$ is invertible for all \mathbf{P}' if $\delta(\mathcal{M}, \mathcal{M}') \leq \|\mathbf{Q}_{\mathcal{M}, \mathcal{N}}\|^{-1}$. The key idea in the necessity part is to find a subspace \mathcal{M}' such that $\delta(\mathcal{M}, \mathcal{M}') = \|\mathbf{Q}_{\mathcal{M}, \mathcal{N}}\|^{-1}$ and so that Proposition 6(a) is violated. The construction given in the proof is to remove a direction orthogonally from \mathcal{M} and to replace it with a direction from \mathcal{N} . The vectors are chosen in such a way that the angle between them is equal (or arbitrarily close to) $\theta_{\min}(\mathcal{M}, \mathcal{N})$. This gives $\mathcal{M}' \cap \mathcal{N} \neq \{0\}$ with $\delta(\mathcal{M}, \mathcal{M}')$ having the required value. (The reader is referred to [19] for another version of this idea.) The additional ingredients in the proof deal with the uniform boundedness condition and the need to impose graphability on the perturbed subspaces.

Remark 3. In the theorem we do not impose any time-invariance and causality constraint on the systems considered. Certainly the implication (a) \Rightarrow (b) of Theorem 3 is still valid when the class of systems is restricted by a causality requirement, but the reverse implication requires a construction different from the one given here.

6. Clarification of uniform boundedness condition. We now present an example to show that, in the time-varying case, the obstruction that limits the largest perturbation ball in the gap metric may be due solely to the lack of uniform boundedness of the closed loop operator, as expressed in Theorem 3.

Let $\mathcal{U} = \mathcal{Y} = \ell_2[0, \infty) =: \mathcal{V}$, $\mathcal{L} = \mathcal{U} \oplus \mathcal{Y}$, and identify \mathcal{U} and \mathcal{Y} with the corresponding subspaces of \mathcal{L} . Consider \mathbf{P} having the matrix representation

$$\mathbf{P} = \begin{pmatrix} 1 & 0 & \dots \\ 0 & 0 & \dots \\ \vdots & \vdots & \end{pmatrix}$$

and let $\mathbf{C} = 0$. Then $\mathcal{M} = \{(\begin{smallmatrix} v \\ (v)_0 \end{smallmatrix}) : v \in \mathcal{V}\}$, where $(v)_0 = (v_0, 0, 0, \dots)$ for any $v = (v_0, v_1, v_2, \dots) \in \mathcal{V}$, and $\mathcal{N} = \{(\begin{smallmatrix} 0 \\ v \end{smallmatrix}) : v \in \mathcal{V}\}$. For any $\mathcal{M}_1 \in \text{Graph}_{\mathcal{U}}$ define \mathbf{P}_1 by $\mathcal{M}_1 = \mathcal{G}_{\mathbf{P}_1}$. Also define $\text{Ball}_{\mathcal{U}}(\mathcal{M}, b) := \text{Ball}(\mathcal{M}, b) \cap \text{Graph}_{\mathcal{U}}$.

PROPOSITION 7. *For the example given above*

$$\sup \{b : \{\mathcal{M}_1 \in \text{Ball}_{\mathcal{U}}(\mathcal{M}, b) \text{ implies that } [\mathbf{P}_1, \mathbf{C}] \text{ is stable}\} = 1.$$

This should be contrasted against the fact that for the particular \mathbf{P}, \mathbf{C} given above

$$\begin{aligned} b_{\mathcal{M}, \mathcal{N}} &= \left\| \begin{pmatrix} \mathbf{I}_{\mathcal{U}} \\ \mathbf{P} \end{pmatrix} ((\mathbf{I}_{\mathcal{U}} - \mathbf{C}\mathbf{P})^{-1}, -\mathbf{C}(\mathbf{I}_{\mathcal{Y}} - \mathbf{P}\mathbf{C})^{-1}) \right\|^{-1} \\ &= \left\| \begin{pmatrix} \mathbf{I}_{\mathcal{U}} \\ \mathbf{P} \end{pmatrix} \right\|^{-1} = (1 + \|\mathbf{P}\|^2)^{-1/2} = \frac{1}{\sqrt{2}}. \end{aligned}$$

Proof of Proposition 7. Since $\mathcal{N} = \mathcal{U}^{\perp}$, for any $\mathcal{M}_1 \in \text{Ball}_{\mathcal{U}}(\mathcal{M}, b)$, $\mathcal{M}_1 \cap \mathcal{N} = \{0\}$. Therefore, $[\mathbf{P}_1, \mathbf{C}]$ is stable $\Leftrightarrow \mathcal{M}_1 + \mathcal{N} = \mathcal{L} \Leftrightarrow \Pi_{\mathcal{U}}\mathcal{M}_1 = \mathcal{U}$. Next note

that $\mathcal{M}^\perp = \left\{ \begin{pmatrix} -(v)_0 \\ v \end{pmatrix} : v \in \mathcal{V} \right\}$. Proposition 3 also implies that any \mathcal{M}_1 such that $\delta(\mathcal{M}, \mathcal{M}_1) < 1$ can be written as

$$\mathcal{M}_1 = \left\{ \begin{pmatrix} v \\ (v)_0 \end{pmatrix} + \begin{pmatrix} -(\mathbf{X}v)_0 \\ \mathbf{X}v \end{pmatrix} : v \in \mathcal{V} \right\},$$

where $\mathbf{X} : \mathcal{V} \rightarrow \mathcal{V}$ is a bounded operator. However,

$$\begin{aligned} \mathcal{M}_1 \cap \mathcal{N} = \{0\} &\Leftrightarrow v - (\mathbf{X}v)_0 = 0 \text{ implies } (v)_0 + \mathbf{X}v = 0 \\ &\Leftrightarrow v = (v)_0 = (\mathbf{X}v)_0 \text{ implies } (v)_0 + \mathbf{X}v = 0 \\ &\Leftrightarrow (\mathbf{X})_{0,0} \neq 1, \end{aligned}$$

where $(\mathbf{X})_{0,0}$ denotes the $(0,0)$ -entry in a matrix representation of \mathbf{X} with respect to the standard basis of $\mathcal{V} = \ell_2[0, \infty)$. Take any $\mathcal{M}_1 \in \text{Ball}_{\mathcal{U}}(\mathcal{M}, 1)$. Then

$$\Pi_{\mathcal{U}}\mathcal{M}_1 = \{v - (\mathbf{X}v)_0 : v \in \mathcal{V}\} = \mathcal{U}$$

since $(\mathbf{X})_{0,0} \neq 1$. Hence, $\mathcal{M}_1 \in \text{Ball}_{\mathcal{U}}(\mathcal{M}, 1)$ implies that $[\mathbf{P}_1, \mathbf{C}]$ is stable. So $b = 1$ is the supremal b . \square

7. Combined plant and controller uncertainty. When both plant and controller are subject simultaneously to gap-ball uncertainty, there is a maximal amount for the combined uncertainty that can be tolerated. The following theorem is a generalization of an elegant result of Qiu and Davison [16] to the time-varying case.

THEOREM 4. *Let $\mathbf{P} \in \mathcal{P}_{\mathcal{U}, \mathcal{Y}}$, $\mathbf{C} \in \mathcal{P}_{\mathcal{Y}, \mathcal{U}}$ and let b_1, b_2 be fixed nonnegative numbers such that $b_1^2 + b_2^2 < 1$. Then the following are equivalent:*

- (a) $[\mathbf{P}, \mathbf{C}]$ is stable and $b_1\sqrt{1-b_2^2} + b_2\sqrt{1-b_1^2} < b_{\mathcal{M}, \mathcal{N}}$;
- (b) $[\mathbf{P}', \mathbf{C}']$ is stable and $\mathbf{Q}_{\mathcal{M}', \mathcal{N}'}$ is uniformly bounded for all \mathbf{P}', \mathbf{C}' with $\mathcal{M}' := \mathcal{G}_{\mathbf{P}'}, \mathcal{N}' := \mathcal{G}_{\mathbf{C}'}, \delta(\mathcal{M}, \mathcal{M}') \leq b_1$ and $\delta(\mathcal{N}, \mathcal{N}') \leq b_2$.

Proof. (a) \Rightarrow (b) Suppose (b) fails and that $[\mathbf{P}, \mathbf{C}]$ is stable. We will show that $b_1\sqrt{1-b_2^2} + b_2\sqrt{1-b_1^2} \geq b_{\mathcal{M}, \mathcal{N}}$. As in the proof of Theorem 3 there are two possibilities:

(i) $\tau(\Pi_{\mathcal{N}'^\perp} |_{\mathcal{M}'})$ is not bounded below for $\mathcal{M}' \in \overline{\text{Ball}}(\mathcal{M}, b_1) \cap \text{Graph}_{\mathcal{U}}$ and $\mathcal{N}' \in \overline{\text{Ball}}(\mathcal{N}, b_2) \cap \text{Graph}_{\mathcal{Y}}$,

(ii) there exists $\mathcal{M}' \in \overline{\text{Ball}}(\mathcal{M}, b_1) \cap \text{Graph}_{\mathcal{U}}$ and $\mathcal{N}' \in \overline{\text{Ball}}(\mathcal{N}, b_2) \cap \text{Graph}_{\mathcal{Y}}$ and $0 \neq z \in \mathcal{N}'^\perp \cap \mathcal{M}'^\perp$.

In case (i), for all $\epsilon > 0$ there exists $\mathcal{M}', \mathcal{N}'$, and $x \in \mathcal{M}'$ of unit norm such that $\|\Pi_{\mathcal{N}'^\perp} x\| < \epsilon$. Setting $y := \Pi_{\mathcal{N}'} x \in \mathcal{N}'$ we have

$$\theta(x, y) := \arccos \frac{|\langle x, y \rangle|}{\|x\| \|y\|} = \arccos \left(\frac{1 - \|\Pi_{\mathcal{N}'^\perp} x\|^2}{\|y\|} \right) < \arcsin \epsilon.$$

Since $\delta(\mathcal{M}, \mathcal{M}') \leq b_1$ it follows that $\|\Pi_{\mathcal{M}^\perp} x\| \leq b_1$. Thus, if $x_0 := \Pi_{\mathcal{M}} x \in \mathcal{M}$, then

$$\theta(x_0, x) \leq \arcsin b_1.$$

Similarly, since $\delta(\mathcal{N}, \mathcal{N}') \leq b_2$,

$$\theta(y_0, y) \leq \arcsin b_2,$$

where $y_0 := \Pi_{\mathcal{N}} y \in \mathcal{N}$. It follows from (15) that

$$\begin{aligned} \arcsin b_1 + \arcsin b_2 + \arcsin \epsilon &> \theta(x_0, x) + \theta(y, y_0) + \theta(x, y) \\ &\geq \theta(x_0, y_0) \\ (31) \quad &\geq \theta_{\min}(\mathcal{M}, \mathcal{N}) = \arcsin b_{\mathcal{M}, \mathcal{N}}. \end{aligned}$$

Since (31) holds for all ϵ we have

$$\arcsin b_1 + \arcsin b_2 \geq \arcsin b_{\mathcal{M}, \mathcal{N}}.$$

Therefore, $b_1 \sqrt{1 - b_2^2} + b_2 \sqrt{1 - b_1^2} \geq b_{\mathcal{M}, \mathcal{N}}$ and so (a) fails. In case (ii) we proceed similarly. Set $z_1 := \Pi_{\mathcal{M}^\perp} z$ and $z_2 := \Pi_{\mathcal{N}^\perp} z$. Since $b_1 \geq \delta(\mathcal{M}, \mathcal{M}') = \delta(\mathcal{M}^\perp, \mathcal{M}'^\perp)$ we have $\theta(z, z_1) \leq \arcsin b_1$. Also, $b_2 \geq \delta(\mathcal{N}, \mathcal{N}') = \delta(\mathcal{N}^\perp, \mathcal{N}'^\perp)$ implies that $\theta(z, z_2) \leq \arcsin b_2$. Thus

$$\begin{aligned} \arcsin b_1 + \arcsin b_2 &\geq \theta(z_1, z_2) \\ &\geq \theta_{\min}(\mathcal{M}^\perp, \mathcal{N}^\perp) \\ &= \arcsin b_{\mathcal{M}^\perp, \mathcal{N}^\perp} = \arcsin b_{\mathcal{M}, \mathcal{N}} \end{aligned}$$

and (a) fails once again.

(b) \Rightarrow (a) Suppose (b) holds for some b_1 and b_2 satisfying

$$(32) \quad b_1 \sqrt{1 - b_2^2} + b_2 \sqrt{1 - b_1^2} \geq b_{\mathcal{M}, \mathcal{N}}.$$

Similar reasoning to the proof of Theorem 3 shows that we may take strict inequality in (32). In particular, if $\|\mathbf{Q}_{\mathcal{M}', \mathcal{N}'}\| \leq c$ in (b), then $\|\mathbf{Q}_{\mathcal{M}'', \mathcal{N}'}\| \leq 2c$ for all

$$\mathcal{M}'' \in \bigcup_{\mathcal{M}' \in \overline{\text{Ball}}_{\mathcal{U}}(\mathcal{M}, b_1)} \text{Ball}_{\mathcal{U}}\left(\mathcal{M}', \frac{1}{2c}\right)$$

and all $\mathcal{N}' \in \text{Ball}_{\mathcal{Y}}(\mathcal{N}, b_2)$. Theorem 1 then shows that statement (b) holds with b_1 replaced by some $b_1 + \epsilon$ for $\epsilon > 0$. Since the left-hand side of (32) is monotonically increasing in b_1 , it follows that (b) holds for some b_1 and b_2 satisfying (32) with strict inequality. Henceforth we will assume that this is the case. We also note from Theorem 3 that $b_1, b_2 < b_{\mathcal{M}, \mathcal{N}}$.

We now show that there are subspaces $\mathcal{M}' \in \overline{\text{Graph}}_{\mathcal{U}}$ and $\mathcal{N}' \in \overline{\text{Graph}}_{\mathcal{Y}}$ with $\delta(\mathcal{M}, \mathcal{M}') < b_1$ and $\delta(\mathcal{N}, \mathcal{N}') < b_2$ such that $\Pi_{\mathcal{N}'^\perp}|_{\mathcal{M}'}$ is not invertible.

As in the proof of Theorem 3, let $\mathbf{A} := \mathbf{A}_{\mathcal{M}, \mathcal{N}}$, \mathbf{E}_λ be the spectral family of $\mathbf{A}^* \mathbf{A}$, and $h \in \mathbf{E}_{\tau(\mathbf{A}) + \epsilon} \mathcal{M}$ of unit norm, for some arbitrary $\epsilon > 0$. Then $\|\mathbf{A}h\| < \tau(\mathbf{A}) + \epsilon = b_{\mathcal{M}, \mathcal{N}} + \epsilon$. Define $p_\lambda = \lambda h + (1 - \lambda)\Pi_{\mathcal{N}}h$ and write $\mathcal{M}_- := \mathcal{M} \ominus \mathbb{C}h$, $\mathcal{N}_- := \mathcal{N} \ominus \mathbb{C}\Pi_{\mathcal{N}}h$, $\mathcal{M}_\lambda := \mathcal{M}_- + \mathbb{C}p_\lambda$, and $\mathcal{N}_\lambda := \mathcal{N}_- + \mathbb{C}p_\lambda$. We also write $q_\lambda := \Pi_{\mathcal{M}_-^\perp} p_\lambda$ and $r_\lambda := \Pi_{\mathcal{N}_-^\perp} p_\lambda$. We first show that

$$(33) \quad \delta(\mathcal{M}, \mathcal{M}_\lambda) = \frac{(1 - \lambda)\|\mathbf{A}h\|\sqrt{1 - \|\mathbf{A}h\|^2}}{\sqrt{1 - (1 - \lambda^2)\|\mathbf{A}h\|^2}} + O(\epsilon) =: c_\lambda + O(\epsilon).$$

From Lemma 3 we know that

$$(34) \quad \delta(\mathcal{M}, \mathcal{M}_\lambda) = \sqrt{1 - |\langle h, \hat{q}_\lambda \rangle|^2}.$$

To evaluate (34) we must compute $\langle h, q_\lambda \rangle$ and $\|q_\lambda\|$. First,

$$\begin{aligned} \langle h, q_\lambda \rangle &= \langle h, p_\lambda \rangle \\ &= \lambda + (1 - \lambda)\|p_0\|^2 \\ &= \lambda + (1 - \lambda)(1 - \|\mathbf{A}h\|^2) \\ (35) \quad &= 1 - (1 - \lambda)\|\mathbf{A}h\|^2. \end{aligned}$$

Next, using (30), we have

$$\begin{aligned}
 \langle q_\lambda, q_\lambda \rangle &= \lambda^2 + 2\lambda(1-\lambda)\|p_0\|^2 + (1-\lambda)^2\|q_0\|^2 \\
 &\simeq \lambda^2 + (2\lambda(1-\lambda) + (1-\lambda)^2)(1 - \|\mathbf{A}h\|^2) \\
 (36) \qquad &= 1 - (1-\lambda^2)\|\mathbf{A}h\|^2,
 \end{aligned}$$

where \simeq denotes equality to $O(\epsilon)$. Equations (35) and (36) together show that

$$|\langle h, \hat{q}_\lambda \rangle|^2 = \frac{(1 - (1-\lambda)\|\mathbf{A}h\|^2)^2}{1 - (1-\lambda^2)\|\mathbf{A}h\|^2} + O(\epsilon)$$

from which (33) follows by simple manipulation. Next we show that

$$(37) \qquad \delta(\mathcal{N}, \mathcal{N}_\lambda) = \frac{\lambda\|\mathbf{A}h\|}{\sqrt{1 - (1-\lambda^2)\|\mathbf{A}h\|^2}} =: d_\lambda.$$

From Lemma 3 we know that

$$(38) \qquad \delta(\mathcal{N}, \mathcal{N}_\lambda) = \sqrt{1 - |\langle \hat{p}_0, \hat{r}_\lambda \rangle|^2}.$$

To evaluate (34) we need the following computations:

$$\begin{aligned}
 \langle p_0, r_\lambda \rangle &= \langle \Pi_{\mathcal{N}} h, (\Pi_{\mathcal{N}^\perp} + \Pi_{\mathcal{T}p_0}) p_\lambda \rangle \\
 &= \langle \Pi_{\mathcal{N}} h, h \rangle \\
 (39) \qquad &= 1 - \|\mathbf{A}h\|^2
 \end{aligned}$$

$$(40) \qquad = \|p_0\|^2$$

and

$$\begin{aligned}
 \langle r_\lambda, r_\lambda \rangle &= \langle (\Pi_{\mathcal{N}^\perp} + \Pi_{\mathcal{T}p_0}) p_\lambda, (\Pi_{\mathcal{N}^\perp} + \Pi_{\mathcal{T}p_0}) p_\lambda \rangle \\
 &= \|\Pi_{\mathcal{N}^\perp} p_\lambda\|^2 + \|\Pi_{\mathcal{T}p_0} p_\lambda\|^2 \\
 &= \lambda^2 \|\Pi_{\mathcal{N}^\perp} h\|^2 + \|\Pi_{\mathcal{N}} h\|^2 \\
 (41) \qquad &= 1 - (1-\lambda^2)\|\mathbf{A}h\|^2.
 \end{aligned}$$

Equations (39)–(41) together show that

$$|\langle \hat{p}_0, \hat{r}_\lambda \rangle|^2 = \frac{1 - \|\mathbf{A}h\|^2}{1 - (1-\lambda^2)\|\mathbf{A}h\|^2}$$

from which (37) follows by simple manipulation. Next we observe from (33) and (37) that $c_\lambda \sqrt{1 - d_\lambda^2} + d_\lambda \sqrt{1 - c_\lambda^2} = \|\mathbf{A}h\|$. Since c_λ is monotonically decreasing in λ on the interval $[0, 1]$ we can choose λ such that $c_\lambda = b_1 - \epsilon$. Then for sufficiently small ϵ , we must have $d_\lambda < b_2$; otherwise, we have a contradiction to (32) with strict inequality. For the above choice of λ and sufficiently small ϵ we set $\mathcal{M}' = \mathcal{M}_\lambda$ and $\mathcal{N}' = \mathcal{N}_\lambda$ which gives $\delta(\mathcal{M}, \mathcal{M}') < b_1$ and $\delta(\mathcal{N}, \mathcal{N}') < b_2$. Lemma 3 shows that $\mathcal{M}' \in \overline{\text{Graph}}_{\mathcal{U}}$ and $\mathcal{N}' \in \overline{\text{Graph}}_{\mathcal{Y}}$. Also $\Pi_{\mathcal{N}'^\perp}|_{\mathcal{M}'}$ is not invertible since $\mathcal{M}' \cap \mathcal{N}' \neq \{0\}$.

Now consider a sequence $\mathcal{M}'_i \in \text{Graph}_{\mathcal{U}}$, $i = 1, 2, \dots$, converging to \mathcal{M}' and a sequence $\mathcal{N}'_i \in \text{Graph}_{\mathcal{Y}}$, $i = 1, 2, \dots$, converging to \mathcal{N}' . If there is a subsequence such that $\Pi_{\mathcal{N}'_i^\perp}|_{\mathcal{M}'_i}$ is not invertible, then there is a contradiction. Otherwise, we can find a subsequence so that $\Pi_{\mathcal{N}'_i^\perp}|_{\mathcal{M}'_i}$ is invertible. First observe that $\lim_{i \rightarrow \infty} \|\Pi_{\mathcal{N}'^\perp} \Pi_{\mathcal{M}'} -$

$\Pi_{\mathcal{N}'^\perp} \Pi_{\mathcal{M}'_i} = 0$. Since $\Pi_{\mathcal{N}'^\perp}|_{\mathcal{M}'}$ is not invertible, for any ϵ we can find an $x \in \mathcal{M}'$ of unit norm such that $\|\Pi_{\mathcal{N}'^\perp} x\| < \epsilon$. Thus $\|\Pi_{\mathcal{N}'^\perp} y_i\| < \epsilon$ for sufficiently large i , where $y_i := \Pi_{\mathcal{M}'_i} x$. Since $\mathcal{M}'_i \rightarrow \mathcal{M}'$ we also have $\|\Pi_{\mathcal{N}'^\perp} \hat{y}_i\| < \epsilon$ for sufficiently large i . This means that $\lim_{i \rightarrow \infty} \|(\Pi_{\mathcal{N}'^\perp}|_{\mathcal{M}'_i})^{-1}\| = \infty$. This violates the hypothesis. \square

Remark. The necessity part of the proof of Theorem 4 requires a simultaneous perturbation of \mathcal{M} and \mathcal{N} . The construction removes orthogonally one-dimensional subspaces from each of \mathcal{M} and \mathcal{N} that are at an angle $\theta_{\min}(\mathcal{M}, \mathcal{N})$ to each other, and replaces them by a convex combination of these directions. The subspaces are each perturbed through the required minimal angles and together violate the direct sum property of Proposition 6(a).

Acknowledgments. The authors would like to thank the reviewers for several helpful comments.

STABILIZABILITY AND EXISTENCE OF SYSTEM REPRESENTATIONS FOR DISCRETE-TIME TIME-VARYING SYSTEMS*

WILBUR N. DALE[†] AND MALCOLM C. SMITH[‡]

Abstract. In this paper, right and left representations as an alternate, but equivalent, framework to coprime factorizations of operators are developed. The main theorem of the paper establishes that a linear, time-varying, discrete-time plant is stabilizable if and only if its graph can be represented as the range (respectively, kernel) of a causal, bounded operator which is left (respectively, right) invertible. The proof relies on certain factorization theorems of Arveson for nest algebras. The paper extends the Youla parametrization of all stabilizing compensators to this framework. Also, it is proven that a time-invariant plant that is not stabilizable by a time-invariant compensator is not stabilizable with a time-varying compensator. An example of a time-varying plant of Feintuch is considered and shown to be not stabilizable. Finally, the continuous-time case is examined and the problems encountered in extending the proof are discussed. However, it is shown that a stabilizable plant must have a closed graph and this is used to prove that an example of a time-invariant, continuous-time system of Shefi is not stabilizable.

Key words. time-varying systems, stabilizability, coprime fractions, graph, nest algebras

1. Notation and definitions. In this section, we will introduce notation and definitions used throughout the paper.

Let \mathbb{Z} be the nonnegative integers and \mathbb{R} be the set of real numbers. Let $\mathbb{R}^{n \times m}$ be the set of real matrices of n rows by m columns with $\mathbb{R}^{n \times 1} = \mathbb{R}^n$ being the n th-dimensional real Hilbert space with the inner product $\langle x, y \rangle = x^T y$, where x^T denotes the transpose of x . The norm of an element of \mathbb{R}^n is $\|x\| = \langle x, x \rangle^{1/2}$.

The set of all square summable sequences of \mathbb{R}^n is $\ell_2^n[0, \infty)$. That is, $\{x_k\} \in \ell_2^n[0, \infty)$ if

$$\sum_{k=0}^{\infty} \|x_k\|^2 < \infty.$$

$\ell_2^n[0, \infty)$ is also a Hilbert space with the inner product

$$\langle \{x_k\}, \{y_k\} \rangle = \sum_{k=0}^{\infty} \langle x_k, y_k \rangle.$$

The norm of an element in ℓ_2^n is $\|\{x_k\}\| = \langle \{x_k\}, \{x_k\} \rangle^{1/2}$.

If \mathcal{S} is a subspace of ℓ_2^n , then $\bar{\mathcal{S}}$ denotes the closure and \mathcal{S}^\perp the orthogonal complement. We denote the domain of an operator $G : \ell_2^m \rightarrow \ell_2^n$ by $\mathcal{D}\{G\}$, its range by $\mathcal{R}\{G\}$, and its kernel by $\mathcal{K}\{G\}$. The operator is defined only on its domain and the domain need not be closed. Let G^* denote the adjoint of the operator G . The graph $\mathcal{G}\{G\}$ of an operator $G : \ell_2^m \rightarrow \ell_2^n$ is defined to be

$$\mathcal{G}\{G\} := \begin{bmatrix} I \\ G \end{bmatrix} \mathcal{D}\{G\}.$$

* Received by the editors January 28, 1991; accepted for publication (in revised form) April 24, 1992.

[†] Edison Welding Institute, Columbus, Ohio 43212.

[‡] Department of Engineering, University of Cambridge, Cambridge CB2 1PZ, United Kingdom.

The *inverse graph* $\mathcal{G}^{-1}\{G\}$ of G is

$$\mathcal{G}^{-1}\{G\} := \begin{bmatrix} G \\ I \end{bmatrix} \mathcal{D}\{G\}.$$

An operator G is *bounded* with *norm* $\|G\|$ if $\mathcal{D}\{G\} = \ell_2^m$ and

$$\|G\| = \sup_{x \in \mathcal{D}\{G\}} \frac{\|Gx\|}{\|x\|} < \infty.$$

Let S_m denote the shift operator on ℓ_2^m

$$S_m \begin{bmatrix} x_0 \\ x_1 \\ x_2 \\ \vdots \end{bmatrix} = \begin{bmatrix} 0 \\ x_0 \\ x_1 \\ \vdots \end{bmatrix}$$

for $\{x_k\} \in \ell_2^m[0, \infty)$. An operator G is said to be *shift-invariant* or *time-invariant* if $S_{m+n}\mathcal{G}\{G\} \subset \mathcal{G}\{G\}$.

Let $P_m(k)$ denote the truncation operator on ℓ_2^m

$$P_m(k) \begin{bmatrix} x_0 \\ x_1 \\ \vdots \\ x_{k-1} \\ x_k \\ x_{k+1} \\ \vdots \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ x_k \\ x_{k+1} \\ \vdots \end{bmatrix}$$

for $\{x_k\} \in \ell_2^m[0, \infty)$. An operator G is said to be *causal* if

$$\mathcal{G}\{G\} \cap \begin{pmatrix} P_m(k)\ell_2^m \\ \ell_2^n \end{pmatrix} \subset P_{m+n}(k)\ell_2^{m+n}$$

for all $k \in \mathbb{Z}$. If G is bounded, this condition reduces to $[I - P_n(k)]GP_m(k) = 0$ for all $k \in \mathbb{Z}$.

Consider the feedback system in Fig. 1, which we denote by $\{G, F\}$. The operators $G: \ell_2^m \rightarrow \ell_2^n$ and $F: \ell_2^n \rightarrow \ell_2^m$ represent the plant and the compensator, respectively. The closed-loop system equations are

$$\begin{bmatrix} u_1 \\ u_2 \end{bmatrix} = \begin{bmatrix} I & F \\ G & I \end{bmatrix} \begin{bmatrix} e_1 \\ e_2 \end{bmatrix}.$$

We will assume throughout that G and F are linear and causal, although possibly time-varying and unbounded.

DEFINITION 1.1. The closed-loop system $\{G, F\}$ is *stable* if

$$\begin{bmatrix} I & F \\ G & I \end{bmatrix} : \mathcal{D}\{G\} \times \mathcal{D}\{F\} \longrightarrow \ell_2^m \times \ell_2^n$$

has a bounded inverse defined on $\ell_2^m \times \ell_2^n$. A plant G is *stabilizable* if there exists a compensator F such that $\{G, F\}$ is stable.

FIG. 1. Standard feedback configuration.

The following result was proved in [6] for the case of linear systems defined over $\ell_2[0, \infty)$.

THEOREM 1.2. *Suppose the closed-loop system $\{G, F\}$ is stable. Then the operator*

$$\begin{bmatrix} I & F \\ G & I \end{bmatrix}^{-1} : \ell_2^m \times \ell_2^n \longrightarrow \mathcal{D}\{G\} \times \mathcal{D}\{F\}$$

is causal.

Proof. Since the mapping

$$K := \begin{bmatrix} I & F \\ G & I \end{bmatrix}$$

is causal, it induces a well-defined linear map from a subspace of $\ell_2^{m+n}[0, k]$ onto $\ell_2^{m+n}[0, k]$ for all k . This mapping must have a matrix representation and the representation must be square and nonsingular, otherwise it cannot be onto. Now suppose that

$$H := \begin{bmatrix} I & F \\ G & I \end{bmatrix}^{-1}$$

is not causal. Then there exists $x, y \in \ell_2^{m+n}$ such that $y = Hx$, with $(I - P_{m+n}(k+1))x = 0$ and $(I - P_{m+n}(k+1))y \neq 0$ for some k . However, $x = Ky$, so the restriction of K to $[0, k]$ must have a kernel. This contradicts the fact that the matrix representation of this restriction is nonsingular. \square

2. Problem description. Coprime factorizations of linear, time-invariant systems have been extensively studied in recent years. The following theorem summarizes several results that have been obtained for the case of linear systems on $\ell_2[0, \infty)$ or $L_2[0, \infty)$ (the continuous-time Lebesgue 2-space). These results are expressed in terms of factorizations of the matrix transfer function over the space H_∞ (the standard Hardy space of the disk or right half plane, respectively). See [3], [18], [17], [10], [15] and the references therein for further details.

THEOREM 2.1. *A linear, time-invariant plant with transfer-function G (either continuous-time or discrete-time) is stabilizable if and only if there exists functions $M, N, X, Y, \widetilde{M}, \widetilde{N}, \widetilde{X}$, and $\widetilde{Y} \in H_\infty$ with*

$$(1) \quad G = NM^{-1} = \widetilde{M}^{-1}\widetilde{N}$$

such that the following double Bezout identity holds

$$(2) \quad \begin{bmatrix} Y & X \\ -\widetilde{N} & \widetilde{M} \end{bmatrix} \begin{bmatrix} M & -\widetilde{X} \\ N & \widetilde{Y} \end{bmatrix} = \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix}.$$

Also, a linear, time-invariant compensator F stabilizes G if and only if

$$(3) \quad \begin{aligned} F &= (-\widetilde{X} - MQ) (\widetilde{Y} - NQ)^{-1} \\ &= (Y - Q\widetilde{N})^{-1} (-X - Q\widetilde{M}) \end{aligned}$$

for some $Q \in H_\infty$.

Several articles have appeared in the literature exploring similar factorizations for time-varying systems or nonlinear systems. Feintuch [4] found a necessary condition for the existence of coprime factorizations for discrete-time systems. Also, an example was presented of a plant that has no coprime factorization. Hammer [9] developed a framework for coprime factorizations for discrete-time, nonlinear systems on ℓ_∞ (see also [8]). Verma [16] examined fractional representations for nonlinear, time-varying systems in a general setting that included continuous-time systems. In both [9], [16], the existence of strong coprime factorizations for both the plant and the compensator was assumed. Thus far, the question of whether all stabilizable plants have strong coprime factorizations has remained unresolved. However, for the set of plants that can be realized by a finite set of state equations, such results do exist. Poolla and Khargonekar [12] examined linear, discrete-time, time-varying, finite-dimensional plants and proved the existence of coprime factorizations for stabilizable plants. Rotea and Khargonekar in [13] proved the existence of coprime factorizations for continuous-time, finite-dimensional, stabilizable plants. However, there are many infinite-dimensional (distributed parameter) plants that do not satisfy this criteria.

In this paper, we develop an alternate, but equivalent framework to the coprime factorization in previous work. In an operator-theoretic approach to coprime factorization, we work with products of operators in the form NM^{-1} and $\widetilde{M}^{-1}\widetilde{N}$. The terms M^{-1} and \widetilde{M}^{-1} can be unbounded and we must ensure that the domains and ranges are properly aligned so that the products are defined. Although this is not an insurmountable difficulty, we prefer to work with graphs of unstable systems and their representations in this paper.

DEFINITION 2.2. A plant G has a *right representation* $\begin{bmatrix} M \\ N \end{bmatrix}$ if M and N are causal, bounded operators such that

$$\mathcal{G}\{G\} = \mathcal{R} \left\{ \begin{bmatrix} M \\ N \end{bmatrix} \right\}.$$

The right representation is a *strong right representation* if it has a causal, bounded left inverse. If the representation has the property that $M^*M + N^*N = I$, then the representation is said to be normalized.

DEFINITION 2.3. A plant G has a *left representation* $\begin{bmatrix} -\widetilde{N} & \widetilde{M} \end{bmatrix}$ if \widetilde{M} and \widetilde{N} are causal, bounded operators such that

$$\mathcal{G}\{G\} = \mathcal{K} \left\{ \begin{bmatrix} -\widetilde{N} & \widetilde{M} \end{bmatrix} \right\}.$$

The left representation is a *strong left representation* if it has a causal, bounded right inverse. If the representation has the property that $\widetilde{M}\widetilde{M}^* + \widetilde{N}\widetilde{N}^* = I$, then the representation is said to be normalized.

The main goal of this paper is to show that the existence of strong right and left representations is equivalent to stabilizability for linear, causal, discrete-time systems. The proof of existence will make use of certain results of Arveson on inner/outer factorizations in nest algebras. The key technical step involves the factorization of the *adjoint* of a certain causal, bounded operator, which can be viewed as belonging to a nest algebra of *anticausal* operators. The paper goes on to develop the Youla parametrization for stabilizable systems in the form of strong representations of graphs. Some implications of the Youla parametrization theorem are examined and an example of Feintuch is proven to be not stabilizable. It is also proven that if a time-invariant plant is not stabilizable with a time-invariant compensator, then it is not stabilizable with a time-varying compensator. Finally, the problems of extending our proof to continuous-time plants is examined, a necessary condition for stabilizability is given, and a continuous-time, time-invariant plant example of Shefi is proven to be not stabilizable. The paper is organized as follows. In §3 some background on nest algebras is given; in §4 the main results are proven; in §5 implications of the Youla parametrization are presented; and in §6 the case of continuous-time plants is discussed.

3. Nest algebras and inner/outer factorizations. The study of linear, causal systems is aided by some theorems in nest algebras. Nest algebras view the inputs and outputs of the system as a chain of subspaces. The only requirement is that the subspaces be linearly ordered (nested). For example, we can write $\ell_2^m[0, \infty) = \cup_{k=0}^{\infty} \mathcal{M}_k$, where $\mathcal{M}_k = P_m(k)\ell_2^m$ and $\mathcal{M}_0 \supset \mathcal{M}_1 \cdots \supset \mathcal{M}_k \supset \mathcal{M}_{k+1} \cdots \supset 0$. Each of these subspaces has an associated orthogonal projection operator $\Pi_{\mathcal{M}_k}$ and the set of projection operators determines an algebra of operators such that $[I - \Pi_{\mathcal{M}_k}]G\Pi_{\mathcal{M}_k} = 0$ for all $k \in \mathbb{Z}$. In our language, this nest algebra is the set of all bounded, causal operators $G : \ell_2^m \rightarrow \ell_2^m$.

A different choice of subspaces yields a different set of operators in the nest algebra. As a second example consider, $\ell_2^m[0, \infty) = \cup_{k=0}^{\infty} \mathcal{M}_k^*$, where $\mathcal{M}_k^* = [I - P_m(k)]\ell_2^m$ and $0 \subset \mathcal{M}_0^* \subset \mathcal{M}_1^* \cdots \subset \mathcal{M}_k^* \subset \mathcal{M}_{k+1}^* \cdots$. Each of these subspaces has an associated orthogonal projection operator $\Pi_{\mathcal{M}_k^*}$ and the set of projection operators determines an algebra of operators such that $[I - \Pi_{\mathcal{M}_k^*}]G^*\Pi_{\mathcal{M}_k^*} = 0$ for all $k \in \mathbb{Z}$. Note that this nest algebra is the set of all bounded, anticausal operators $G^* : \ell_2^m \rightarrow \ell_2^m$. Also, the adjoint of any operator in the first nest algebra is an operator in the second nest algebra.

Similar constructions are possible for the continuous-time case of $L_2^m[0, \infty)$. In this case, the subspaces are indexed by the real numbers and the nest is called a continuous nest.

Arveson in [1] defined inner/outer factorizations for time-varying operators in a nest algebra. The results of Arveson and others are brought together in a unified fashion in [2]. Few of the properties that define inner and outer are used in this paper. However, the existence of inner/outer factorizations with certain properties is crucial to our proofs. For completeness, we include the following definitions. An operator A is *outer* if the range projection $\Pi_{\overline{\mathcal{R}\{A\}}}$ commutes with the subspace projection $\Pi_{\mathcal{M}_k}$ for all k and $A\mathcal{M}_k$ is dense in $\mathcal{M}_k \cap \mathcal{R}\{A\}$. An operator U is *inner* if U is a partial isometry and U^*U commutes with $\Pi_{\mathcal{M}_k}$ for all k . The following theorem can be found in [1, Thm. 3.2, 3.3 and Cor. 1] and [2, Thms. 14.20 and 14.21].

THEOREM 3.1. *Let \mathcal{N} be a nest algebra. If every \mathcal{M}_k has an immediate successor, then every operator $G \in \mathcal{N}$ has an inner/outer factorization $G = UA$ such that $U \in \mathcal{N}$ is inner, $A \in \mathcal{N}$ is outer, $\overline{\mathcal{R}\{G\}} = \overline{\mathcal{R}\{U\}}$, $\overline{\mathcal{R}\{A\}} = \mathcal{K}\{U\}^\perp$, and $\mathcal{K}\{A\} = \mathcal{K}\{G\}$.*

In addition if $G^*G = A^*A = B^*B$ with B outer, then there exists a partial isometry $V \in \mathcal{N} \cap \mathcal{N}^*$ such that $V^*V = \Pi_{\overline{\mathcal{R}\{A\}}}$, $VV^* = \Pi_{\overline{\mathcal{R}\{B\}}}$, $VA = B$ and $G = WB$ is another inner/outer factorization with $W = UV^*$ inner and B outer.

Since the subspace \mathcal{M}_k has an immediate successor \mathcal{M}_{k+1} , the inner/outer factorizations exist for discrete-time systems. However, this is not the case for continuous-time systems and will be discussed in a later section.

The two examples of nest algebras and Theorem 3.1 assume the operators are “square”, i.e., have equal number of inputs and outputs. We need a factorization result for “tall” operators with more outputs than inputs. The extension is accomplished by packing the operator with zero operators such that the new operator is square and using Theorem 3.1. We will also need the following result [2, Thm. 14.19].

THEOREM 3.2. *If $\{\mathcal{M}_k\}$ is a well-ordered nest, then every positive operator Q factors as A^*A where A is outer.*

Applying Theorem 3.1 to the packed operator we obtain

$$G = \begin{bmatrix} G_1 & 0 \\ G_2 & 0 \end{bmatrix} = \begin{bmatrix} U_{11} & U_{12} \\ U_{21} & U_{22} \end{bmatrix} \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix} = UA$$

with U inner and A outer. Since $\mathcal{K}\{G\} = \mathcal{K}\{A\}$, we have

$$G = \begin{bmatrix} G_1 & 0 \\ G_2 & 0 \end{bmatrix} = \begin{bmatrix} U_{11} & U_{12} \\ U_{21} & U_{22} \end{bmatrix} \begin{bmatrix} A_{11} & 0 \\ A_{21} & 0 \end{bmatrix} = UA.$$

We also have that

$$G^*G = A^*A = \begin{bmatrix} A_{11}^*A_{11} + A_{21}^*A_{21} & 0 \\ 0 & 0 \end{bmatrix}.$$

Since $A_{11}^*A_{11} + A_{21}^*A_{21}$ is a positive, square operator, there exists an outer square operator B_{11} such that

$$G^*G = B^*B = \begin{bmatrix} B_{11}^* & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} B_{11} & 0 \\ 0 & 0 \end{bmatrix}$$

and furthermore B is outer in the larger nest algebra.

By Theorem 3.1, there exists an inner W such that $G = WB$. Hence,

$$G = \begin{bmatrix} G_1 & 0 \\ G_2 & 0 \end{bmatrix} = \begin{bmatrix} W_{11} & W_{12} \\ W_{21} & W_{22} \end{bmatrix} \begin{bmatrix} B_{11} & 0 \\ 0 & 0 \end{bmatrix} = WB.$$

Since $\mathcal{K}\{W\}^\perp = \overline{\mathcal{R}\{B\}}$, then

$$G = \begin{bmatrix} G_1 & 0 \\ G_2 & 0 \end{bmatrix} = \begin{bmatrix} W_{11} & 0 \\ W_{21} & 0 \end{bmatrix} \begin{bmatrix} B_{11} & 0 \\ 0 & 0 \end{bmatrix} = WB.$$

By unpacking the above operators, we obtain the following corollary.

COROLLARY 3.3. *Let $G : \ell_2^m \rightarrow \ell_2^n$ ($n \geq m$) be a bounded causal (respectively, anti-causal) operator. Then there exist bounded causal (respectively, anticausal) operators $U : \ell_2^m \rightarrow \ell_2^n$ and $A : \ell_2^m \rightarrow \ell_2^m$ such that $G = UA$, U is a partial isometry, $\overline{\mathcal{R}\{G\}} = \overline{\mathcal{R}\{U\}}$, $\overline{\mathcal{R}\{A\}} = \mathcal{K}\{U\}^\perp$, and $\mathcal{K}\{A\} = \mathcal{K}\{G\}$.*

4. Existence of strong representations. In this section, we prove the main theorem of the paper, which establishes the existence of strong representations for stabilizable systems.

Let G and F be linear and suppose that the closed-loop system $\{G, F\}$ is stable. Then

$$\begin{bmatrix} I & F \\ G & I \end{bmatrix}^{-1} = \begin{bmatrix} (I - FG)^{-1} & -F(I - GF)^{-1} \\ -G(I - FG)^{-1} & (I - GF)^{-1} \end{bmatrix} =: R,$$

where all four elements of R are bounded. This can be seen by writing out the feedback equations with $u_1 = 0$ and $u_2 = 0$ in turn. For the stable (causal) closed-loop system $\{G, F\}$ define the following two operators:

$$(4) \quad P_1 = \begin{bmatrix} I \\ G \end{bmatrix} \begin{bmatrix} (I - FG)^{-1} & -F(I - GF)^{-1} \end{bmatrix}$$

$$(5) \quad P_2 = \begin{bmatrix} F \\ I \end{bmatrix} \begin{bmatrix} -G(I - FG)^{-1} & (I - GF)^{-1} \end{bmatrix}.$$

Note that they are causal and bounded and satisfy

$$\begin{aligned} \begin{bmatrix} I & 0 \\ 0 & -I \end{bmatrix} R &= P_1 - \begin{bmatrix} 0 & 0 \\ 0 & I \end{bmatrix} \\ &= -P_2 + \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix}. \end{aligned}$$

It was pointed out in Foias, Georgiou, and Smith [5] that P_1 is the parallel projection operator onto $\mathcal{G}\{G\}$ along $\mathcal{G}^{-1}\{F\}$. In particular $P_1^2 = P_1$. Also, P_2 is the parallel projection operator onto $\mathcal{G}^{-1}\{F\}$ along $\mathcal{G}\{G\}$ and $P_2^2 = P_2$ with $P_1 + P_2 = I$.

We now present our main theorem, which shows that stabilizability implies the existence of strong representations.

THEOREM 4.1. *Let G and F be causal, discrete-time operators and suppose that the closed-loop system $\{G, F\}$ is stable (and causal). Then there exist bounded, causal operators $M, N, X, Y, \widetilde{M}, \widetilde{N}, \widetilde{X},$ and \widetilde{Y} such that*

$$P_1 = \begin{bmatrix} M \\ N \end{bmatrix} \begin{bmatrix} Y & X \end{bmatrix} \text{ and } P_2 = \begin{bmatrix} -\widetilde{X} \\ \widetilde{Y} \end{bmatrix} \begin{bmatrix} -\widetilde{N} & \widetilde{M} \end{bmatrix}.$$

For any such factorizations, $\begin{bmatrix} M \\ N \end{bmatrix}$ is a strong right representation of G , $\begin{bmatrix} -\widetilde{N} & \widetilde{M} \end{bmatrix}$ is a strong left representation of G , and the double Bezout identity

$$\begin{aligned} \begin{bmatrix} Y & X \\ -\widetilde{N} & \widetilde{M} \end{bmatrix} \begin{bmatrix} M & -\widetilde{X} \\ N & \widetilde{Y} \end{bmatrix} &= \begin{bmatrix} M & -\widetilde{X} \\ N & \widetilde{Y} \end{bmatrix} \begin{bmatrix} Y & X \\ -\widetilde{N} & \widetilde{M} \end{bmatrix} \\ &= \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix} \end{aligned}$$

is satisfied. Further, both right and left representations of G can be taken to be normalized.

Proof. Write

$$P_1 = \begin{bmatrix} I \\ G \end{bmatrix} \begin{bmatrix} A_1 & A_2 \end{bmatrix},$$

where

$$A := \begin{bmatrix} A_1 & A_2 \end{bmatrix} := \begin{bmatrix} (I - FG)^{-1} & -F(I - GF)^{-1} \end{bmatrix}.$$

Since A is bounded and causal, its adjoint A^* is bounded and anti-causal. Applying Corollary 3.3 to A^* we have a factorization

$$A^* = \begin{bmatrix} Y^* \\ X^* \end{bmatrix} V^*,$$

where $\begin{bmatrix} Y^* \\ X^* \end{bmatrix}$ is a partial isometry and $\mathcal{K} \left\{ \begin{bmatrix} Y^* \\ X^* \end{bmatrix} \right\}^\perp = \overline{\mathcal{R}} \{V^*\}$. Taking the adjoint we have

$$A = V \begin{bmatrix} Y & X \end{bmatrix}$$

with V and $\begin{bmatrix} Y & X \end{bmatrix}$ being bounded and causal. We now write

$$P_1 = \begin{bmatrix} V \\ GV \end{bmatrix} \begin{bmatrix} Y & X \end{bmatrix} =: \begin{bmatrix} M \\ N \end{bmatrix} \begin{bmatrix} Y & X \end{bmatrix}.$$

Observe that $\begin{bmatrix} M \\ N \end{bmatrix}$ is causal since both V and G are causal operators. We now wish to show that $\begin{bmatrix} M \\ N \end{bmatrix}$ is bounded. Since the adjoint of a partial isometry is a partial isometry, $\begin{bmatrix} Y & X \end{bmatrix}$ is a partial isometry and

$$I - \begin{bmatrix} Y & X \end{bmatrix} \begin{bmatrix} Y^* \\ X^* \end{bmatrix}$$

is an orthogonal projection onto

$$\begin{aligned} \overline{\mathcal{R}} \left\{ \begin{bmatrix} Y & X \end{bmatrix} \right\}^\perp &= \mathcal{K} \left\{ \begin{bmatrix} Y^* \\ X^* \end{bmatrix} \right\} \\ &= \overline{\mathcal{R}} \{V^*\}^\perp = \mathcal{K} \{V\} = \mathcal{K} \left\{ \begin{bmatrix} M \\ N \end{bmatrix} \right\}. \end{aligned}$$

Hence,

$$\begin{aligned} &\begin{bmatrix} M \\ N \end{bmatrix} \\ &= \begin{bmatrix} M \\ N \end{bmatrix} \begin{bmatrix} Y & X \end{bmatrix} \begin{bmatrix} Y^* \\ X^* \end{bmatrix} + \begin{bmatrix} M \\ N \end{bmatrix} \left\{ I - \begin{bmatrix} Y & X \end{bmatrix} \begin{bmatrix} Y^* \\ X^* \end{bmatrix} \right\} \\ (6) \quad &= P_1 \begin{bmatrix} Y^* \\ X^* \end{bmatrix} \end{aligned}$$

and so $\begin{bmatrix} M \\ N \end{bmatrix}$ is bounded because it is the product of two bounded operators. We also deduce from (6) and the fact that

$$\mathcal{R} \left\{ \begin{bmatrix} Y^* \\ X^* \end{bmatrix} \right\} \perp \mathcal{K} \left\{ \begin{bmatrix} Y & X \end{bmatrix} \right\}$$

that

$$\mathcal{R} \left\{ \begin{bmatrix} M \\ N \end{bmatrix} \right\} = \mathcal{R} \{P_1\} = \mathcal{G} \{G\}.$$

Thus, $\begin{bmatrix} M \\ N \end{bmatrix}$ is a right representation of G .

Similar reasoning for P_2 yields the factorization

$$P_2 = \begin{bmatrix} -\tilde{X} \\ \tilde{Y} \end{bmatrix} \begin{bmatrix} -\tilde{N} & \tilde{M} \end{bmatrix},$$

where the operators \tilde{M} , \tilde{N} , \tilde{X} , and \tilde{Y} are causal and bounded and $\begin{bmatrix} -\tilde{N} & \tilde{M} \end{bmatrix}$ is a left representation of G .

Now consider *any* bounded, causal M , N , X , Y , \tilde{M} , \tilde{N} , \tilde{X} , and \tilde{Y} such that

$$P_1 = \begin{bmatrix} M \\ N \end{bmatrix} \begin{bmatrix} Y & X \end{bmatrix}$$

and

$$P_2 = \begin{bmatrix} -\tilde{X} \\ \tilde{Y} \end{bmatrix} \begin{bmatrix} -\tilde{N} & \tilde{M} \end{bmatrix}.$$

Then

$$\begin{aligned} & \begin{bmatrix} M & -\tilde{X} \\ N & \tilde{Y} \end{bmatrix} \begin{bmatrix} Y & X \\ -\tilde{N} & \tilde{M} \end{bmatrix} \\ &= \begin{bmatrix} M \\ N \end{bmatrix} \begin{bmatrix} Y & X \end{bmatrix} + \begin{bmatrix} -\tilde{X} \\ \tilde{Y} \end{bmatrix} \begin{bmatrix} -\tilde{N} & \tilde{M} \end{bmatrix} \\ &= P_1 + P_2 = I. \end{aligned}$$

Both the matrix operators on the left-hand side of the above equation are causal, bounded operators on ℓ_2^{m+n} . They therefore have lower triangular matrix representations. Since their product is equal to the identity, the diagonal blocks must all be nonsingular. Hence, neither operator has a kernel and so they are inverses of each other. Thus,

$$\begin{bmatrix} Y & X \\ -\tilde{N} & \tilde{M} \end{bmatrix} \begin{bmatrix} M & -\tilde{X} \\ N & \tilde{Y} \end{bmatrix} = \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix}$$

and the double Bezout identity is satisfied. Since $\begin{bmatrix} -\tilde{X} \\ \tilde{Y} \end{bmatrix}$ is left invertible, it has no kernel and

$$\mathcal{G}\{G\} = \mathcal{K}\{P_2\} = \mathcal{K}\left\{\begin{bmatrix} -\tilde{N} & \tilde{M} \end{bmatrix}\right\}.$$

Hence, $\begin{bmatrix} -\tilde{N} & \tilde{M} \end{bmatrix}$ is a strong left representation of G . Similarly, since $\begin{bmatrix} Y & X \end{bmatrix}$ is right invertible,

$$\mathcal{G}\{G\} = \mathcal{R}\{P_1\} = \mathcal{R}\left\{\begin{bmatrix} M \\ N \end{bmatrix}\right\}$$

and so $\begin{bmatrix} M \\ N \end{bmatrix}$ is a strong right representation of G .

Finally, note that, for *any* strong right representation of G , we can inner/outer factorize

$$\begin{bmatrix} M \\ N \end{bmatrix} = \begin{bmatrix} M_1 \\ N_1 \end{bmatrix} U.$$

Moreover, $\begin{bmatrix} M_1 \\ N_1 \end{bmatrix}$ is also left invertible and has range $\mathcal{G}\{G\}$. Since $\begin{bmatrix} M_1 \\ N_1 \end{bmatrix}$ is a partial isometry it must be a *normalized* strong representation of G . Similarly, a *normalized* left representation can be obtained from an arbitrary strong representation by means of an inner/outer factorization on $\begin{bmatrix} -\tilde{N}^* \\ \tilde{M}^* \end{bmatrix}$. \square

In [15], in the time-invariant case, reduction of fractional representations to co-prime representations was achieved by *two* inner/outer factorizations (one on the H_∞ matrix $\begin{bmatrix} M \\ N \end{bmatrix}$ and the other on the transpose of this matrix). It is easy to check that both these factorizations are necessary in general. It is interesting to note that a similar reduction was achieved in the proof of the above theorem by means of just *one* inner/outer factorization of the adjoint operator in the star algebra.

THEOREM 4.2 (Youla parametrization). *Let G be a discrete-time, causal, possibly time-varying plant G that is stabilizable (i.e., $\{G, F\}$ is stable and causal for some F). Consider any bounded, causal operators $M, N, X, Y, \tilde{M}, \tilde{N}, \tilde{X}$, and \tilde{Y} with $\begin{bmatrix} M \\ N \end{bmatrix}$ a strong right representation of G and $\begin{bmatrix} -\tilde{N} & \tilde{M} \end{bmatrix}$ a strong left representation of G such that the following double Bezout identity holds*

$$\begin{bmatrix} Y & X \\ -\tilde{N} & \tilde{M} \end{bmatrix} \begin{bmatrix} M & -\tilde{X} \\ N & \tilde{Y} \end{bmatrix} = \begin{bmatrix} M & -\tilde{X} \\ N & \tilde{Y} \end{bmatrix} \begin{bmatrix} Y & X \\ -\tilde{N} & \tilde{M} \end{bmatrix} \\ = \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix}.$$

Then, a compensator F stabilizes G (i.e., $\{G, F\}$ is stable and causal for F) if and only if F has a strong right representation

$$\begin{bmatrix} \tilde{Y} - NQ \\ -\tilde{X} - MQ \end{bmatrix}$$

and a strong left representation

$$\begin{bmatrix} X + Q\tilde{M} & Y - Q\tilde{N} \end{bmatrix}$$

for some causal, bounded Q .

Proof. Assume that F stabilizes G . Then F also has a strong left and right representation that satisfy the double Bezout identity. Thus, there exist bounded, causal operators such that

$$\mathcal{G}\{F\} = \mathcal{R}\left\{\begin{bmatrix} M_F \\ N_F \end{bmatrix}\right\} = \mathcal{K}\left\{\begin{bmatrix} -\tilde{N}_F & \tilde{M}_F \end{bmatrix}\right\}$$

and

$$\begin{bmatrix} Y_F & X_F \\ -\tilde{N}_F & \tilde{M}_F \end{bmatrix} \begin{bmatrix} M_F & -\tilde{X}_F \\ N_F & \tilde{Y}_F \end{bmatrix} = \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix}.$$

Define

$$H := \begin{bmatrix} \widetilde{M}_F & -\widetilde{N}_F \end{bmatrix} \begin{bmatrix} M \\ N \end{bmatrix}.$$

Since the left representation of the compensator is right invertible and the right representation of the plant is left invertible, $\mathcal{R}\{[\widetilde{M}_F \ -\widetilde{N}_F]\} = \ell_2^m$, $\mathcal{K}\{[\begin{smallmatrix} M \\ N \end{smallmatrix}]\} = 0$, $\mathcal{R}\{[\begin{smallmatrix} M \\ N \end{smallmatrix}]\} = \mathcal{G}\{G\}$, and $\mathcal{K}\{[\widetilde{M}_F \ -\widetilde{N}_F]\} = \mathcal{G}^{-1}\{F\}$. Because $\{G, F\}$ is stable, we must have $\mathcal{G}\{G\} + \mathcal{G}^{-1}\{F\} = \ell_2^{m+n}$ and $\mathcal{G}\{G\} \cap \mathcal{G}^{-1}\{F\} = 0$. Therefore, $\mathcal{R}\{H\} = \ell_2^m$ and $\mathcal{K}\{H\} = 0$, which means that H has an inverse H^{-1} . We will now establish that H^{-1} is bounded and causal. Define

$$\Phi := \begin{bmatrix} M \\ N \end{bmatrix} H^{-1} \begin{bmatrix} \widetilde{M}_F & -\widetilde{N}_F \end{bmatrix}.$$

Therefore, $\mathcal{K}\{\Phi\} = \mathcal{G}^{-1}\{F\}$, $\mathcal{R}\{\Phi\} = \mathcal{G}\{G\}$, and $\Phi^2 = \Phi$. Thus, Φ is a parallel projection onto $\mathcal{G}\{G\}$ along $\mathcal{G}^{-1}\{F\}$ (which is the bounded, causal operator P_1 defined in terms of the closed-loop operators in (4)). We now write

$$\begin{aligned} \begin{bmatrix} Y & X \end{bmatrix} \Phi \begin{bmatrix} \widetilde{Y}_F \\ -\widetilde{X}_F \end{bmatrix} &= \\ \begin{bmatrix} Y & X \end{bmatrix} \begin{bmatrix} M \\ N \end{bmatrix} H^{-1} \begin{bmatrix} \widetilde{M}_F & -\widetilde{N}_F \end{bmatrix} \begin{bmatrix} \widetilde{Y}_F \\ -\widetilde{X}_F \end{bmatrix} &= H^{-1}, \end{aligned}$$

where the last equality follows from the double Bezout identities. Then H^{-1} is bounded and causal since it is the product of three bounded, causal operators. Hence,

$$\mathcal{G}\{F\} = \mathcal{K}\left\{\begin{bmatrix} -H^{-1}\widetilde{N}_F & H^{-1}\widetilde{M}_F \end{bmatrix}\right\},$$

$$\begin{bmatrix} Y_F & X_F \\ -H^{-1}\widetilde{N}_F & H^{-1}\widetilde{M}_F \end{bmatrix} \begin{bmatrix} M_F & -\widetilde{X}_F H \\ N_F & \widetilde{Y}_F H \end{bmatrix} = \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix},$$

and

$$\begin{bmatrix} H^{-1}\widetilde{M}_F & -H^{-1}\widetilde{N}_F \end{bmatrix} \begin{bmatrix} M \\ N \end{bmatrix} = I.$$

Thus, *without loss of generality*, we can assume

$$\begin{bmatrix} \widetilde{M}_F & -\widetilde{N}_F \end{bmatrix} \begin{bmatrix} M \\ N \end{bmatrix} = I.$$

Since we also have

$$\begin{bmatrix} Y & X \end{bmatrix} \begin{bmatrix} M \\ N \end{bmatrix} = I,$$

then

$$\begin{bmatrix} \widetilde{M}_F - Y & -\widetilde{N}_F - X \end{bmatrix} \begin{bmatrix} M \\ N \end{bmatrix} = 0.$$

Define the causal, bounded operator

$$Q := \begin{bmatrix} \widetilde{M}_F - Y & -\widetilde{N}_F - X \end{bmatrix} \begin{bmatrix} -\widetilde{X} \\ \widetilde{Y} \end{bmatrix}.$$

Then

$$\begin{aligned} \begin{bmatrix} Y - Q\widetilde{N} & X + Q\widetilde{M} \end{bmatrix} &= \begin{bmatrix} Y & X \end{bmatrix} + Q \begin{bmatrix} -\widetilde{N} & \widetilde{M} \end{bmatrix} \\ &= \begin{bmatrix} Y & X \end{bmatrix} + \begin{bmatrix} \widetilde{M}_F - Y & -\widetilde{N}_F - X \end{bmatrix} \begin{bmatrix} -\widetilde{X} \\ \widetilde{Y} \end{bmatrix} \begin{bmatrix} -\widetilde{N} & \widetilde{M} \end{bmatrix} \\ &= \begin{bmatrix} Y & X \end{bmatrix} \\ &\quad + \begin{bmatrix} \widetilde{M}_F - Y & -\widetilde{N}_F - X \end{bmatrix} \left\{ \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix} - \begin{bmatrix} M \\ N \end{bmatrix} \begin{bmatrix} Y & X \end{bmatrix} \right\} \\ &= \begin{bmatrix} \widetilde{M}_F & -\widetilde{N}_F \end{bmatrix} - \left\{ \begin{bmatrix} \widetilde{M}_F - Y & -\widetilde{N}_F - X \end{bmatrix} \begin{bmatrix} M \\ N \end{bmatrix} \right\} \begin{bmatrix} Y & X \end{bmatrix} \\ &= \begin{bmatrix} \widetilde{M}_F & -\widetilde{N}_F \end{bmatrix}. \end{aligned}$$

Since $\begin{bmatrix} X + Q\widetilde{M} & Y - Q\widetilde{N} \end{bmatrix} = \begin{bmatrix} -\widetilde{N}_F & \widetilde{M}_F \end{bmatrix}$, all stabilizing compensators have a strong *left* representation in the form of the Youla parametrization.

Conversely, choose a bounded, causal operator for Q . This yields a compensator F with a *right* representation

$$\mathcal{G}\{F\} = \mathcal{R} \left\{ \begin{bmatrix} \widetilde{Y} - NQ \\ -\widetilde{X} - MQ \end{bmatrix} \right\}.$$

Choose $e_1 \in \mathcal{D}\{G\}$ and $e_2 \in \mathcal{D}\{F\}$ and calculate the closed-loop system inputs as follows:

$$\begin{aligned} \begin{pmatrix} u_1 \\ u_2 \end{pmatrix} &= \begin{bmatrix} I \\ G \end{bmatrix} e_1 + \begin{bmatrix} F \\ I \end{bmatrix} e_2 = \begin{bmatrix} M \\ N \end{bmatrix} w_1 + \begin{bmatrix} -\widetilde{X} - MQ \\ \widetilde{Y} - NQ \end{bmatrix} w_2 \\ &= \begin{bmatrix} M & -\widetilde{X} \\ N & \widetilde{Y} \end{bmatrix} \begin{bmatrix} I & -Q \\ 0 & I \end{bmatrix} \begin{pmatrix} w_1 \\ w_2 \end{pmatrix}. \end{aligned}$$

Because the range of the right representation is the graph of the operator, we are guaranteed that w_1 and w_2 exist.

By direct multiplication of the operators and simplification using the double Bezout identities, we obtain

$$\begin{aligned} &\left\{ \begin{bmatrix} I & Q \\ 0 & I \end{bmatrix} \begin{bmatrix} Y & X \\ -\widetilde{N} & \widetilde{M} \end{bmatrix} \right\} \left\{ \begin{bmatrix} M & -\widetilde{X} \\ N & \widetilde{Y} \end{bmatrix} \begin{bmatrix} I & -Q \\ 0 & I \end{bmatrix} \right\} \\ &= \left\{ \begin{bmatrix} M & -\widetilde{X} \\ N & \widetilde{Y} \end{bmatrix} \begin{bmatrix} I & -Q \\ 0 & I \end{bmatrix} \right\} \left\{ \begin{bmatrix} I & Q \\ 0 & I \end{bmatrix} \begin{bmatrix} Y & X \\ -\widetilde{N} & \widetilde{M} \end{bmatrix} \right\} \\ &= \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix}. \end{aligned}$$

Therefore,

$$\begin{bmatrix} M & -\tilde{X} \\ N & \tilde{Y} \end{bmatrix} \begin{bmatrix} I & -Q \\ 0 & I \end{bmatrix}$$

is a bounded, causal operator with a bounded, causal inverse. Hence,

$$\begin{pmatrix} w_1 \\ w_2 \end{pmatrix} = \begin{bmatrix} I & Q \\ 0 & I \end{bmatrix} \begin{bmatrix} Y & X \\ -\tilde{N} & \tilde{M} \end{bmatrix} \begin{pmatrix} u_1 \\ u_2 \end{pmatrix}$$

and

$$\begin{aligned} \begin{pmatrix} e_1 \\ e_2 \end{pmatrix} &= \begin{bmatrix} M & 0 \\ 0 & \tilde{Y} - NQ \end{bmatrix} \begin{pmatrix} w_1 \\ w_2 \end{pmatrix} \\ &= \begin{bmatrix} M & 0 \\ 0 & \tilde{Y} - NQ \end{bmatrix} \begin{bmatrix} I & Q \\ 0 & I \end{bmatrix} \begin{bmatrix} Y & X \\ -\tilde{N} & \tilde{M} \end{bmatrix} \begin{pmatrix} u_1 \\ u_2 \end{pmatrix} \\ &= \begin{bmatrix} I & F \\ G & I \end{bmatrix}^{-1} \begin{pmatrix} u_1 \\ u_2 \end{pmatrix}. \end{aligned}$$

Thus, $\begin{bmatrix} I & F \\ G & I \end{bmatrix}^{-1}$ is bounded for all bounded Q and the system is closed-loop stable. Hence, all strong *right* representations from the Youla parametrization stabilize the plant.

To complete the proof, we will show that, for the same Q , the strong right and strong left representations correspond to the same operator F . Select an arbitrary, causal, bounded Q . Then the controller defined by

$$\mathcal{G}^{-1}\{F\} = \mathcal{R} \left\{ \begin{bmatrix} -\tilde{X} - MQ \\ \tilde{Y} - NQ \end{bmatrix} \right\}$$

stabilizes G . Furthermore,

$$\begin{bmatrix} M & -\tilde{X} - MQ \\ N & \tilde{Y} - NQ \end{bmatrix}$$

is invertible and has range ℓ_2^{m+n} . Hence,

$$\begin{aligned} \begin{bmatrix} Y - Q\tilde{N} & X + Q\tilde{M} \end{bmatrix} \begin{bmatrix} M & -\tilde{X} - MQ \\ N & \tilde{Y} - NQ \end{bmatrix} \begin{pmatrix} w_1 \\ w_2 \end{pmatrix} &= \begin{pmatrix} 0 \\ 0 \end{pmatrix} \\ \iff \begin{bmatrix} I & 0 \end{bmatrix} \begin{pmatrix} w_1 \\ w_2 \end{pmatrix} &= \begin{pmatrix} 0 \\ 0 \end{pmatrix} \end{aligned}$$

if and only if $w_1 = 0$. Thus

$$\mathcal{K} \left\{ \begin{bmatrix} Y - Q\tilde{N} & X + Q\tilde{M} \end{bmatrix} \right\} = \mathcal{R} \left\{ \begin{bmatrix} -\tilde{X} - MQ \\ \tilde{Y} - NQ \end{bmatrix} \right\}.$$

This establishes the required equality and the proof is complete. \square

5. Implications of the Youla parametrization. In this section, we will prove two theorems that are implied by the Youla parametrization theorem and show that an example given by Feintuch in [4] is not stabilizable.

First, we will prove the following lemma.

LEMMA 5.1. *If a square operator J is bounded and causal with a bounded inverse K , then K is also causal.*

Proof. Because J and K are bounded, each has a matrix representation. Because J is causal, its matrix representation is lower triangular. Hence,

$$J = \begin{bmatrix} J_{00} & 0 & 0 & \cdots \\ J_{10} & J_{11} & 0 & \cdots \\ J_{20} & J_{21} & J_{22} & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{bmatrix}$$

and

$$J^{-1} = K = \begin{bmatrix} K_{00} & K_{01} & K_{02} & \cdots \\ K_{10} & K_{11} & K_{12} & \cdots \\ K_{20} & K_{21} & K_{22} & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{bmatrix}.$$

Because $JK = I$ and all the diagonal blocks are square, we must have $J_{00}K_{00} = I$ and $J_{00}K_{0i} = 0$ for $i > 0$. Thus, $K_{0i} = 0$ for $i > 0$ and we proceed inductively for each row of K to conclude that K is lower triangular and thus, causal. \square

We now present a theorem that can be used to prove that a plant is not stabilizable.

THEOREM 5.2. *If a plant G is stabilizable, then any right (respectively, left) representation that has no kernel (respectively, has full range) is a strong right (respectively, strong left) representation. Furthermore, two strong right (respectively, strong left) representations are related to one another by multiplication on the right (respectively, left) by a bounded, causal, square, invertible operator.*

Proof. Define the right representation of the plant as $\begin{bmatrix} M \\ N \end{bmatrix}$ and the left representation of the plant as $\begin{bmatrix} -\widetilde{N} & \widetilde{M} \end{bmatrix}$. Since the plant is stabilizable, there exists a strong right representation, $\begin{bmatrix} M_1 \\ N_1 \end{bmatrix}$, and a strong left representation, $\begin{bmatrix} -\widetilde{N}_1 & \widetilde{M}_1 \end{bmatrix}$ such that the following double Bezout identity holds:

$$\begin{bmatrix} Y_1 & X_1 \\ -\widetilde{N}_1 & \widetilde{M}_1 \end{bmatrix} \begin{bmatrix} M_1 & -\widetilde{X}_1 \\ N_1 & \widetilde{Y}_1 \end{bmatrix} = \begin{bmatrix} M_1 & -\widetilde{X}_1 \\ N_1 & \widetilde{Y}_1 \end{bmatrix} \begin{bmatrix} Y_1 & X_1 \\ -\widetilde{N}_1 & \widetilde{M}_1 \end{bmatrix} \\ = \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix}.$$

Choose a stabilizing compensator from the Youla parametrization by setting $Q = 0$. Since $\{G, F\}$ is stable, we must have $\mathcal{G}\{G\} + \mathcal{G}^{-1}\{F\} = \ell_2^{m+n}$ and $\mathcal{G}\{G\} \cap \mathcal{G}^{-1}\{F\} = 0$. We also have that $\begin{bmatrix} Y_1 & X_1 \end{bmatrix}$ is right invertible and thus, has full range. Therefore,

$$\mathcal{R} \left\{ \begin{bmatrix} M & -\widetilde{X}_1 \\ N & \widetilde{Y}_1 \end{bmatrix} \right\} = \ell_2^{m+n},$$

$$\mathcal{K} \left\{ \begin{bmatrix} M & -\widetilde{X}_1 \\ N & \widetilde{Y}_1 \end{bmatrix} \right\} = 0,$$

$$\mathcal{K} \left\{ \begin{bmatrix} Y_1 & X_1 \\ -\widetilde{N} & \widetilde{M} \end{bmatrix} \right\} = 0,$$

and we can write

$$\begin{aligned} \begin{bmatrix} Y_1 & X_1 \\ -\widetilde{N} & \widetilde{M} \end{bmatrix} \begin{bmatrix} M & -\widetilde{X}_1 \\ N & \widetilde{Y}_1 \end{bmatrix} &= \begin{bmatrix} Y_1 M + X_1 N & 0 \\ 0 & \widetilde{N} \widetilde{X}_1 + \widetilde{M} \widetilde{Y}_1 \end{bmatrix} \\ &=: \begin{bmatrix} J_1 & 0 \\ 0 & J_2 \end{bmatrix} =: J. \end{aligned}$$

Because $\begin{bmatrix} M & -\widetilde{X}_1 \\ N & \widetilde{Y}_1 \end{bmatrix}$ has full range, we have

$$\begin{aligned} \mathcal{R}\{J_1\} &= \mathcal{R}\{Y_1 M + X_1 N\} = \mathcal{R} \left\{ \begin{bmatrix} Y_1 & X_1 \end{bmatrix} \begin{bmatrix} M & -\widetilde{X}_1 \\ N & \widetilde{Y}_1 \end{bmatrix} \right\} \\ &= \mathcal{R} \left\{ \begin{bmatrix} Y_1 & X_1 \end{bmatrix} \right\} = \ell_2^m. \end{aligned}$$

Similarly $\mathcal{R}\{J_2\} = \ell_2^n$, and so $\mathcal{R}\{J\} = \ell_2^{m+n}$. We also have that $\mathcal{K}\{J\} = 0$, so J is one-to-one and onto. A consequence of the open mapping theorem is [14, Thm. 5.10], a bounded operator that is one-to-one and maps a Banach space onto a Banach space has a bounded inverse. Therefore, J^{-1} exists and is bounded. By the lemma, J^{-1} is also causal as are J_1^{-1} and J_2^{-1} .

The first part of the theorem now follows by noting that

$$\begin{bmatrix} J_1^{-1} Y_1 & J_1^{-1} X_1 \\ -\widetilde{N} & \widetilde{M} \end{bmatrix} \begin{bmatrix} M & -\widetilde{X}_1 J_2^{-1} \\ N & \widetilde{Y}_1 J_2^{-1} \end{bmatrix} = \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix}.$$

Thus $\begin{bmatrix} M \\ N \end{bmatrix}$ and $\begin{bmatrix} -\widetilde{N} & \widetilde{M} \end{bmatrix}$ have left and right inverses, respectively.

To prove the second part of the theorem, we note that

$$\begin{bmatrix} Y_1 & X_1 \\ -J_2^{-1} \widetilde{N} & J_2^{-1} \widetilde{M} \end{bmatrix} \begin{bmatrix} M J_1^{-1} & -\widetilde{X}_1 \\ N J_1^{-1} & \widetilde{Y}_1 \end{bmatrix} = \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix}$$

and define

$$\begin{aligned} \Psi &:= \begin{bmatrix} M J_1^{-1} & -\widetilde{X}_1 \\ N J_1^{-1} & \widetilde{Y}_1 \end{bmatrix} \begin{bmatrix} Y_1 & X_1 \\ -J_2^{-1} \widetilde{N} & J_2^{-1} \widetilde{M} \end{bmatrix} \\ &= \begin{bmatrix} M & -\widetilde{X}_1 \\ N & \widetilde{Y}_1 \end{bmatrix} \begin{bmatrix} J_1^{-1} & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} I & 0 \\ 0 & J_2^{-1} \end{bmatrix} \begin{bmatrix} Y_1 & X_1 \\ -\widetilde{N} & \widetilde{M} \end{bmatrix}. \end{aligned}$$

Since $\mathcal{K}\{\Psi\} = 0$ and $\Psi^2 = \Psi$, then $\Psi = I$. By direct computation we have

$$\begin{bmatrix} Y_1 & X_1 \\ -J_2^{-1} \widetilde{N} & J_2^{-1} \widetilde{M} \end{bmatrix} \begin{bmatrix} M_1 & -\widetilde{X}_1 \\ N_1 & \widetilde{Y}_1 \end{bmatrix} = \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix}.$$

Since inverses are unique, we have

$$\begin{bmatrix} -J_2^{-1}\tilde{N} & J_2^{-1}\tilde{M} \end{bmatrix} = \begin{bmatrix} -\tilde{N}_1 & \tilde{M}_1 \end{bmatrix} \text{ and } \begin{bmatrix} MJ_1^{-1} \\ NJ_1^{-1} \end{bmatrix} = \begin{bmatrix} M_1 \\ N_1 \end{bmatrix}. \quad \square$$

We now apply the above result to show that an example presented by Feintuch in [4] is not stabilizable. Consider the following single-input, single-output, unbounded operator

$$G = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 \\ 0 & 2 & 0 & 0 & 0 & \cdots \\ 0 & 0 & 3 & 0 & 0 \\ 0 & 0 & 0 & 4 & 0 \\ & \vdots & & & \ddots \end{bmatrix}.$$

Let

$$M = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1/2 & 0 & 0 & 0 \\ 0 & 0 & 1/3 & 0 & 0 & \cdots \\ 0 & 0 & 0 & 1/4 & 0 \\ 0 & 0 & 0 & 0 & 1/5 \\ & \vdots & & & \ddots \end{bmatrix}$$

and

$$N = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & \cdots \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ & \vdots & & & \ddots \end{bmatrix}.$$

It can be seen that $\begin{bmatrix} M \\ N \end{bmatrix}$ is a right representation of G . In addition, $\mathcal{K}\{\begin{bmatrix} M \\ N \end{bmatrix}\} = 0$. Following Feintuch[4], assume the existence of a bounded, causal left inverse $\begin{bmatrix} Y & X \end{bmatrix}$. Since N has zeros on its diagonal, XN will also have zeros on its diagonal. Therefore, YM must have ones on its diagonal. This implies that the diagonal of Y is $\{1, 2, 3, 4, \dots\}$, which implies that Y is unbounded. Thus, $\begin{bmatrix} M \\ N \end{bmatrix}$ has no left inverse. By Theorem 5.2, if G is stabilizable, then $\begin{bmatrix} M \\ N \end{bmatrix}$ must have a left inverse. Thus, G is not stabilizable.

Finally, we prove the following theorem about time-invariant systems.

THEOREM 5.3. *Let G be time-invariant and causal. If G is not stabilizable with a time-invariant, causal compensator F , then it is not stabilizable with a time-varying, causal F .*

Proof. In this proof we will be changing our viewpoint between time and frequency domain several times. Thus, we present the following notation. Let M be a shift-invariant operator in the time domain and $\mathbf{M}(z)$ be the corresponding H_∞ matrix multiplication operator. Also, let $y(t)$ be a signal of finite energy in the time domain and $\mathbf{y}(z)$ be the corresponding H_2 vector function.

In the first part of the proof, we construct a sequence of inputs to show that the right representation is not left invertible. The argument used is closely related to a proof in [7, Prop. 7].

From the Beurling-Lax Theorem, we can write (in the frequency domain)

$$\mathcal{G}\{G(z)\} = \begin{bmatrix} M(z) \\ N(z) \end{bmatrix} H_2^m,$$

where $M(z)$ and $N(z)$ are matrices over H_∞ such that

$$M(z)^* M(z) + N(z)^* N(z) = I$$

and H_p^m is the Hardy p -space of vector valued functions on the disc. Since G is not stabilizable by a time-invariant, causal F , $\begin{bmatrix} M(z) \\ N(z) \end{bmatrix}$ is not left invertible as a matrix over H_∞ . This means that $\inf_{|z|<1} \sigma_{\min} \begin{bmatrix} M(z) \\ N(z) \end{bmatrix} = 0$ by the matrix valued Corona (Fuhrmann) theorem. Thus, we can find a sequence z_i with $|z_i| < 1$ and complex m -vectors x_i of unit norm such that $\begin{bmatrix} M(z_i) \\ N(z_i) \end{bmatrix} x_i \rightarrow 0$ as $i \rightarrow \infty$. Construct the $(H_2^m)^\perp = L_2^m \ominus H_2^m$ vectors

$$y_i''(z) = \left(\frac{c_i}{z - z_i} \right) x_i,$$

where c_i are complex constants chosen so that $\|y_i''(z)\|_2 = 1$. Then

$$\begin{aligned} w_i''(z) &:= \begin{bmatrix} M(z) \\ N(z) \end{bmatrix} y_i''(z) \\ &= \begin{bmatrix} M(z_i) \\ N(z_i) \end{bmatrix} y_i''(z) + \begin{bmatrix} M(z) - M(z_i) \\ N(z) - N(z_i) \end{bmatrix} y_i''(z) \\ &=: (w_i'')^-(z) + (w_i'')^+(z), \end{aligned}$$

where $\|w_i''(z)\|_2 = 1$, $(w_i'')^-(z) \in (H_2^m)^\perp$, and $(w_i'')^+(z) \in H_2^m$. Furthermore, $\|(w_i'')^-(t)\|_2 \rightarrow 0$ as $i \rightarrow \infty$.

Consider the $\ell_2^m(-\infty, -1)$ vector corresponding to $y_i''(z)$. There exist normalized truncations $y_i'(t) \in \ell_2^m(-k_i, -1)$ such that $\|y_i'(t)\|_2 = 1$ and

$$w_i'(z) := \begin{bmatrix} M(z) \\ N(z) \end{bmatrix} y_i'(z) =: (w_i')^+(z) + (w_i')^-(z),$$

where $(w_i')^-(z) \in (H_2^m)^\perp$, $(w_i')^+(z) \in H_2^m$, and $\|(w_i')^-(z)\|_2 \rightarrow 0$. This follows since $\begin{bmatrix} M(z) \\ N(z) \end{bmatrix}$ is a bounded operator on L_2^m of the unit circle.

Shifting $y_i'(t)$ yields $y_i(t) \in \ell_2^m(0, k_i - 1)$ with $\|y_i(t)\|_2 = 1$ and

$$w_i(t) := \begin{bmatrix} M \\ N \end{bmatrix} y_i(t) =: w_i^-(t) + w_i^+(t),$$

where $w_i^-(t) \in \ell_2^m(0, k_i - 1)$, $w_i^+(t) \in \ell_2^m(k_i, \infty)$, and $\|w_i^-(t)\|_2 \rightarrow 0$.

The proof now proceeds by contradiction. Suppose G is stabilizable with a time-varying, causal F . Then $\begin{bmatrix} M \\ N \end{bmatrix}$ is a strong right representation of G by Theorem 5.2. Hence, there exists bounded, causal operators Y and X such that

$$\begin{bmatrix} Y & X \end{bmatrix} \begin{bmatrix} M \\ N \end{bmatrix} = I.$$

Let $\| \begin{bmatrix} Y & X \end{bmatrix} \| = c$. Then

$$\begin{aligned} 1 &= \|y_i(t)\|_2 = \| [I - P_m(k_i)] y_i(t) \|_2 \\ &= \left\| [I - P_m(k_i)] \begin{bmatrix} Y & X \end{bmatrix} \begin{bmatrix} M \\ N \end{bmatrix} y_i(t) \right\|_2 \\ &= \left\| [I - P_m(k_i)] \begin{bmatrix} Y & X \end{bmatrix} [I - P_{m+n}(k_i)] \begin{bmatrix} M \\ N \end{bmatrix} y_i(t) \right\|_2 \\ &\leq c \left\| [I - P_{m+n}(k_i)] \begin{bmatrix} M \\ N \end{bmatrix} y_i(t) \right\|_2 = c \|w_i^-(t)\|_2 \rightarrow 0, \end{aligned}$$

which is a contradiction. \square

6. Continuous-time plants. In this section, we will discuss problems encountered in extending our proof to continuous-time plants, give a necessary condition for a linear plant to be stabilizable with a linear compensator, and prove that a continuous-time plant of Shefi is not stabilizable.

Our proof of the equivalence of stabilizability and the existence of strong right and strong left system representations fails for continuous-time plants in two important steps. The first step where the proof fails is that inner/outer factorizations do not exist for continuous-time operators as stated in the following theorem found in [2, Thm. 14.20].

THEOREM 6.1. *Let \mathcal{N} be a nest algebra. If there exists \mathcal{M}_k that has no immediate successor, then there exists an operator $G \in \mathcal{N}$ that does not have an inner/outer factorization.*

For a continuous-time nest algebra, the subspaces have no immediate successor and the inner/outer factorizations may not exist. Thus, our proof cannot be used in the continuous-time case. However, the properties of U that we use in our proof are that U is a partial isometry with $\overline{\mathcal{R}}\{G\} = \overline{\mathcal{R}}\{U\}$ and that $\overline{\mathcal{R}}\{A\} = \mathcal{K}\{U\}^\perp$ and $\mathcal{K}\{A\} = \mathcal{K}\{G\}$. Thus, if a factorization can be found that possesses these properties, this step in the proof would carry over to the continuous-time case.

The second step where our proof fails is in proving

$$\begin{bmatrix} Y & X \\ -\tilde{N} & \tilde{M} \end{bmatrix} \begin{bmatrix} M & -\tilde{X} \\ N & \tilde{Y} \end{bmatrix} = I.$$

In this step, we used the fact that all bounded, causal operators on ℓ_2^m have a lower triangular matrix representation.

The following is a necessary condition for stabilizability in both the continuous-time and discrete-time cases.

THEOREM 6.2. *If a continuous-time or discrete-time plant G is linear, possibly time-varying, and stabilizable, then it has a closed graph.*

Proof. Since G is stabilizable, choose a compensator F such that the closed-loop system $\{G, F\}$ is stable. From (4), the parallel projection P_1 onto $\mathcal{G}\{G\}$ along $\mathcal{G}^{-1}\{F\}$ is defined in terms of the closed-loop operators. Thus,

$$\begin{bmatrix} e_1 \\ y_1 \end{bmatrix} = P_1 \begin{bmatrix} u_1 \\ u_2 \end{bmatrix},$$

where P_1 is a bounded, linear operator that maps ℓ_2^{m+n} onto $\mathcal{G}\{G\}$ and $P_1^2 = P_1$. If $e_1 \in \mathcal{D}\{G\}$ and $y_1 = Ge_1$ then, $\begin{bmatrix} e_1 \\ y_1 \end{bmatrix} = P_1 \begin{bmatrix} e_1 \\ y_1 \end{bmatrix}$. Now consider a Cauchy sequence

$\begin{bmatrix} e_{1i} \\ y_{1i} \end{bmatrix}$ on $\mathcal{G}\{G\}$ with a limit point $\begin{bmatrix} e'_1 \\ y'_1 \end{bmatrix}$. Since P_1 is a bounded, linear operator, it has a closed graph. Thus,

$$\left(\begin{bmatrix} e_{1i} \\ y_{1i} \\ P_1 \begin{bmatrix} e_{1i} \\ y_{1i} \end{bmatrix} \end{bmatrix} \right) = \begin{pmatrix} e_{1i} \\ y_{1i} \\ e_{1i} \\ y_{1i} \end{pmatrix} \rightarrow \begin{pmatrix} e'_1 \\ y'_1 \\ e'_1 \\ y'_1 \end{pmatrix} \in \mathcal{G}\{P_1\}.$$

Hence,

$$\begin{bmatrix} e'_1 \\ y'_1 \end{bmatrix} = P_1 \begin{bmatrix} e'_1 \\ y'_1 \end{bmatrix} \quad \text{and} \quad \begin{bmatrix} e'_1 \\ y'_1 \end{bmatrix} \in \mathcal{G}\{G\}$$

and the graph of G is closed. \square

Note how the plant inherits the property of having a closed graph from the closed graph of the closed-loop system. This is not true for nonlinear systems since there exist stable, nonlinear plants that do not have a closed graph.

We now present a continuous-time, time-invariant plant example by Shefi from [11, Ex. 1.1–1] and prove that it is not stabilizable with any linear, possibly time-varying compensator. Consider a single-input, single-output, continuous-time plant G defined on all piecewise continuous functions over $[0, \infty)$ having only a finite number of simple jump discontinuities in a finite time. For an input x , the output Gx at any time t is the algebraic sum of the jumps of the input x from 0 up to the present time t . Since we are interested only in L_2 signals, the $\mathcal{D}\{G\}$ is the intersection of L_2 with the above piecewise continuous functions that also yield L_2 output functions.

It is easy to show that the plant G is linear and time-invariant. However, we will show that the graph is not closed. First note that if a pulse of finite amplitude and duration is applied to the input, the output is a pulse of the same amplitude and duration. Since the continuous functions are dense in L_2 and the output to any continuous L_2 function is 0, we can construct a Cauchy sequence of continuous functions on $\mathcal{G}\{G\}$ such that the input sequence converges to a pulse and the output sequence is always 0. Thus, the graph is not closed nor is $\overline{\mathcal{G}}\{G\}$ the graph of any operator because $\overline{\mathcal{G}}\{G\}$ has multiple possible output functions for one input function. Since the graph is not closed, the plant is not stabilizable with any linear, possibly time-varying compensator.

AN ALGORITHM FOR A CLASS OF CONTINUOUS LINEAR PROGRAMS*

MALCOLM C. PULLAN†

Abstract. This paper discusses a class of continuous linear programs posed in a function space called separated continuous linear programs (SCLP). A dual linear program and a corresponding discrete approximation are introduced followed by a discussion of their properties. The discrete approximation gives rise to an improvement step which is constructed from any given feasible (nonoptimal) solution for SCLP. A strong duality result follows from this. There are a variety of possible implementations of an algorithm for solving SCLP problems using this improvement step. Finally some computational results are given from one possible implementation.

Key words. continuous linear program, duality, discrete approximation, simplex-like algorithm.

1. Introduction. The following problem,

$$\begin{aligned} \text{CLP: maximize } & \int_0^T c^T(t)x(t) dt \\ \text{subject to } & B(t)x(t) + \int_0^t K(s,t)x(s) ds \leq b(t), \\ & x(t) \geq 0, \quad t \in [0, T], \end{aligned}$$

was first considered by Bellman [7] in 1957 in an attempt to model some economic processes which he called “Bottleneck Processes.” Since then the problem has been studied by a number of authors whose work can be loosely divided into two areas, those concerned with establishing strong duality theorems and those concerned with computational methods.

In the area of duality, Bellman himself established a weak duality result. This was later followed by, for example, Tyndall [19], Levinson [15], and Grinold [12], all of whom gave strong duality results with varying algebraic restrictions on the problem. The dual problems which these authors have considered have all been in the space of bounded measurable functions.

On the computational side, two main approaches can be found. The simpler of the two is to solve the problem via a series of discrete approximations, called discretizations, to the original CLP. Such is the approach taken by Buie and Abrahm [8]. These discrete approximations work by partitioning the interval $[0, T]$ into a finite number of smaller subintervals, normally of equal size. From the point of view of actually solving problems, this approach has had the most success as the solutions for the discretizations converge to the solution for CLP as the discretizations become finer. However, these methods fail to address the infinite-dimensional nature of the problem and this has two major disadvantages. First, the computation times involved can be very large as a result of solving a very large finite-dimensional linear program, and, second, the problem may have an optimal solution of a simple form that is obscured in the discretized version.

These observations have lead a number of authors to attempt to solve the problem directly. The natural approach here has been to extend the simplex method for finite-dimensional linear programs to the continuous-time or infinite-dimensional problem. This involves extending such concepts as “basic solutions,” “dual variables,” and “pivots.” This approach was started by Lehman [14] and continued by Drews [10], Hartberger [13], and Segers [18]. Major progress was not made in this direction until the work of Perold [17], later continued by Anstreicher [6]. The algorithm described by Perold, however, is both complicated and incomplete, reflecting the difficult nature of the problem.

In this paper we consider a subclass of CLP, called separated continuous linear programs SCLP. This is defined as follows (we choose to minimize rather than maximize as this is how most optimization problems are now stated),

$$\begin{aligned}
 \text{SCLP: minimize} \quad & \int_0^T c^T(t)x(t) dt \\
 \text{(1)} \quad & \text{subject to} \quad \int_0^t Gx(s) ds + y(t) = a(t), \\
 \text{(2)} \quad & Hx(t) + z(t) = b(t), \\
 & x(t), y(t), z(t) \geq 0, \quad t \in [0, T].
 \end{aligned}$$

Here $x(t)$, $z(t)$, $b(t)$ and $c(t)$ are bounded measurable functions and $y(t)$ and $a(t)$ are continuous functions. The dimensions of $x(t)$, $y(t)$ and $z(t)$ are n_1 , n_2 , and n_3 , respectively. We let $n = n_1 + n_2 + n_3$ and $\omega^T(t) = (x^T(t), y^T(t), z^T(t))$.

This problem was first introduced by Anderson [1] in an attempt to model job-shop scheduling problems. He gave a preliminary combined primal-dual algorithm and a few simple problems were solved; however, full implementation of an algorithm along these lines proved difficult. In 1986 Anderson and Philpott [4] restricted the problem of SCLP even further to the important class of continuous network programs and developed, for the first time, an algorithm for solving these problems directly on a computer, which addresses the infinite dimensionality of the problem. This is made possible by allowing only piecewise linear components of $a(t)$ and $c(t)$ and piecewise constant $b(t)$.

In this paper we develop an algorithm for solving SCLP under the same piecewise linearity constraints as for the network program. Our algorithm combines elements from both the discrete and simplex method approaches outlined above. Our first step in developing the algorithm is to introduce a dual problem, SCLP* (§2), which, in some sense, contains the one considered by Tyndall [19] and others. A new discretization for SCLP is then introduced (§3), which differs from the standard one. This turns out to be a natural discretization for SCLP*. This is followed by a discussion of its properties, which includes a convergence result for a discrete algorithm. We then establish an improvement step by showing how to construct an improved feasible solution starting from any given feasible (non-optimal) solution for SCLP (§4). This leads to a strong duality result.

Many possible implementations of an algorithm can arise from this approach and an outline is given of some of them in §5. One of these is very similar to the algorithm for networks given in [4]. Finally, some computational results are given from solving two problems using a straightforward (although not very efficient) method. One of these examples shows that it is possible to obtain the exact solution in a finite number of steps. This extends the problem class for which direct infinite-dimensional solutions are available from networks to SCLP.

We now introduce some standard definitions and notation which we will use throughout the remainder of this paper.

DEFINITION 1.

1. A set $P = \{t_0, \dots, t_m\}$ is said to be a *partition* of $[0, T]$ if

$$0 = t_0 < t_1 < \dots < t_m = T.$$

2. A partition Q of $[0, T]$ is said to be a *refinement* of a partition P of $[0, T]$ if $P \subseteq Q$.

3. The *norm*, $\|P\|$, of a partition $P = \{t_0, \dots, t_m\}$, is defined by

$$\|P\| = \max_i (t_i - t_{i-1}).$$

4. We say that a function $f(t)$ is piecewise constant (linear) with a partition $P = \{t_0, \dots, t_m\}$, if $f(t)$ is constant (linear) on $[t_{i-1}, t_i)$ for $i = 1, \dots, m$. We say that f is piecewise constant (linear) on $[0, T]$ if f is piecewise constant (linear) with some partition of $[0, T]$.

5. For any linear program LP we will write $V[\text{LP}]$ for its optimal value.

6. For a function $f(t)$ we will use the notations

$$f(t-) = \lim_{s \rightarrow t-} f(s) \quad \text{and} \quad f(t+) = \lim_{s \rightarrow t+} f(s),$$

when the above limits exist.

2. The dual problem. In this section we introduce a dual linear program for SCLP and give a weak duality result (Lemma 2.1). The dual problem SCLP* is defined as follows

$$\begin{aligned} \text{SCLP*}: \quad & \text{maximize} \quad - \int_0^T d\pi^T(t)a(t) - \int_0^T \eta^T(t)b(t) dt \\ & \text{subject to} \quad c(t) - G^T\pi(t) + H^T\eta(t) \geq 0, \\ & \quad \eta(t) \geq 0, \text{ a.e. on } [0, T], \\ & \quad \pi(t) \text{ monotonic increasing and right continuous} \\ & \quad \text{on } [0, T] \text{ with } \pi(T) = 0. \end{aligned}$$

Here the components of $\eta(t)$ are in $L_1[0, T]$. It will be convenient to write $\theta(t)$ for the complete set of variables of SCLP* and $\psi(t)$ for the left-hand side of the first constraint. Thus

$$\theta^T(t) = (\pi^T(t), \eta^T(t)) \text{ and } \psi(t) = c(t) - G^T\pi(t) + H^T\eta(t).$$

LEMMA 2.1 (Weak duality). $V[\text{SCLP*}] \leq V[\text{SCLP}]$.

Proof. Suppose $\omega(t)$ is feasible for SCLP and $\theta(t)$ is feasible for SCLP*. Then

$$\begin{aligned} & - \int_0^T d\pi^T(t)a(t) - \int_0^T \eta^T(t)b(t) dt \\ & = - \int_0^T d\pi^T(t) \left(\int_0^t Gx(s) ds + y(t) \right) - \int_0^T \eta^T(t)(Hx(t) + z(t)) dt \\ & = \int_0^T (G^T\pi(t) - H^T\eta(t))^T x(t) dt - \int_0^T d\pi^T(t)y(t) - \int_0^T \eta^T(t)z(t) dt, \end{aligned}$$

by a standard result (see Dunford and Schwartz [11, p. 154]). Hence

$$\begin{aligned} & \int_0^T c^T(t)x(t) dt + \int_0^T d\pi^T(t)a(t) + \int_0^T \eta^T(t)b(t) dt \\ &= \int_0^T \psi^T(t)x(t) dt + \int_0^T d\pi^T(t)y(t) + \int_0^T \eta^T(t)z(t) dt \\ &\geq 0, \end{aligned}$$

by the feasibility of $\omega(t)$ and $\theta(t)$. This gives the result. \square

Another dual linear program for SCLP is given in Anderson and Nash [3] (for the form of SCLP that is a maximization rather than a minimization) and is defined as follows:

$$\begin{aligned} \text{SCLP}^*: \text{ maximize } & - \int_0^T a^T(t)u(t) dt - \int_0^T b^T(t)v(t) dt \\ \text{subject to } & c(t) + \int_t^T G^T u(s) ds + H^T v(t) \geq 0, \\ & u(t), v(t) \geq 0, \quad t \in [0, T], \end{aligned}$$

with $u(t)$ and $v(t)$ in the space of bounded measurable functions. It is worth noting that if $\theta(t)$ is feasible for SCLP* and $\pi(t)$ is absolutely continuous, then

$$u(t) = \dot{\pi}(t) \quad \text{and} \quad v(t) = \eta(t),$$

is feasible for SCLP*' and the objective function values are the same in their respective linear programs. Conversely, if $u(t)$ and $v(t)$ are feasible for SCLP*' then

$$\pi(t) = - \int_t^T u(s) ds \quad \text{and} \quad \eta(t) = v(t),$$

is feasible for SCLP* and again the two solutions have the same objective function value in their respective linear programs. Because of the above weak duality result, this implies that previous strong duality results between SCLP and SCLP*', such as those given in Tyndall [19], carry over to SCLP and SCLP* under the same restrictions.

Yet another dual linear program with a corresponding strong duality theorem has been considered by Papageorgiou [16]; however, he restricts the variables of the primal to be of bounded variation. Also, his dual problem has all its variables in the space of functions of bounded variation and this makes it possible to construct a feasible solution for this dual linear program from one for SCLP*. The resulting costs of the two solutions are, however, different.

3. Discretizations. In this section we introduce two discretizations for SCLP, the standard and natural one, DP, and a new, less obvious one, AP. This new discretization will turn out to have many interesting properties; for example we will show that its optimal value provides a lower bound for the optimal value of SCLP. However, unlike DP, a solution for AP does not directly give a feasible solution for SCLP with the same cost, but instead one can be constructed in a fairly simple procedure with cost difference that tends to zero with decreasing partition norm. These ideas will lead to the improvement step for SCLP which we describe in the

next section. The proof of the results in §3.2 will rely heavily on the weak duality result for SCLP and SCLP* established in the previous section.

Before proceeding we must make an assumption on the nature of the functions $a(t)$, $b(t)$ and $c(t)$.

ASSUMPTION 1. *The functions $a(t)$ and $c(t)$ are piecewise linear and the function $b(t)$ is piecewise constant on $[0, T]$.*

We shall assume this restriction throughout the rest of this paper. The possibility of weakening or removing this restriction is still an open question. It is shown in Anderson, Nash, and Perold [2] that if the feasible region for SCLP is bounded then Assumption 1 guarantees the existence of an optimal solution for SCLP in which the components of $x(t)$ are piecewise constant. This leads us to introduce the following assumption, which will occasionally be required.

ASSUMPTION 2. *The feasible region for SCLP is bounded.*

In what follows we will consider a fixed arbitrary partition $P = \{t_0, \dots, t_m\}$ of $[0, T]$ so that $a(t)$ and $c(t)$ are piecewise linear and $b(t)$ is piecewise constant with partition P . Given P , we now let

$$Q = \left\{ t_0, \frac{t_0 + t_1}{2}, t_1, \dots, t_{m-1}, \frac{t_{m-1} + t_m}{2}, t_m \right\},$$

i.e., P with each interval split in half.

3.1. The standard discretization. We now state the standard discretization, $DP(P)$, and give some of its properties. This is the discretization used in the early duality work, such as Tyndall [19], and in the computational results of Buie and Abrham [8].

$$\begin{aligned} DP(P): \quad & \text{minimize} \quad \sum_{i=1}^m (t_i - t_{i-1}) \hat{x}^T(t_{i-1}+) c\left(\frac{t_i + t_{i-1}}{2}\right) \\ & \text{subject to} \quad (t_1 - t_0) G \hat{x}(t_0+) + \hat{y}(t_1) = a(t_1), \\ & \quad (t_i - t_{i-1}) G \hat{x}(t_{i-1}+) + \hat{y}(t_i) - \hat{y}(t_{i-1}) = a(t_i) - a(t_{i-1}), \\ & \quad \quad \quad i = 2, \dots, m, \\ & \quad H \hat{x}(t_{i-1}+) + \hat{z}(t_{i-1}+) = b(t_{i-1}+), \quad i = 1, \dots, m, \\ & \quad \hat{x}(t_{i-1}+), \hat{y}(t_i), \hat{z}(t_{i-1}+) \geq 0, \quad i = 1, \dots, m. \end{aligned}$$

For brevity we will write this in matrix form as

$$\begin{aligned} DP(P): \quad & \text{minimize} \quad \hat{c}_D^T \hat{\omega}_D \\ & \text{subject to} \quad A_D \hat{\omega}_D = \hat{b}_D, \\ & \quad \hat{\omega}_D \geq 0, \end{aligned}$$

for some appropriate matrix A_D and vectors \hat{c}_D and \hat{b}_D . The labelling of the variables as $\hat{x}(t_i)$ and $\hat{y}(t_i)$, etc., is for convenience and does not mean that they explicitly refer to a function but rather in an implicit way as shown in the following definition. For this use we will also define $\hat{y}(t_0) = a(t_0)$.

DEFINITION 2. Let $P = \{t_0, \dots, t_m\}$ be a partition of $[0, T]$. Suppose we have a set of $m + 1$ variables called $\hat{f}(t_0), \hat{f}(t_1), \dots, \hat{f}(t_m)$ (e.g., \hat{y} above), then the function $f(t)$ defined by

$$f(t) = \left(\frac{t_i - t}{t_i - t_{i-1}} \right) \hat{f}(t_{i-1}) + \left(\frac{t - t_{i-1}}{t_i - t_{i-1}} \right) \hat{f}(t_i), \text{ for } t \in [t_{i-1}, t_i], \text{ for } i = 1, \dots, m,$$

is called the *piecewise linear extension* of \hat{f} .

Similarly, if we have a set of $2m$ variables called $\hat{f}(t_0+), \hat{f}(t_1-), \hat{f}(t_1+), \dots, \hat{f}(t_m-)$, then the function $f(t)$ defined by

$$f(t) = \begin{cases} \hat{f}(t_i+), & \text{if } t = t_0, \dots, t_{m-1}, \\ 0, & t = T, \\ \left(\frac{t_i - t}{t_i - t_{i-1}}\right) \hat{f}(t_{i-1}+) + \left(\frac{t - t_{i-1}}{t_i - t_{i-1}}\right) \hat{f}(t_i-), & \text{for } t \in (t_{i-1}, t_i), \\ & i = 1, \dots, m, \end{cases}$$

is also called the *piecewise linear extension* of \hat{f} .

Finally, if we have a set of m variables called $\hat{f}(t_0+), \hat{f}(t_1+), \dots, \hat{f}(t_{m-1}+)$ (e.g., \hat{x} or \hat{z} above), then the function $f(t)$ defined by

$$f(t) = \begin{cases} \hat{f}(t_{m-1}+), & t = T, \\ \hat{f}(t_{i-1}+), & t \in [t_{i-1}, t_i), \text{ for } i = 1, \dots, m, \end{cases}$$

is called the *piecewise constant extension* of \hat{f} .

It is now easy to deduce the following properties of $\text{DP}(P)$.

LEMMA 3.1. Suppose $\hat{\omega}_D$ is feasible for $\text{DP}(P)$. If $x(t)$ and $z(t)$ are the piecewise constant extensions of \hat{x} and \hat{z} , respectively, and $y(t)$ is the piecewise linear extension of \hat{y} then $\omega^T(t) = (x^T(t), y^T(t), z^T(t))$ is feasible for SCLP and

$$(3) \quad \int_0^T c^T(t)x(t) dt = \hat{c}_D^T \hat{\omega}_D.$$

Conversely, if $\omega(t)$ is feasible for SCLP with $x(t)$ piecewise constant with partition P , then $x(t_{i-1}+), y(t_i), z(t_{i-1}+), i = 1, \dots, m$, form a feasible solution $\hat{\omega}_D$ for $\text{DP}(P)$ and (3) holds.

3.2. A new discretization. We now introduce the discretization $\text{AP}(P)$.

$$\begin{aligned} \text{AP}(P): \quad & \text{minimize} \quad \sum_{i=1}^m \left(\frac{t_i - t_{i-1}}{2}\right) (c^T(t_{i-1}+)\hat{x}(t_{i-1}+) + c^T(t_i-)\hat{x}(t_i-)) \\ & \text{subject to} \quad \left(\frac{t_1 - t_0}{2}\right) G\hat{x}(t_0+) + \hat{y}\left(\frac{t_1 + t_0}{2}\right) = a\left(\frac{t_1 + t_0}{2}\right), \\ & \quad \left(\frac{t_i - t_{i-1}}{2}\right) G\hat{x}(t_i-) + \hat{y}(t_i) - \hat{y}\left(\frac{t_i + t_{i-1}}{2}\right) \\ & \quad \quad = a(t_i) - a\left(\frac{t_i + t_{i-1}}{2}\right), \quad i = 1, \dots, m, \\ & \quad \left(\frac{t_i - t_{i-1}}{2}\right) G\hat{x}(t_{i-1}+) + \hat{y}\left(\frac{t_i + t_{i-1}}{2}\right) - \hat{y}(t_{i-1}) \\ & \quad \quad = a\left(\frac{t_i + t_{i-1}}{2}\right) - a(t_{i-1}), \quad i = 2, \dots, m, \\ & \quad H\hat{x}(t_{i-1}+) + \hat{z}(t_{i-1}+) = b(t_{i-1}+), \quad i = 1, \dots, m, \\ & \quad H\hat{x}(t_i-) + \hat{z}(t_i-) = b(t_i-), \quad i = 1, \dots, m, \\ & \quad \hat{x}(t_{i-1}+), \hat{x}(t_i-), \hat{y}(t_i), \hat{y}\left(\frac{t_i + t_{i-1}}{2}\right), \\ & \quad \hat{z}(t_{i-1}+), \hat{z}(t_i-) \geq 0, \quad i = 1, \dots, m, \end{aligned}$$

or, in matrix form,

$$\begin{aligned} \text{AP}(P): \quad & \text{minimize} \quad \hat{c}^T \hat{\omega} \\ & \text{subject to} \quad A\hat{\omega} = \hat{b}, \\ & \quad \hat{\omega} \geq 0, \end{aligned}$$

for some appropriate matrix A and vectors \hat{c} and \hat{b} . Again we define for convenience, $\hat{y}(0) = a(0)$. Note that the constraints of $\text{AP}(P)$ are exactly the same as those for $\text{DP}(Q)$, i.e., for the standard discretization with twice as many points (thus the vectors \hat{b} and \hat{c} are twice the dimension of \hat{b}_D and \hat{c}_D). The important difference between AP and DP is in the costs. Instead of taking the average cost on each interval of the partition we take the cost at the end points. We now state an obvious result showing the connections between feasible solutions of $\text{AP}(P)$ and $\text{DP}(P)$.

LEMMA 3.2. *Suppose $\hat{\omega}_D$ is feasible for $\text{DP}(P)$, then by augmenting $\hat{\omega}_D$ using*

$$\begin{aligned} \hat{x}(t_i-) &= \hat{x}(t_{i-1}+), \\ \hat{y}\left(\frac{t_i + t_{i-1}}{2}\right) &= \frac{\hat{y}(t_i) + \hat{y}(t_{i-1})}{2}, \\ \hat{z}(t_i-) &= \hat{z}(t_{i-1}+), \quad \text{for } i = 1, \dots, m, \end{aligned}$$

we obtain a feasible solution $\hat{\omega}$ for $\text{AP}(P)$ with

$$(4) \quad \hat{c}^T \hat{\omega} = \hat{c}_D^T \hat{\omega}_D.$$

Conversely, if $\hat{\omega}$ is feasible for $\text{AP}(P)$ and $\hat{x}(t_{i-1}+) = \hat{x}(t_i-)$ for $i = 1, \dots, m$, then $\hat{x}(t_{i-1}+)$, $\hat{y}(t_i)$, $\hat{z}(t_{i-1}+)$, $i = 1, \dots, m$, form a feasible solution $\hat{\omega}_D$ for $\text{DP}(P)$ and (4) holds.

Now $\text{AP}(P)$ has as its dual

$$\begin{aligned} \text{AP}^*(P): \quad & \text{maximize} \quad \hat{b}^T \hat{\theta} \\ & \text{subject to} \quad \hat{\theta}^T A \leq \hat{c}. \end{aligned}$$

After making the simplifications that $b(t_{i-1}+) = b(t_i-)$ and

$$a\left(\frac{t_i + t_{i-1}}{2}\right) - a(t_{i-1}) = a(t_i) - a\left(\frac{t_i + t_{i-1}}{2}\right),$$

we can write $\text{AP}^*(P)$ as

$$\begin{aligned} \text{AP}^*(P): \quad & \text{maximize} \quad \hat{\pi}^T(t_0+)a(t_0) \\ & \quad + \sum_{i=1}^m (\hat{\pi}(t_{i-1}+) + \hat{\pi}(t_i-))^T \left(a(t_i) - a\left(\frac{t_i + t_{i-1}}{2}\right) \right) \\ & \quad - \sum_{i=1}^m \left(\frac{t_i - t_{i-1}}{2} \right) (\hat{\eta}(t_{i-1}+) + \hat{\eta}(t_i-))^T b(t_i-) \\ \text{subject to} \quad & c(t_i-) - G^T \hat{\pi}(t_i-) + H^T \hat{\eta}(t_i-) \geq 0, \quad i = 1, \dots, m, \\ & c(t_{i-1}+) - G^T \hat{\pi}(t_{i-1}+) + H^T \hat{\eta}(t_{i-1}+) \geq 0, \quad i = 1, \dots, m, \\ & \hat{\eta}(t_i-), \hat{\eta}(t_{i-1}+) \geq 0, \quad i = 1, \dots, m, \\ & \hat{\pi}(t_i-) - \hat{\pi}(t_{i-1}+) \geq 0, \quad i = 1, \dots, m, \\ & \hat{\pi}(t_i+) - \hat{\pi}(t_i-) \geq 0, \quad i = 1, \dots, m-1, \\ & \hat{\pi}(t_m-) \leq 0. \end{aligned}$$

We now present a series of results concerning AP, AP*, SCLP, and SCLP*, most of which can be verified by straightforward algebra, so we will not include all the details in our proofs. The first result shows that we can construct a feasible solution for SCLP* in a natural way from a feasible solution for AP* with the same cost.

THEOREM 3.3. *Suppose $\hat{\theta}$ is feasible for AP*(P), then $\theta^T(t) = (\pi^T(t), \eta^T(t))$, with $\pi(t)$ and $\eta(t)$ the piecewise linear extensions of $\hat{\pi}$ and $\hat{\eta}$, respectively, is feasible for SCLP*. Moreover,*

$$(5) \quad \hat{b}^T \hat{\theta} = - \int_0^T d\pi^T a(t) - \int_0^T \eta^T(t) b(t) dt.$$

Conversely, if $\theta(t)$ is feasible for SCLP with $\pi(t)$ and $\eta(t)$ piecewise linear with partition P , then $\eta(t_{i-1}+)$, $\eta(t_i-)$, $\pi(t_{i-1}+)$, $\pi(t_i-)$, $i = 1, \dots, m$, form a feasible solution $\hat{\theta}$ for AP*(P) and (5) holds.*

Proof. Suppose $\hat{\theta}$ is feasible for AP*(P). By inspection of the inequalities, $\hat{\theta}^T A \leq \hat{c}$ and by the fact that $\pi(t)$ and $\eta(t)$ are piecewise linear with partition P we have $\psi(t)$, $\eta(t) \geq 0$ for all $t \in [0, T]$ and that $\pi(t)$ is monotonic increasing on $[0, T]$ with $\pi(T) = 0$, i.e., that $\theta(t)$ is feasible for SCLP*. Now by the piecewise linearity of $a(t)$ and $\pi(t)$ we have (with the notation that $\pi(t_m+) = \pi(T)$)

$$\begin{aligned} \int_{(t_{i-1}, t_i)} d\pi^T(t) a(t) &= \frac{1}{2} (\pi(t_i-) - \pi(t_{i-1}+))^T (a(t_i) + a(t_{i-1})), \quad i = 1, \dots, m, \\ \int_{\{t_i\}} d\pi^T(t) a(t) &= (\pi(t_i+) - \pi(t_i-))^T a(t_i), \quad i = 1, \dots, m, \\ \int_{\{t_0\}} d\pi^T(t) a(t) &= 0. \end{aligned}$$

Also as $\eta(t)$ is piecewise linear and $b(t)$ is piecewise constant with partition P we have

$$\int_{t_{i-1}}^{t_i} \eta^T(t) b(t) dt = \left(\frac{t_i - t_{i-1}}{2} \right) (\hat{\eta}(t_{i-1}+) + \hat{\eta}(t_i-))^T b(t_i-), \quad i = 1, \dots, m.$$

The proof that the objective functions of the two linear programs is the same is now a straightforward algebraic exercise.

The proof of the converse is similar. \square

The next result is the analogous result for AP(P) and SCLP. However, the result is not as strong in that a feasible solution for SCLP gives one for AP(P) of the same cost but not all feasible solutions for AP(P) correspond to feasible solutions for SCLP.

THEOREM 3.4. *Suppose $\omega(t)$ is feasible for SCLP with $x(t)$ piecewise constant with partition P . Then $x(t_{i-1}+)$, $x(t_i-)$, $y(t_i)$, $z(t_{i-1}+)$, $z(t_i-)$, $i = 1, \dots, m$, form a feasible solution $\hat{\omega}$ for AP(P). Moreover,*

$$(6) \quad \hat{c}^T \hat{\omega} = \int_0^T c^T(t) x(t) dt.$$

Conversely, if $\hat{\omega}$ is feasible for AP(P) and $\hat{x}(t_{i-1}+) = \hat{x}(t_i-)$ for $i = 1, \dots, m$, then the $\omega(t)$ formed by taking $y(t)$ as the piecewise linear extension of \hat{y} and $x(t)$ and $z(t)$ as the piecewise constant extensions of \hat{x} and \hat{z} , respectively, is feasible for SCLP and (6) holds.

Proof. The result follows immediately from Lemmas 3.1 and 3.2. \square

Using Theorem 3.3 we can now show, by using the strong duality theorem for finite-dimensional linear programming (see, e.g., Dantzig [9]), that the optimal value of the problem $AP(P)$ constructed from a feasible solution for SCLP with $x(t)$ piecewise constant with partition P , provides a lower bound on the optimal value of SCLP.

THEOREM 3.5. *Suppose $\omega(t)$ is feasible for SCLP with $x(t)$ piecewise constant with partition P . Then*

$$V[AP(P)] \leq V[SCLP^*] \leq V[SCLP].$$

Proof. See Fig. 1. By Theorem 3.3 and the duality theorem for finite-dimensional linear programming we have $V[AP(P)] = V[AP^*(P)] \leq V[SCLP^*]$. The result now follows by Lemma 2.1. \square

COROLLARY 3.6. *Suppose $\omega(t)$ is feasible for SCLP and that the corresponding $\hat{\omega}$ is optimal for $AP(P)$, then $\omega(t)$ is optimal for SCLP.*

Proof. By Theorem 3.4 we have

$$V[SCLP] \leq \int_0^T c^T(t)x(t) dt = V[AP(P)],$$

and so the result follows by Theorem 3.5. \square

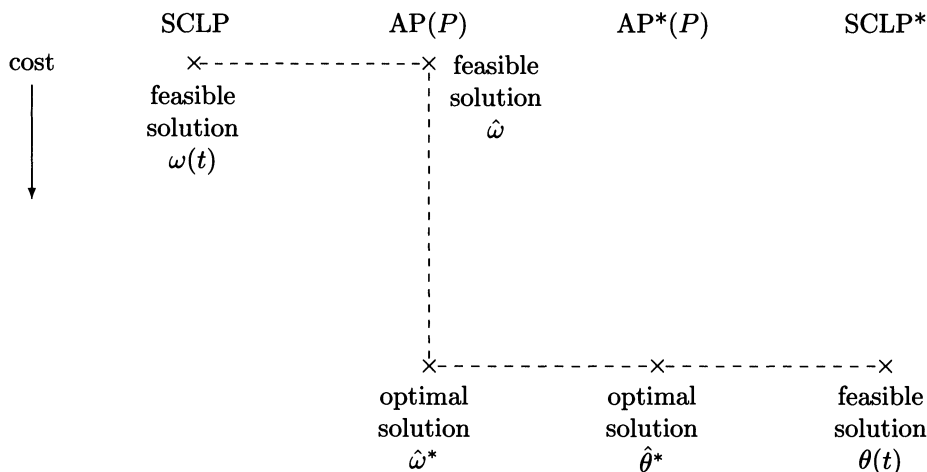

FIG. 1. Cost relationship between solutions of SCLP, $AP(P)$, $AP^*(P)$ and $SCLP^*$.

The next step is to construct a feasible solution for SCLP which in some way is similar to a given one for $AP(P)$. To do this we extend the solution for $AP(P)$ across each interval of the partition making it piecewise constant with partition Q . Suppose $\hat{\omega}$ is feasible for $AP(P)$. Define

$$x(t) = \begin{cases} \hat{x}(t_{i-1}+), & t \in \left[t_{i-1}, \frac{t_i + t_{i-1}}{2} \right), \quad i = 1, \dots, m, \\ \hat{x}(t_i-), & t \in \left[\frac{t_i + t_{i-1}}{2}, t_i \right), \quad i = 1, \dots, m, \\ \hat{x}(t_m-), & t = T. \end{cases}$$

We then define $y(t)$ and $z(t)$ from the constraints of SCLP (i.e., satisfying (1) and (2)) and set

$$\omega^T(t) = (x^T(t), y^T(t), z^T(t)).$$

Finally we let

$$(7) \quad \alpha(\omega) = \hat{c}^T \hat{\omega} - \int_0^T c^T(t)x(t) dt.$$

The next theorem gives the properties of $\omega(t)$.

THEOREM 3.7. $\omega(t)$ is feasible for SCLP. Moreover,

$$\alpha(\omega) = \sum_{i=1}^m \left(\frac{(t_i - t_{i-1})^2}{8} \right) (x(t_i-) - x(t_{i-1}+))^T \dot{c}(t_i-).$$

Proof. It is not difficult to show that $y(t)$ is the piecewise linear extension of \hat{y} in $\hat{\omega}$ and that

$$z(t) = \begin{cases} \hat{z}(t_{i-1}+), & t \in \left[t_{i-1}, \frac{t_i + t_{i-1}}{2} \right), \quad i = 1, \dots, m, \\ \hat{z}(t_i-), & t \in \left[\frac{t_i + t_{i-1}}{2}, t_i \right), \quad i = 1, \dots, m, \\ \hat{z}(t_m), & t = T, \end{cases}$$

and so from this it is clear that $\omega(t)$ is feasible for SCLP. The cost relationship follows after simple integration and algebra. \square

Finally we consider what happens when the partition is made finer and finer. From Theorem 3.7 we are now able to deduce that, under Assumption 2, as the norm of the partition tends to zero, the values of the linear programs SCLP and AP tend to the same value. This gives the result that $V[\text{SCLP}] = V[\text{SCLP}^*]$ as an immediate consequence, however this result will be strengthened in the next section to show that SCLP* actually attains $V[\text{SCLP}^*]$ (Corollary 4.5). We first give an additional lemma about sequences.

LEMMA 3.8. Suppose $\{a_n\}_{n=1}^\infty$ and $\{b_n\}_{n=1}^\infty$ are sequences such that

$$b_n - a_m \geq 0, \quad m, n = 1, 2, \dots, \\ \lim_{n \rightarrow \infty} (b_n - a_n) = 0.$$

then $\lim_{n \rightarrow \infty} a_n$ and $\lim_{n \rightarrow \infty} b_n$ exist and

$$\lim_{n \rightarrow \infty} a_n = \lim_{n \rightarrow \infty} b_n.$$

Proof. Let

$$\varepsilon = \inf_n b_n - \sup_n a_n,$$

then $\varepsilon \geq 0$. Now since $b_n - a_n \geq \varepsilon$ for every n we must have $\varepsilon = 0$. Let $L = \inf_n b_n = \sup_n a_n$. Now since $a_m \leq L \leq b_n$ for all m ,

$$(L - a_n) \leq (b_n - a_n) \quad \text{and} \quad (b_n - L) \leq (b_n - a_n),$$

and so the result follows. \square

COROLLARY 3.9. Suppose Assumption 2 holds and that $\omega(t)$ is feasible for SCLP with $x(t)$ piecewise constant with partition P , then

$$(8) \quad \lim_{\substack{\|Q\| \rightarrow 0 \\ P \subseteq Q}} V[\text{AP}(Q)] = \lim_{\substack{\|Q\| \rightarrow 0 \\ P \subseteq Q}} \int_0^T c^T(t)x_Q(t) dt,$$

where $x_Q(t)$ is obtained from the optimal solution for $\text{AP}(Q)$ as outlined above, and hence

$$(9) \quad \lim_{\substack{\|Q\| \rightarrow 0 \\ P \subseteq Q}} \int_0^T c^T(t) x_Q(t) dt = V[\text{SCLP}] = V[\text{SCLP}^*].$$

Proof. Suppose for any feasible $x(t)$, $\|x(t)\| \leq M$. Also suppose that $\|\dot{c}(t)\| \leq C$ for $t \in [0, T] - P$. Let $Q = \{s_1, \dots, s_k\} \supseteq P$. Then

$$|\alpha(\omega_Q)| \leq \frac{MC}{4} \sum_{i=1}^k (s_i - s_{i-1})^2 \leq \frac{MC\|Q\|T}{4},$$

and so $\alpha(\omega_Q) \rightarrow 0$ as $\|Q\| \rightarrow 0$.

Let $\{Q_n\}_{n=1}^\infty$ be any sequence of partitions with $\lim_{n \rightarrow \infty} \|Q_n\| = 0$ and $P \subseteq Q_n$. Let

$$a_n = V[\text{AP}(Q_n)], \quad \text{and} \quad b_n = \int_0^T c^T(t) x_{Q_n}(t) dt,$$

then by the above we see that $\lim_{n \rightarrow \infty} (b_n - a_n) = 0$. Also by Theorem 3.5 we have $b_n - a_m \geq 0$ for all m and n and so (8) now follows by Lemma 3.8. We now have (9) again by Theorem 3.5. \square

4. Constructing an improved solution. In this section we show how to construct an improved solution for SCLP, if one exists, from some starting feasible solution for SCLP. This will form the basis of an algorithm for solving SCLP. To do this we use the results the previous section. We will again fix the partition P as in the previous section and any reference to AP will denote $\text{AP}(P)$.

We begin by giving an outline of our approach. Any feasible solution for SCLP with $x(t)$ piecewise constant with partition P generates a feasible solution for $\text{AP}(P)$ (Theorem 3.4). If the finite-dimensional program AP is not optimal it is possible to find a solution for AP with strictly improved objective function. From the previous section we are able to construct a feasible solution for SCLP based on this solution in a fairly natural way. We then “patch” this solution together with our old one to produce another solution whose x value is the same as the original one in some time intervals and the same as the one constructed from AP otherwise. If this is done in an appropriate way, we obtain a new feasible solution for SCLP with strictly improved objective function. If, however, the current SCLP solution is optimal for AP, then by Corollary 3.6, our current solution is optimal for SCLP.

Let $\omega^T(t) = (x^T(t), y^T(t), z^T(t))$ be feasible for SCLP with $x(t)$ piecewise constant with partition P . Using the notation of the previous section, let $\hat{\omega}$ denote the corresponding solution for AP constructed from the partition P . Suppose $\hat{\omega}$ is not optimal for AP. Then $\hat{\hat{\omega}}$ exists, feasible for AP, with strictly improved objective function, i.e.,

$$\delta \stackrel{\text{def}}{=} c^T \hat{\hat{\omega}} - c^T \hat{\omega} < 0.$$

Let $\tilde{\omega}^T(t) = (\tilde{x}^T(t), \tilde{y}^T(t), \tilde{z}^T(t))$ be the feasible solution for SCLP generated by $\hat{\hat{\omega}}$ as defined in the previous section. Then $\tilde{\omega}(t)$ is constant on $[t_{i-1}, (t_{i-1} + t_i)/2)$ and on $[(t_{i-1} + t_i)/2, t_i]$ for $i = 1, \dots, m$.

FIG. 2. Construction of $\bar{x}_\varepsilon(t)$.

We now “patch” together $\omega(t)$ and $\tilde{\omega}(t)$ as follows (see Fig. 2). Let

$$\tau = \min_{i=1, \dots, m} \left(\frac{t_i - t_{i-1}}{2} \right),$$

and $\varepsilon \in [0, \tau]$. Define

$$\varepsilon_i = \frac{(t_i - t_{i-1})\varepsilon}{2\tau}.$$

Note that if $\varepsilon = \tau$ then $\varepsilon_i = (t_i - t_{i-1})/2$. Define

$$\bar{x}_\varepsilon(t) = \begin{cases} \tilde{x}(t), & t \in [t_{i-1}, t_{i-1} + \varepsilon_i) \cup [t_i - \varepsilon_i, t_i), \quad i = 1, \dots, m, \\ x(t), & \text{otherwise.} \end{cases}$$

Let $\bar{y}_\varepsilon(t)$ and $\bar{z}_\varepsilon(t)$ be given by the constraints of SCLP, i.e.,

$$\begin{aligned} \int_0^t G\bar{x}_\varepsilon(s) ds + \bar{y}_\varepsilon(t) &= a(t), \\ H\bar{x}_\varepsilon(t) + \bar{z}_\varepsilon(t) &= b(t), \quad t \in [0, T]. \end{aligned}$$

We now claim that $\bar{\omega}_\varepsilon^T(t) = (\bar{x}_\varepsilon^T(t), \bar{y}_\varepsilon^T(t), \bar{z}_\varepsilon^T(t))$ is feasible for SCLP.

Clearly $\bar{x}_\varepsilon(t) \geq 0$ for all $t \in [0, T]$ as $x(t), \tilde{x}(t) \geq 0$ for all $t \in [0, T]$ by the feasibility of $\omega(t)$ and $\tilde{\omega}(t)$. Also for $t \in [t_{i-1} + \varepsilon_i, t_i - \varepsilon_i)$, $\bar{x}_\varepsilon(t) = x(t)$, so $\bar{z}_\varepsilon(t) = z(t)$ for $t \in [t_{i-1} + \varepsilon_i, t_i - \varepsilon_i)$ and for other t , $\bar{x}_\varepsilon(t) = \tilde{x}(t)$, and so $\bar{z}_\varepsilon(t) = \tilde{z}(t)$. Hence $\bar{z}_\varepsilon(t) \geq 0$ for all $t \in [0, T]$, again by the feasibility of $\omega(t)$ and $\tilde{\omega}(t)$.

Thus to establish the feasibility of $\bar{\omega}_\varepsilon(t)$ it remains to show that $\bar{y}_\varepsilon(t) \geq 0$. As $\bar{x}_\varepsilon(t)$ is constant on the intervals $[t_{i-1}, t_{i-1} + \varepsilon_i)$, $[t_{i-1} + \varepsilon_i, t_i - \varepsilon_i)$ and $[t_i - \varepsilon_i, t_i)$ for $i = 1, \dots, m$, $\bar{y}_\varepsilon(t)$ is linear on these intervals, so it is sufficient to show that $\bar{y}_\varepsilon(t_{i-1})$, $\bar{y}_\varepsilon(t_{i-1} + \varepsilon_i)$, $\bar{y}_\varepsilon(t_i - \varepsilon_i)$ and $\bar{y}_\varepsilon(t_i) \geq 0$ for $i = 1, \dots, m$. This is the content of the next lemma.

LEMMA 4.1.

$$(10) \quad \bar{y}_\varepsilon(t_{i-1} + \varepsilon_i) = \left(1 - \frac{\varepsilon}{\tau}\right) y(t_{i-1}) + \frac{\varepsilon}{\tau} \tilde{y}\left(\frac{t_i + t_{i-1}}{2}\right),$$

$i = 1, \dots, m,$

$$(11) \quad \bar{y}_\varepsilon(t_i - \varepsilon_i) = \left(1 - \frac{\varepsilon}{\tau}\right) y(t_i) + \frac{\varepsilon}{\tau} \tilde{y}\left(\frac{t_i + t_{i-1}}{2}\right),$$

$i = 1, \dots, m,$

$$(12) \quad \bar{y}_\varepsilon(t_i) = \left(1 - \frac{\varepsilon}{\tau}\right) y(t_i) + \frac{\varepsilon}{\tau} \tilde{y}(t_i),$$

$i = 0, \dots, m.$

Proof. We establish these equalities by induction. Clearly $\bar{y}_\varepsilon(0) = \tilde{y}(0) = y(0) = a(0)$ so (12) is true for $i = 0$. Assume (12) is true for $i - 1$. We show that (10)–(12) are true for i .

Now $\bar{x}_\varepsilon(t) = \tilde{x}(t)$ on $[t_{i-1}, t_{i-1} + \varepsilon_i]$, so

$$\begin{aligned} \bar{y}_\varepsilon(t_{i-1} + \varepsilon_i) - \bar{y}_\varepsilon(t_{i-1}) &= \tilde{y}(t_{i-1} + \varepsilon_i) - \tilde{y}(t_{i-1}) \\ &= \frac{2\varepsilon_i}{t_i - t_{i-1}} \left[\tilde{y}\left(\frac{t_i + t_{i-1}}{2}\right) - \tilde{y}(t_{i-1}) \right], \end{aligned}$$

as \tilde{y} is linear on $\left[t_{i-1}, \frac{t_i + t_{i-1}}{2}\right]$. Hence

$$\bar{y}_\varepsilon(t_{i-1} + \varepsilon_i) - \bar{y}_\varepsilon(t_{i-1}) = \frac{\varepsilon}{\tau} \left[\tilde{y}\left(\frac{t_i + t_{i-1}}{2}\right) - \tilde{y}(t_{i-1}) \right].$$

So by the assumption that (12) holds for $i - 1$,

$$\bar{y}_\varepsilon(t_{i-1} + \varepsilon_i) = \left(1 - \frac{\varepsilon}{\tau}\right) y(t_{i-1}) + \frac{\varepsilon}{\tau} \tilde{y}\left(\frac{t_i + t_{i-1}}{2}\right),$$

i.e., (10) is satisfied for i .

Similarly, $\bar{x}_\varepsilon(t) = x(t)$ on $[t_{i-1} + \varepsilon_i, t_i - \varepsilon_i]$, so

$$\begin{aligned} \bar{y}_\varepsilon(t_i - \varepsilon_i) - \bar{y}_\varepsilon(t_{i-1} + \varepsilon_i) &= y(t_i - \varepsilon_i) - y(t_{i-1} + \varepsilon_i) \\ &= \left(1 - \frac{2\varepsilon_i}{t_i - t_{i-1}}\right) (y(t_i) - y(t_{i-1})), \end{aligned}$$

again as y is linear on $[t_{i-1}, t_i]$. Hence as (10) is true for i so is (11).

A similar argument shows that (12) is true for i and hence the lemma is established by induction. \square

COROLLARY 4.2. $\bar{\omega}_\varepsilon$ is feasible for all $\varepsilon \in [0, \tau]$.

Proof. We just need to establish that $\bar{y}_\varepsilon(t) \geq 0$ for all $t \in [0, T]$. Now $\bar{y}_\varepsilon(t_i)$ is a convex combination of $y(t_i)$ and $\tilde{y}(t_i)$ and so as $\omega(t)$ and $\tilde{\omega}(t)$ are feasible for SCLP, $y(t_i), \tilde{y}(t_i) \geq 0$. Hence $\bar{y}_\varepsilon(t_i) \geq 0$ for $i = 0, \dots, m$. Similarly, $\bar{y}_\varepsilon(t_{i-1} + \varepsilon_i), \bar{y}_\varepsilon(t_i - \varepsilon_i) \geq 0$ for $i = 1, \dots, m$. The result now follows from the piecewise linearity of \bar{y}_ε . \square

Having established the feasibility of $\bar{\omega}_\varepsilon$ the next step is to show that for small enough ε an improvement in the objective function can always be made. This is the content of the next lemma and following corollary.

LEMMA 4.3.

$$\int_0^T c^T(t) \bar{x}_\varepsilon(t) dt - \int_0^T c^T(t) x(t) dt = \frac{\varepsilon}{\tau} \left(\delta - \frac{\varepsilon \alpha}{\tau} \right),$$

where $\alpha = \alpha(\tilde{\omega})$ as given by (7).

Proof. As $c(t)$ is linear on (t_{i-1}, t_i) for $i = 1, \dots, m$, we have

$$\begin{aligned} \int_{t_{i-1}}^{t_{i-1}+\varepsilon_i} c(t) dt &= \frac{\varepsilon_i}{2} (c(t_{i-1}+) + c(t_{i-1} + \varepsilon_i)) \\ &= \varepsilon_i c(t_{i-1}+) + \frac{\varepsilon_i^2 (t_i - t_{i-1})^2}{8\tau^2} \dot{c}(t_{i-1}). \end{aligned}$$

Similarly,

$$\int_{t_i-\varepsilon_i}^{t_i} c(t) dt = \varepsilon_i c(t_i-) - \frac{\varepsilon_i^2 (t_i - t_{i-1})^2}{8\tau^2} \dot{c}(t_i-).$$

Now for $t \in [0, T)$,

$$\bar{x}_\varepsilon(t) - x(t) = \begin{cases} \tilde{x}(t_{i-1}+) - x(t_{i-1}+), & t \in [t_{i-1}, t_{i-1} + \varepsilon_i), \quad i = 1, \dots, m, \\ \tilde{x}(t_i-) - x(t_i-), & t \in [t_i - \varepsilon_i, t_i), \quad i = 1, \dots, m, \\ 0, & \text{otherwise.} \end{cases}$$

So

$$\begin{aligned} &\int_0^T c^T(t) \bar{x}_\varepsilon(t) dt - \int_0^T c^T(t) x(t) dt \\ &= \sum_{i=1}^m \int_{t_{i-1}}^{t_{i-1}+\varepsilon_i} c^T(t) (\tilde{x}(t) - x(t)) dt + \sum_{i=1}^m \int_{t_i-\varepsilon_i}^{t_i} c^T(t) (\tilde{x}(t) - x(t)) dt \\ &= \sum_{i=1}^m (\tilde{x}(t_{i-1}+) - x(t_{i-1}+))^T \left(\varepsilon_i c(t_{i-1}+) + \frac{\varepsilon_i^2 (t_i - t_{i-1})^2}{8\tau^2} \dot{c}(t_{i-1}) \right) \\ &\quad + \sum_{i=1}^m (\tilde{x}(t_i-) - x(t_i-))^T \left(\varepsilon_i c(t_i-) - \frac{\varepsilon_i^2 (t_i - t_{i-1})^2}{8\tau^2} \dot{c}(t_i-) \right). \end{aligned}$$

The result now follows after a little algebra and the fact that

$$\begin{aligned} \delta &= \hat{c}^T \hat{\tilde{\omega}} - \hat{c}^T \hat{\omega} \\ &= \sum_{i=1}^m \left(\frac{t_i - t_{i-1}}{2} \right) (\tilde{x}(t_{i-1}+) - x(t_{i-1}+))^T c(t_{i-1}+) \\ &\quad + \sum_{i=1}^m \left(\frac{t_i - t_{i-1}}{2} \right) (\tilde{x}(t_i-) - x(t_i-))^T c(t_i-). \quad \square \end{aligned}$$

COROLLARY 4.4. For ε sufficiently small, $\int_0^T c^T(t) \bar{x}_\varepsilon(t) dt < \int_0^T c^T(t) x(t) dt$ and

$$\min_{\varepsilon} \int_0^T c^T(t) \bar{x}_\varepsilon(t) dt - \int_0^T c^T(t) x(t) dt = \begin{cases} \frac{\delta^2}{4\alpha}, & \alpha < 0 \text{ and } \frac{\delta}{2\alpha} < 1, \\ \delta - \alpha, & \text{otherwise,} \end{cases}$$

and occurs at

$$(13) \quad \varepsilon^* = \begin{cases} \frac{\delta\tau}{2\alpha}, & \alpha < 0 \text{ and } \frac{\delta}{2\alpha} < 1, \\ \tau, & \text{otherwise.} \end{cases}$$

We now have a strong duality result. This is the main result in Tyndall [19] proved for the dual SCLP* and via a sequence of discretizations of the form $DP(P_n)$. However, while Tyndall's result is not restricted to problems with piecewise constant $x(t)$, it is restricted to positive G , H , $a(t)$, and $b(t)$. The result was later strengthened by a number of authors, e.g., Grinold [12] and Tyndall [20] but again there is some restriction on the form of the problem.

COROLLARY 4.5 (Strong duality). *Suppose Assumption 2 holds. If $\omega(t)$ is optimal for SCLP then there exists $\theta(t)$ optimal for SCLP* with*

$$\int_0^T c^T(t)x(t) dt = - \int_0^T d\pi^T(t)a(t) - \int_0^T \eta^T(t)b(t) dt.$$

Proof. If $\omega(t)$ is optimal for SCLP then we can assume that $x(t)$ is piecewise constant by a previous remark. The corresponding $\hat{\omega}$ is then optimal for AP, otherwise we can construct an improved solution for SCLP as outlined above. The result now follows by Corollary 3.6. \square

5. Implementations of the algorithm and computational results. We now have all the ingredients for implementing an algorithm to solve SCLP. In this section we outline different possible ways of putting these ingredients together and discuss computational results from one such implementation.

1. *Pure discretization.* Solve $AP(P)$ for some partition P and construct a feasible solution for SCLP as outlined in §3.2. This has two advantages over just solving $DP(P)$. First, by Theorem 3.5, the cost of the AP solution provides a lower bound on the cost of the optimal solution for SCLP. Second, if we have Assumption 2, then by using Theorem 3.7 and Corollary 3.9 we can construct a partition so that the SCLP solution will be within any desired amount of the optimal solution.

2. *Continuous time.* Given a feasible solution for SCLP, construct an improvement as outlined in §4, if possible, repeating until the solution is within a prescribed limit. This has several variations, some of which we outline below.

- By Lemma 3.1, a solution for SCLP generates one for $DP(P)$ for some P at the same cost. $DP(P)$ can then be solved, or at least improved, and this solution used as the starting feasible SCLP solution from which an improved SCLP solution is obtained along the lines of §4. Solving $DP(P)$ completely will produce the best SCLP solution for the partition P .

- By Theorem 3.4, a solution for SCLP generates one for $AP(P)$ for some P at the same cost. Solving $AP(P)$ to completion and using this as the improved $AP(P)$ solution for patching together with the old one also produces a lower bound on the objective function, as was shown in the discrete algorithm above.

- Given the SCLP solution, we construct the AP solution, purify this (i.e., construct a basic feasible solution) and perform one (or only a few) simplex pivots. This is the improved AP solution, which, after patching together with the old one, produces an improved SCLP solution.

It is still not clear which of these implementations will produce the best results. However, one simple change that can be applied to each implementation above does

seem to improve the solution time considerably, as well as improving the convergence of the partition points. This change involves removing unwanted partition points. After completing each iteration of the algorithm we check to see if the new SCLP solution (as well as $\dot{a}(t)$, $b(t)$, and $\dot{c}(t)$) is constant across two or more intervals of the new partition. If it is, then we remove partition points so that there is only one such interval. This will produce a new partition with fewer points and with each point corresponding to a discontinuity in one or more components of $x(t)$, $\dot{a}(t)$, $b(t)$ or $\dot{c}(t)$.

Before proceeding to give computational results we give a brief discussion of the algorithm for networks given in Anderson and Philpott [4]. In this paper the authors give an optimality test followed by a discussion of a simplex-like algorithm for the problem by showing how to perform a pivot when one of the conditions of the optimality test is violated. Two different types of pivot are performed depending on which optimality conditions are violated. These two conditions are called first- and second-order suboptimality, with most pivots arising from the first-order suboptimality case. It can be shown that their optimality test is no more than a statement of our weak duality theorem (Lemma 2.1). Moreover, the pivot for the first-order suboptimality case also corresponds to one possible implementation of our algorithm. We describe this pivot in the context of our SCLP algorithm. The pivot starts off with a basic feasible solution for SCLP (in this case CNP), which is also basic for $AP(P)$ for some P . One simplex pivot is then performed on $AP(P)$ and the solution patched together with the old one to produce a new feasible solution for CNP. A complicated purification step then follows to produce a new basic feasible solution for CNP.

The pivot arising from the second-order suboptimality case, while not one of our implementations, is very similar and so further improvements to the algorithm for CNP could be made by considering the SCLP algorithm discussed here.

The method we use in the examples below is no doubt inefficient but has the advantage of being easy to implement. It follows along the lines of a combination of the first two continuous-time examples given above. Given a partition P , we solve $DP(P)$ to optimality. $AP(P)$ is then solved to optimality and the objective function then provides a bound on the optimal objective function for SCLP. We then combined the DP and AP solutions using the method described in §4 with ε given by (13), to produce a new partition. Finally, unwanted partition points are removed to produce the partition Q . This was the new partition for the next step.

We now present results from solving two simple problems. The first is a network problem and has been solved in Anderson and Philpott [5] using their algorithm for networks. The second is taken from Anderson [1].

Problem 1. $T = 10$, $n_1 = 5$, $n_2 = 8$, $n_3 = 5$.

$$G = \begin{bmatrix} 1 & 1 & 0 & 0 & 0 \\ -1 & 0 & 1 & 1 & 0 \\ 0 & -1 & -1 & 0 & 1 \\ 0 & 0 & 0 & -1 & -1 \\ -1 & -1 & 0 & 0 & 0 \\ 1 & 0 & -1 & -1 & 0 \\ 0 & 1 & 1 & 0 & -1 \\ 0 & 0 & 0 & 1 & 1 \end{bmatrix}, \quad H = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix}.$$

$$a_1(t) = \begin{cases} 4t, & t \in [0, 5], \\ 2(t+5), & t \in [5, 10]. \end{cases} \quad a_2(t) = \begin{cases} t, & t \in [0, 5], \\ 2t-5, & t \in [5, 10]. \end{cases}$$

$$a_3(t) = \begin{cases} -t, & t \in [0, 5], \\ 5-2t, & t \in [5, 10]. \end{cases} \quad a_4(t) = -3t, \\ a_i(t) = \infty, \text{ for } i = 5, 6, 7, 8.$$

$$b_i(t) = \begin{cases} 1, & i = 3, \\ 2, & \text{otherwise.} \end{cases}$$

$$c_1(t) = 10 - \frac{3}{5}t, \quad c_2(t) = 7, \\ c_3(t) = 6 - \frac{3}{5}t, \quad c_4(t) = 4, \\ c_5(t) = 2 + t.$$

The optimal solution is

$$x_1^*(t) = \begin{cases} 1, & t \in [0, 3.75), \\ 2, & t \in [3.75, 5), \\ 1, & t \in [5, 8.75), \\ 0, & t \in [8.75, 10]. \end{cases} \quad x_2^*(t) = 2.$$

$$x_3^*(t) = \begin{cases} 0, & t \in [0, 3.75), \\ 1, & t \in [3.75, 10]. \end{cases} \quad x_4^*(t) = \begin{cases} 2, & t \in [0, 8.75), \\ 1, & t \in [8.75, 10]. \end{cases}$$

$$x_5^*(t) = \begin{cases} 1, & t \in [0, 8.75), \\ 2, & t \in [8.75, 10]. \end{cases}$$

and has objective function 396.25.

An initial partition consisting of the points where the functions $a(t)$, $b(t)$ and $c(t)$ change was chosen, i.e., $P_0 = \{0, 5, 10\}$. The results are given in Table 1. At the beginning of each iteration we start off with the partition given in the partition column. DP is then solved for this partition and the cost of this (feasible SCLP) solution is given. Then AP is solved and the cost of this (feasible SCLP*) solution is given. The cost of the SCLP solution constructed from this AP solution is then given, followed by the cost of the solution obtained from patching together this solution with the DP solution. It is worth noting that the cost obtained its optimal value at the

TABLE 1

Iteration	Partition	DP	AP	SCLP	Combined
1	{0,5,10}	397.5	392.5	397.5	396.25
2	{0,3.75,5,8.75,10}	396.25	396.25	396.5625	-

end of the first iteration and in fact the combined solution was exactly $x^*(t)$ given above. However, it was not until an SCLP* solution with the same cost was obtained that the algorithm was able to detect optimality. Note also that the SCLP solution constructed from the AP one on the second iteration was not the optimal one.

Problem 2. $T = 2$, $n_1 = 2$, $n_2 = 2$, $n_3 = 1$.

$$G = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad H = \begin{bmatrix} 1 & 2 \end{bmatrix}.$$

$a_1(t) = 4 + t, \quad a_2 = 3 + 2t.$

$b_1(t) = 10.$

$c_1(t) = t - 2, \quad c_2(t) = t - 2.$

The optimal solution is

$$x_1^*(t) = \begin{cases} 10, & t \in [0, \frac{4}{9}), \\ 1, & t \in [\frac{4}{9}, 2]. \end{cases} \quad x_2^*(t) = \begin{cases} 0, & t \in [0, \frac{4}{9}), \\ \frac{9}{2}, & t \in [\frac{4}{9}, 2]. \end{cases}$$

and has objective function $-14\frac{5}{9}$.

This example has the advantage that the algorithm can be seen to converge to the optimum rather than obtain it explicitly as is the case of the first example.

Again an initial partition consisting of the points where the functions $a(t)$, $b(t)$, and $c(t)$ change was chosen, i.e., $P_0 = \{0, 2\}$. The results are presented in Tables 2 and 3.

9	-14.555541992	-14.555557251	-14.555549622	-

The algorithm stopped at the ninth iteration as the difference in cost between the SCLP solution and that for SCLP* was within the prescribed limit of 10^{-5} . The final SCLP solution was

$$x_1(t) = \begin{cases} 10, & t \in [0, 0.4414062492), \\ 8.0000038147, & t \in [0.4414062492, 0.4453124985), \\ 1, & t \in [0.4453124985, 2]. \end{cases}$$
$$x_2(t) = \begin{cases} 0, & t \in [0, 0.4414062492), \\ 0.9999982715, & t \in [0.4414062492, 0.4453124985), \\ 4.5, & t \in [0.4453124985, 2]. \end{cases}$$

Several points are worth mentioning. First, it can be seen from the above example that in deleting partition points where the SCLP solution is constant, care needs to be taken to avoid numerical problems. This is because the intervals of the partition are then of very different sizes, thus giving rise to very different sized numbers in the \hat{b} or \hat{b}_D . The problem should be easily overcome by scaling the constraints, or better, by replacing a constraint such as

$$(t_i - t_{i-1})G\hat{x}(t_{i-1}+) + \hat{y}(t_i) - \hat{y}(t_{i-1}) = a(t_i) - a(t_{i-1}),$$

in $DP(P)$ by

$$G\hat{x}(t_{i-1}+) + \hat{y}(t_{i-1}+) = \dot{a}(t_{i-1}+),$$

with similar changes in $AP(P)$.

Second, it has been observed that the results obtained in this example are very sensitive to the way AP or DP are solved. For example, by changing the way an initial basic feasible solution was chosen for either AP or DP , it was possible to produce results where there was a very large partition size with many points clustered around $4/9$. Another change lead to a partition size of only three, with the middle value approaching $4/9$. However, in all cases, convergence of the cost was observed. The reason for this is that because $c_1(t)$ and $c_2(t)$ are the same, it is possible to produce different solutions with the same cost, which could lead to solutions with a differing number of partition points. This effect could then be compounded over several iterations. This is a type of degeneracy and as with degeneracy in the finite-dimensional setting, this problem can be overcome by slightly perturbing the two costs.

Acknowledgments. The author thanks Dr. E. J. Anderson for his many helpful suggestions and discussions and Trinity College, Cambridge for providing funds to make this research possible.

A PATH-FOLLOWING ALGORITHM FOR LINEAR PROGRAMMING USING QUADRATIC AND LOGARITHMIC PENALTY FUNCTIONS*

PAUL TSENG†

Abstract. Motivated by a recent work of Setiono, a path-following algorithm for linear programming using both logarithmic and quadratic penalty functions is proposed. In the algorithm, a logarithmic and a quadratic penalty is placed on, respectively, the nonnegativity constraints and an arbitrary subset of the equality constraints; Newton's method is applied to solve the penalized problem, and after each Newton step the penalty parameters are decreased. This algorithm maintains neither primal nor dual feasibility and does not require a Phase I. It is shown that if the initial iterate is chosen appropriately and the penalty parameters are decreased to zero in a particular way, then the algorithm is linearly convergent. Numerical results are also presented suggesting that the algorithm may be competitive with interior point algorithms in practice, requiring typically between 30–45 iterations to accurately solve each Netlib problem tested.

Key words. linear program, path-following, Newton step, penalty function

AMS subject classifications. 49, 90

1. Introduction. Since the pioneering work of Karmarkar [Kar84], much interest has focused on solving linear programs using interior point algorithms. These interior point algorithms may be classified roughly as either (i) projective-scaling (or potential reduction), (ii) affine-scaling, or (iii) path-following. We will not attempt to review the literature on this subject, which is vast (see for example [Meg89], [Tod89] for surveys). Our interest is in algorithms of the path-following type, of the sort discussed in [GaZ81]. These interior point algorithms typically penalize the nonnegativity constraints by a logarithmic function and use Newton's method to solve the penalized problem, with the penalty parameters decreased after each Newton step (see, for example, [Gon89], [GMSTW86], [KMY89], [MoA87], [Ren88], [Tse89]).

One disadvantage of interior point algorithms is the need for an initial interior feasible solution. A common technique for handling this is to add an artificial column (see [AKRV89], [BDDW89], [GMSTW86], [Lus90], [MMS89], [MSSPB89], [MoM87]), but this itself has disadvantages. For example, the cost of the artificial column must be estimated, and some type of rank-1 updating is needed to solve each least square problem which can significantly increase the solution time and degrade the numerical accuracy of the solutions.

Recently, Setiono [Set89] proposed an interesting algorithm that combines features of a path-following algorithm with those of the method of multipliers [HaB70], [Hes69], [Pow69] (also see [Roc76], [Ber82]). This algorithm does not require a feasible solution to start and is comparable to interior point algorithms both in terms of work per iteration and, according to the numerical results reported in [Set89], in terms of the total number of iterations. To describe the basic idea in Setiono's algorithm, consider

a linear program in the standard dual form

$$\begin{array}{ll} \text{minimize} & -b^T p \\ \text{subject to} & t + A^T p = c, \quad t \geq 0, \end{array}$$

where A is some matrix and b and c are vectors of appropriate dimension. Let us attach a Lagrange multiplier vector x to the constraints $t + A^T p = c$ and apply the method of multipliers to the above linear program. This produces the following iterations

$$x^{k+1} = x^k + \frac{1}{\epsilon^k}(t^k + A^T p^k - c), \quad k = 1, 2, \dots,$$

where $\{\epsilon^k\}$ is a sequence of monotonically decreasing positive scalars and (t^k, p^k) is some (inexact) solution of the augmented Lagrangian subproblem

$$(1.1) \quad \begin{array}{ll} \text{minimize} & -b^T p + (x^k)^T(t + A^T p - c) + \frac{1}{2\epsilon^k} \|t + A^T p - c\|^2 \\ \text{subject to} & t \geq 0. \end{array}$$

(An advantage of the above multiplier iterations is that they do not need a feasible solution to start.) A key issue associated with the above multiplier iterations concerns the efficient generation of an inexact solution (t^k, p^k) of the convex quadratic program (1.1) for each k . (Note that as ϵ^k decreases, the objective function of (1.1) becomes progressively more ill-conditioned.) Setiono's algorithm may be viewed as the method of multipliers in which (t^k, p^k) is generated according to the following scheme, reminiscent of the path-following idea: Add a logarithmic penalty function $-\gamma^k \sum_{j=1}^m \ln(t_j)$ to the objective of (1.1), where γ^k is some positive scalar monotonically decreasing with k , and apply a single Newton step, starting from (t^{k-1}, p^{k-1}) , to the resulting problem. (If the t^k thus obtained lies outside the positive orthant, it is moved back towards t^{k-1} until it becomes positive.¹)

In this paper, inspired by the preceding work of Setiono, we study an algorithm that also adds to the objective a quadratic penalty on the equality constraints and a logarithmic penalty on the nonnegativity constraints; and then solves the penalized problem using Newton's method, with the penalty parameters decreased after each Newton step. Unlike Setiono's algorithm, our algorithm does not use the multiplier vector x^k (so it may be viewed as a pure penalty method) and allows any subset of the equality constraints to be penalized. We show that if the problem is primal non-degenerate and the iterates start near the optimal solution of the initial penalized problem, then the penalty parameters can be decreased at the rate of a geometric progression and the iterates converge linearly. To the best of our knowledge, this is the first (global) linear convergence result for an noninterior point path-following algorithm. We also present numerical results indicating that the algorithm may potentially be competitive with interior point algorithms in practice. We remark that penalty methods that use either the quadratic or the logarithmic penalty function have been well studied (see, for example, [Ber82], [FiM68], [Fri57], [JiO78], [Man84],

¹ More precisely, t^k is given by the formula

$$t^k = t^{k-1} + .98\lambda^k \Delta t^k,$$

where Δt^k is the Newton direction (projected onto the space of t) and λ^k is the largest $\lambda \in (0, 1]$ for which $t^{k-1} + \lambda \Delta t^k$ is nonnegative. (The choice of .98 is arbitrary—any number between 0 and 1 would do.)

[WBD88]), but very little is known about penalty methods that use both types of penalty functions (called mixed interior point-exterior point algorithms in [FiM68]).

Upon completion of this paper, the author learned from Professor O. L. Mangasarian that the algorithm discussed here is essentially the IDLN (Interior Dual Least Norm) algorithm described in the recent Ph.D. thesis of Setiono [Set90] (also see the report [Set91]), with minor differences in the choice of the penalty parameters. The same reference includes an (asymptotic) linear rate convergence analysis and extensive numerical results showing that the IDLN algorithm outperforms the popular simplex code MINOS by a factor of 2 or more on the 63 Netlib problems tested. In short, Setiono's independent work provides further evidence of the practical efficiency of the mixed interior point-exterior point solution approach. Finally, we note that while this paper was under review, other noninterior point methods relating to that studied here have been proposed. One method, brought to our attention by one of the referees, is a certain augmented Lagrangian algorithm for stochastic programming (see [MuR90]); another method is a primal-dual exterior point algorithm for linear programming (see [KMM91]). However, neither of these methods has been shown to possess the nice theoretical/numerical properties enjoyed by the algorithm studied here. For example, no convergence result is given for the method in [MuR90] and no numerical or rate of convergence result is given for the method in [KMM91].

This paper proceeds as follows: In §2 we describe the basic algorithm; in §3 we analyze its convergence; and in §4 we recount our numerical experience with it. In §5 we discuss extensions of this work.

In our notation, every vector is a column vector in some k -dimensional real space \Re^k , and superscript T denotes transpose. For any vector x , we denote by x_j the j th coordinate of x , by $\text{Diag}(x)$ the diagonal matrix whose j th diagonal entry is x_j , and by $\|x\|_1$, $\|x\|$, $\|x\|_\infty$ the L_1 -norm, the L_2 -norm, and the L_∞ -norm of x , respectively. For any matrix A , we denote by A_j the j th column of A . We also denote by e the vector of 1's (whose dimension will be clear from the context) and denote by $\ln(\cdot)$ the natural logarithm function.

2. Algorithm description. Let A be an $n \times m$ matrix, B be an $l \times m$ matrix, b be an n -vector, c be an m -vector, and d be an l -vector. Consider the following linear program associated with A , B , b , c , and d :

$$\begin{aligned}
 (\mathcal{D}) \quad & \text{minimize } -b^T p \\
 & \text{subject to } t + A^T p = c, \quad Bt = d, \quad t \geq 0,
 \end{aligned}$$

which we call the dual problem. The dual problem may be viewed as a standard linear program in t , in which we arbitrarily partition the equality constraints into two subsets and express one subset in the generator form $t + A^T p = c$. (To see this, consider the problem of minimizing $a^T t$ subject to $t \in R \cap S$, $t \geq 0$, where a is an m -vector and R and S are affine sets in \Re^m . We can always express $R = \{ t \mid t = c - A^T p \text{ for some } p \}$ and $S = \{ t \mid Bt = d \}$ for some matrices A and B and some vectors c and d . Using $t = c - A^T p$ to eliminate t from the objective function, the problem is now in the form (\mathcal{D}) .) The constraints $t + A^T p = c$ can be thought of as the complicating constraints which, if removed, would make (\mathcal{D}) much easier to solve. The advantages of splitting the constraints in this manner will be explained at the end of §2. Finally, we note that the form in which we write the equality constraints is unimportant, and the above form is adopted for notational convenience only.

By attaching Lagrange multiplier vectors x and y to the constraints $c - A^T p = t$

and $Bt = d$, respectively, we obtain the following dual of (\mathcal{D}) :

$$(\mathcal{P}) \quad \begin{aligned} & \text{minimize } c^T x + d^T y \\ & \text{subject to } Ax = b, \quad x + B^T y \geq 0, \end{aligned}$$

which we call the primal problem.

We make the following blanket assumptions, which are standard for interior point algorithms, regarding (\mathcal{D}) and (\mathcal{P}) .

Assumption A.

- (a) $\{ (x, y) \mid Ax = b, x + B^T y > 0 \}$ is nonempty.
- (b) $\{ (t, p) \mid Bt = d, t > 0, t + A^T p = c \}$ is nonempty.
- (c) A has full row rank.

It is well known that, under parts (a) and (b) of Assumption A, both (\mathcal{D}) and (\mathcal{P}) have nonempty bounded optimal solution sets.

Consider the dual problem (\mathcal{D}) . Suppose that we place a quadratic penalty on the constraints $t + A^T p = c$ with a penalty parameter $1/\epsilon$ ($\epsilon > 0$) and we place a logarithmic penalty on the constraints $t \geq 0$ with a penalty parameter $\gamma > 0$. This gives the following approximation to (\mathcal{D}) :

$$(\mathcal{D}_{\epsilon, \gamma}) \quad \begin{aligned} & \text{minimize } f_{\epsilon, \gamma}(t, p) \\ & \text{subject to } Bt = d, \quad t > 0, \end{aligned}$$

where $f_{\epsilon, \gamma} : (0, \infty)^m \times \mathbb{R}^n$ is the penalized objective function given by

$$(2.1) \quad f_{\epsilon, \gamma}(t, p) = \frac{1}{2} \|c - t - A^T p\|^2 - \epsilon \gamma \sum_{j=1}^m \ln(t_j) - \epsilon b^T p \quad \forall t > 0, \forall p.$$

The penalized problem $(\mathcal{D}_{\epsilon, \gamma})$ has the advantage that its objective function $f_{\epsilon, \gamma}$ is twice differentiable and the Hessian $\nabla^2 f_{\epsilon, \gamma}$ is positive definite everywhere (via Assumption A(c)). Since the feasible set of $(\mathcal{D}_{\epsilon, \gamma})$ is nonempty (by Assumption A(b)) and its intersection with any level set of $f_{\epsilon, \gamma}$ is bounded (by Assumption A(a)), it is readily seen that $(\mathcal{D}_{\epsilon, \gamma})$ has an optimal solution which, by the strict convexity of $f_{\epsilon, \gamma}$, is unique.

Note 1. We can use penalty functions other than the quadratic and the logarithmic. For example, we can use a cubic in place of the quadratic and $t_j \ln(t_j)$ in place of $-\ln(t_j)$. The quadratic and the logarithmic function, however, have nice properties (such as the second derivative of the logarithmic function equals minus the square of its first derivative) which make global convergence analysis possible.

It is well known (see [Roc70]) that (t, p) is the optimal solution of $(\mathcal{D}_{\epsilon, \gamma})$ if and only if it satisfies, together with some $u \in \mathbb{R}^l$, the Kuhn–Tucker conditions

$$(2.2) \quad t > 0, \quad Bt = d, \quad \nabla f_{\epsilon, \gamma}(t, p) + \begin{pmatrix} B^T u \\ 0 \end{pmatrix} = 0.$$

Straightforward calculation using (2.1) finds that

$$(2.3) \quad \nabla f_{\epsilon, \gamma}(t, p) = \begin{pmatrix} t + A^T p - c - \epsilon \gamma (T)^{-1} e \\ A(t + A^T p - c) - \epsilon b \end{pmatrix},$$

$$(2.4) \quad \nabla^2 f_{\epsilon, \gamma}(t, p) = \begin{pmatrix} I + \epsilon \gamma (T)^{-2} & A^T \\ A & AA^T \end{pmatrix},$$

where $T = \text{Diag}(t)$. The above formulas will be used extensively in the subsequent analysis. Note that $\nabla^2 f_{\epsilon, \gamma}$ is ill-conditioned at the boundary of its domain.

It is not difficult to show that, as ϵ and γ tend to zero, the optimal solution of $(\mathcal{D}_{\epsilon, \gamma})$ approaches the optimal solution set of (\mathcal{D}) (see Lemma 3.1). This suggests the following algorithm for solving $(\mathcal{D}_{\epsilon, \gamma})$. At each iteration, we are given ϵ , γ and a (t, p) which is an approximate solution of $(\mathcal{D}_{\epsilon, \gamma})$; we apply a Newton step to $(\mathcal{D}_{\epsilon, \gamma})$ at (t, p) to generate a new (t, p) and then we decrease ϵ and γ . In other words, we consider a sequence of penalized problems $(\mathcal{D}_{\epsilon^k, \gamma^k})$, $k = 1, 2, \dots$, with $\epsilon^k \downarrow 0$ and $\gamma^k \downarrow 0$, and we use a Newton step to follow the optimal solution of one penalized problem to that of the next. We now formally state this algorithm, which we call the QLPPF (short for Quadratic-Logarithmic Penalty Path-Following) algorithm.

QLPPF Algorithm

Iteration 0. Choose $\epsilon^1 > 0$ and $\gamma^1 > 0$. Choose $(t^1, p^1) \in (0, \infty)^m \times \mathbb{R}^n$ with $Bt^1 = d$.

Iteration k . Given $(t^k, p^k) \in (0, \infty)^m \times \mathbb{R}^n$ with $Bt^k = d$, compute $(\Delta t^k, \Delta p^k, u^k)$ to be a solution of

$$(2.5) \quad \nabla^2 f_{\epsilon^k, \gamma^k}(t^k, p^k) \begin{pmatrix} \Delta t^k \\ \Delta p^k \end{pmatrix} + \nabla f_{\epsilon^k, \gamma^k}(t^k, p^k) + \begin{pmatrix} B^T u^k \\ 0 \end{pmatrix} = 0, \quad B\Delta t^k = 0,$$

and set

$$(2.6) \quad t^{k+1} = t^k + \Delta t^k, \quad p^{k+1} = p^k + \Delta p^k,$$

$$(2.7) \quad \gamma^{k+1} = \alpha^k \gamma^k, \quad \epsilon^{k+1} = \alpha^k \epsilon^k,$$

where α^k is some scalar in $(0, 1)$.

Note 2. As we noted earlier, the QLPPF Algorithm is closely linked to the algorithms proposed by Setiono. In particular, it can be seen from (2.3), (2.4) that, in the special case where B is the zero matrix, the direction finding problem (2.5) is identical to that in the IDLN algorithm of Setiono (see [Set91, Eq. (16)]) and differs from that in the IDPP algorithm of Setiono (see [Set89, Eq. (6)]) by only an order ϵ^k term on the right-hand side (which tends to zero as ϵ^k tends to zero).

Note 3. A unique feature of the QLPPF Algorithm lies in its handling of the two sets of constraints $t + A^T p = c$ and $Bt = d$, whereby quadratic penalties are placed only on the first set while the second set is maintained to be satisfied at all iterations. This feature has the advantage that it enables the QLPPF Algorithm to provide a unified framework for interior point methods and exterior point methods. As an example, if we put all the equality constraints into $Bt = d$ (and correspondingly set $A = I$ and $c = 0$), then it can be seen that the QLPPF Algorithm with $\gamma^k = 1$ for all k reduces to the well-known primal path-following algorithm for maximizing $b^T t$ subject to the constraints $Bt = d$, $t \geq 0$ (see [Gon89], [Tse89], [Ye87]). If we put all the equality constraints into $t + A^T p = c$ (and correspondingly set $B = 0$ and $d = 0$), then, as was noted above, the QLPPF Algorithm reduces to the IDLN algorithm for maximizing $b^T p$ subject to the constraints $t + A^T p = c$, $t \geq 0$. For other choices of constraint splitting, we obtain algorithms somewhere in between. We can then envision choosing a constraint splitting so the corresponding QLPPF Algorithm is in some sense most efficient (e.g., fastest convergence) for the given problem. Alternatively, we may choose a constraint splitting so to ensure that certain “critical” equality constraints are satisfied exactly at all iterations (by putting these constraints into $Bt = d$).

3. Global convergence. In this section, we show that if (\mathcal{D}) is in some sense primal nondegenerate and if (t^1, p^1) is “close” to the optimal solution of $(\mathcal{D}_{\epsilon^1, \gamma^1})$ in the QLPPF Algorithm, then, by decreasing the α^k 's at an appropriate rate, the iterates $\{(t^k, p^k)\}$ generated by the QLPPF Algorithm approach the optimal solution set of (\mathcal{D}) (see Theorem 3.4). Because the Hessian $\nabla^2 f_{\epsilon, \gamma}$ is ill-conditioned at the boundary of its domain, the proof of this result is quite involved and relies critically on finding a suitable Lyapunov (i.e., merit) function to monitor the progress of the algorithm.

For any $\epsilon > 0$ and $\gamma > 0$, let $\rho_{\epsilon, \gamma} : (0, \infty)^m \times \mathbb{R}^n \times \mathbb{R}^l$ be the function given by

$$(3.1) \quad \rho_{\epsilon, \gamma}(t, p, u) = \max \left\{ \frac{1}{\epsilon \gamma} \|T(c - t - A^T p - B^T u) + \epsilon \gamma e\|, \right. \\ \left. \frac{1}{\sqrt{\epsilon \gamma}} \|A(c - t - A^T p) + \epsilon b\| \right\} \quad \forall t > 0, \forall p, \forall u,$$

where $T = \text{Diag}(t)$. From (2.2) and (2.3) we see that (t, p) is a solution of $(\mathcal{D}_{\epsilon, \gamma})$ if and only if (t, p) satisfies $Bt = d$, $t > 0$ and $\rho_{\epsilon, \gamma}(t, p, u) = 0$ for some u . Hence $\rho_{\epsilon, \gamma}$ acts as a Lyapunov function which measures how far (t, p) is from solving $(\mathcal{D}_{\epsilon, \gamma})$. This notion is made precise in the following lemma.

For any $\epsilon > 0$, let

$$(3.2) \quad \mathcal{Y}_\epsilon = \{ (t, p) \mid A(c - t - A^T p) = -\epsilon b, \quad Bt = d, \quad t > 0 \}.$$

The following lemma shows that any $(t, p) \in \mathcal{Y}_\epsilon$ that satisfies $\rho_{\epsilon, \gamma}(t, p, u) \leq \beta$, for some u , is within an order of $\epsilon + (1 + \beta)\gamma$ of being an optimal solution of (\mathcal{D}) .

LEMMA 3.1. *Fix any $\epsilon > 0$, $\gamma > 0$ and $\beta \in (0, 1]$. For any $(t, p) \in \mathcal{Y}_\epsilon$ that satisfies $\rho_{\epsilon, \gamma}(t, p, u) \leq \beta$ for some u , the vector (x, y) given by*

$$(3.3) \quad x = (t + A^T p - c)/\epsilon, \quad y = u/\epsilon$$

is feasible for (\mathcal{P}) and, together with (t, p) , satisfies

$$\begin{aligned} c^T x + d^T y &\leq v^* + \eta^* \epsilon + m(1 + \beta)\gamma, \\ b^T p &\geq v^* - m(1 + \beta)\gamma, \\ \|t + A^T p - c\|^2 &\leq 2(\eta^*(\epsilon)^2 + m(1 + \beta)\epsilon\gamma), \end{aligned}$$

where v^ denotes the optimal cost of (\mathcal{P}) and $\eta^* = \min\{ \|x^*\|^2/2 \mid (x^*, y^*) \text{ is an optimal solution of } (\mathcal{P}) \text{ for some } y^* \}$.*

Proof. Since (t, p) is in \mathcal{Y}_ϵ , it follows from the definition of \mathcal{Y}_ϵ (see (3.2)) and (3.3) that $Ax = b$. Since $\rho_{\epsilon, \gamma}(t, p, u) \leq \beta$, we have from the definition of $\rho_{\epsilon, \gamma}$ (see (3.1)) and (3.3) that $\|T(-x - B^T y) + \gamma e\| \leq \gamma\beta$, where $T = \text{Diag}(t)$. Thus

$$(3.4) \quad \gamma(1 - \beta)e \leq T(x + B^T y) \leq \gamma(1 + \beta)e.$$

Since $t > 0$ and $\beta \leq 1$, the first inequality in (3.4) yields $x + B^T y \geq \gamma(1 - \beta)T^{-1}e \geq 0$. Hence, (x, y) is feasible for (\mathcal{P}) .

Let

$$\begin{aligned} d_\epsilon(\tau, \pi) &= b^T \pi - \frac{1}{2\epsilon} \|\tau + A^T \pi - c\|^2 \quad \forall (\tau, \pi), \\ p_\epsilon(\xi, \psi) &= \frac{\epsilon}{2} \|\xi\|^2 + c^T \xi + d^T \psi \quad \forall (\xi, \psi). \end{aligned}$$

Straightforward algebra using (3.3) yields

$$p_\epsilon(x, y) = d_\epsilon(t, p) + t^T(x + B^T y).$$

Also, it follows from strong duality for a convex quadratic program and its dual that

$$\min_{(\xi, \psi)} \{ p_\epsilon(\xi, \psi) \mid A\xi = b, \xi + B^T \psi \geq 0 \} = \max_{(\tau, \pi)} \{ d_\epsilon(\tau, \pi) \mid B\tau = d, \tau \geq 0 \}.$$

Thus, by letting (x^*, y^*) be any optimal solution of (\mathcal{P}) with $\|x^*\|^2/2 = \eta^*$, we obtain from the above two relations and $c^T x^* + d^T y^* = v^*$ that

$$\begin{aligned} \frac{\epsilon}{2} \|x\|^2 + c^T x + d^T y &= p_\epsilon(x, y) \\ &= d_\epsilon(t, p) + t^T(x + B^T y) \\ &\leq p_\epsilon(x^*, y^*) + t^T(x + B^T y) \\ &= \epsilon \eta^* + v^* + t^T(x + B^T y), \end{aligned}$$

Similarly, by letting (t^*, p^*) be any optimal solution of (\mathcal{D}) , we obtain from the same two relations and the facts $b^T p^* = v^*$ and $t^* + A^T p^* = c$ that

$$\begin{aligned} b^T p - \frac{1}{2\epsilon} \|t + A^T p - c\|^2 &= d_\epsilon(t, p) \\ &= p_\epsilon(x, y) - t^T(x + B^T y) \\ &\geq d_\epsilon(t^*, p^*) - t^T(x + B^T y) \\ &= v^* - t^T(x + B^T y). \end{aligned}$$

Since $0 \leq t^T(x + B^T y) \leq m(1 + \beta)\gamma$ (cf. (3.4)), the above two relations yield

$$\begin{aligned} c^T x + d^T y &\leq v^* + \epsilon \eta^* + m(1 + \beta)\gamma \\ b^T p &\geq v^* - m(1 + \beta)\gamma. \end{aligned}$$

Finally, since (x, y) is feasible for (\mathcal{P}) so that $c^T x + d^T y \geq v^*$, the first of these two relations also yields

$$\frac{\epsilon}{2} \|x\|^2 + v^* \leq \epsilon \eta^* + v^* + m(1 + \beta)\gamma.$$

Canceling v^* from both sides and using (3.3) completes the proof. \square

Since we are dealing with linear programs, Lemma 3.1 implies that, as $\epsilon \downarrow 0$ and $\gamma \downarrow 0$, the (x, y) given by (3.3) approaches the optimal solution set of (\mathcal{P}) and (t, p) approaches the optimal solution set of (\mathcal{D}) . In fact, it suffices to decrease ϵ and γ as far as $2^{\kappa L}$, where κ is some scalar constant and L is the size of the problem encoding in binary (defined as, say, in [Kar84]), at which time an optimal solution of (\mathcal{P}) and of (\mathcal{D}) can be recovered by using the techniques described in, for example, [Kar84] and [PaS82].

For each $\lambda > 0$, let $\theta_\lambda : (0, \infty)^m \rightarrow [0, \infty)$ be the function given by

$$(3.5) \quad \theta_\lambda(t) = (\|E + ED^{1/2}A^T FAD^{1/2}E\| + \|ED^{1/2}A^T F\|)^2 \quad \forall t > 0,$$

where

$$(3.6) \quad D = (I + \lambda T^{-2})^{-1},$$

$$(3.7) \quad E = I - D^{1/2}B^T[BDB^T]^{-1}BD^{1/2},$$

$$(3.8) \quad F = [A(I - D^{1/2}ED^{1/2})A^T]^{-1},$$

and $T = \text{Diag}(t)$. (F is well defined because $\|E\| \leq 1$ (E is a projection matrix) and $\|D\| < 1$, so that $I - D^{1/2}ED^{1/2}$ is positive definite. We also use the assumption that A has full row rank.) The quantity $\theta_\lambda(t)$ estimates the norm squared of certain projection-like operator depending on λ and t , and it will be used extensively in our analysis. In general, $\theta_\lambda(t)$ is rather cumbersome to evaluate, but, as we shall see, it suffices for our analysis to bound $\theta_\lambda(t)$ from above (see Lemma 3.3(b)).

3.1. Analyzing a Newton step. In this subsection we prove a key lemma that states that if (\bar{t}, \bar{p}) is “close” to the optimal solution of $(\mathcal{D}_{\bar{\epsilon}, \bar{\gamma}})$, then (t, p) generated by applying one Newton step to (\mathcal{D}) at (\bar{t}, \bar{p}) is close to the optimal solution of $(\mathcal{D}_{\epsilon, \gamma})$ for some $\epsilon < \bar{\epsilon}$ and some $\gamma < \bar{\gamma}$. The notion of “closeness” is measured by the Lyapunov function $\rho_{\epsilon, \gamma}$ and the proof of the lemma is based on the ideas used in [Tse89, §2].

LEMMA 3.2. *For any $\bar{\epsilon} > 0$, any $\bar{\gamma} > 0$ and any $(\bar{t}, \bar{p}, \bar{u}) \in (0, \infty)^m \times \mathbb{R}^n \times \mathbb{R}^l$ with $B\bar{t} = d$, let (t, p, u) be given by*

$$(3.9) \quad t = \bar{t} + \Delta t,$$

$$(3.10) \quad p = \bar{p} + \Delta p,$$

where u and $(\Delta t, \Delta p)$ together solve the following system of linear equations

$$(3.11) \quad \nabla^2 f_{\bar{\epsilon}, \bar{\gamma}}(\bar{t}, \bar{p}) \begin{pmatrix} \Delta t \\ \Delta p \end{pmatrix} + \nabla f_{\bar{\epsilon}, \bar{\gamma}}(\bar{t}, \bar{p}) + \begin{pmatrix} B^T u \\ 0 \end{pmatrix} = 0, \quad B\Delta t = 0.$$

Suppose that $\rho_{\bar{\epsilon}, \bar{\gamma}}(\bar{t}, \bar{p}, \bar{u}) \leq \beta$ for some $\beta < \min\{1, 1/\theta_{\bar{\epsilon}\bar{\gamma}}(\bar{t})\}$. Then the following hold:

(a) $(t, p) \in \mathcal{Y}_{\bar{\epsilon}}$.

(b) For any α satisfying

$$(3.12) \quad \max \left\{ \sqrt{\frac{\theta_{\bar{\epsilon}\bar{\gamma}}(\bar{t})(\beta)^2 + \sqrt{m}}{\beta + \sqrt{m}}}, \frac{1}{1 + \beta\sqrt{\bar{\gamma}/\bar{\epsilon}}/\|b\|} \right\} \leq \alpha \leq 1,$$

we have $\rho_{\alpha\bar{\epsilon}, \alpha\bar{\gamma}}(t, p, u) \leq \beta$.

Proof. Let

$$(3.13) \quad \bar{r} = \bar{T}(c - \bar{t} - A^T \bar{p} - B^T \bar{u}) + \bar{\epsilon}\bar{\gamma}e,$$

$$(3.14) \quad \bar{s} = A(c - \bar{t} - A^T \bar{p}) + \bar{\epsilon}b,$$

where $\bar{T} = \text{Diag}(\bar{t})$. Then, by (3.1),

$$(3.15) \quad \max\{\|\bar{r}\|/(\bar{\epsilon}\bar{\gamma}), \|\bar{s}\|/\sqrt{\bar{\epsilon}\bar{\gamma}}\} = \rho_{\bar{\epsilon}, \bar{\gamma}}(\bar{t}, \bar{p}, \bar{u}) \leq \beta.$$

By using (2.3), (2.4) and (3.13), (3.14), we write (3.11) equivalently as

$$\begin{aligned} D^{-1}\Delta t + A^T \Delta p + B^T(u - \bar{u}) &= \bar{T}^{-1}\bar{r}, \\ A\Delta t + AA^T \Delta p &= \bar{s}, \\ B\Delta t &= 0, \end{aligned}$$

where for convenience we let $D = (I + \bar{\epsilon}\bar{\gamma}\bar{T}^{-2})^{-1}$. Solving for Δt gives

$$\Delta t = D^{1/2}(E + ED^{1/2}A^T F AD^{1/2}E)D^{1/2}\bar{T}^{-1}\bar{r} - D^{1/2}ED^{1/2}A^T F \bar{s},$$

where we let $E = I - D^{1/2}B^T[BDB^T]^{-1}BD^{1/2}$ and $F = [A(I - D^{1/2}ED^{1/2})A^T]^{-1}$. (F is well defined by the same reasoning that the matrix given by (3.8) is well defined.) Then, we can bound $\bar{T}^{-1}\Delta t$ as follows:

$$\|\bar{T}^{-1}\Delta t\| \leq \|\bar{T}^{-1}D^{1/2}\|^2 \|E + ED^{1/2}A^T F AD^{1/2}E\| \|\bar{r}\| + \|\bar{T}^{-1}D^{1/2}\| \|ED^{1/2}A^T F\| \|\bar{s}\|.$$

Since $\bar{T}^{-2}D$ is diagonal and each of its diagonal entry is less than $1/(\bar{\epsilon}\bar{\gamma})$, we obtain that $\|\bar{T}^{-2}D\| < 1/(\bar{\epsilon}\bar{\gamma})$ and hence

$$\begin{aligned} \|\bar{T}^{-1}\Delta t\| &\leq \|E + ED^{1/2}A^T FAD^{1/2}E\| \|\bar{r}\|/(\bar{\epsilon}\bar{\gamma}) + \|ED^{1/2}A^T F\| \|\bar{s}\|/\sqrt{\bar{\epsilon}\bar{\gamma}} \\ (3.16) \quad &\leq \sqrt{\theta_{\bar{\epsilon}\bar{\gamma}}(\bar{t})}\beta, \end{aligned}$$

where the last inequality follows from (3.15) and the definition of \bar{T} , D , E , F , and $\theta_{\bar{\epsilon}\bar{\gamma}}(\bar{t})$ (see (3.5)–(3.8)).

Now, by using (2.3) and (2.4), we can write (3.11) equivalently as $B\Delta t = 0$ and

$$(3.17) \quad \bar{\epsilon}\bar{\gamma}\bar{T}^{-1}\Delta t = \bar{T}(c - \bar{t} - \Delta t - A^T\bar{p} - A^T\Delta p - B^Tu) + \bar{\epsilon}\bar{\gamma}e,$$

$$(3.18) \quad 0 = A(c - \bar{t} - \Delta t - A^T\bar{p} - A^T\Delta p) + \bar{\epsilon}b,$$

so from (3.9) and (3.10) we obtain

$$\begin{aligned} T(c - t - A^Tp - B^Tu) + \bar{\epsilon}\bar{\gamma}e &= (\bar{T} + \Delta T)(c - \bar{t} - \Delta t - A^T\bar{p} - A^T\Delta p - B^Tu) + \bar{\epsilon}\bar{\gamma}e \\ &= \bar{T}(c - \bar{t} - \Delta t - A^T\bar{p} - A^T\Delta p - B^Tu) \\ &\quad + \bar{\epsilon}\bar{\gamma}e + \Delta T(c - \bar{t} - \Delta t - A^T\bar{p} - A^T\Delta p - B^Tu) \\ &= \bar{\epsilon}\bar{\gamma}\bar{T}^{-1}\Delta t + \Delta T(c - \bar{t} - \Delta t - A^T\bar{p} - A^T\Delta p - B^Tu) \\ &= \bar{T}^{-1}\Delta T(\bar{\epsilon}\bar{\gamma}e) + \bar{T}(c - \bar{t} - \Delta t - A^T\bar{p} - A^T\Delta p - B^Tu) \\ &= \bar{\epsilon}\bar{\gamma}\bar{T}^{-2}\Delta T\Delta t, \end{aligned}$$

where $T = \text{Diag}(t)$, $\Delta T = \text{Diag}(\Delta t)$, and the third and the last equality follow from (3.17). This implies

$$\begin{aligned} \|T(c - t - A^Tp - B^Tu) + \bar{\epsilon}\bar{\gamma}e\| &\leq \bar{\epsilon}\bar{\gamma}\|\bar{T}^{-2}\Delta T\Delta t\| \\ &\leq \bar{\epsilon}\bar{\gamma}\|\bar{T}^{-2}\Delta T\Delta t\|_1 \\ &= \bar{\epsilon}\bar{\gamma}\|\bar{T}^{-1}\Delta t\|^2 \\ (3.19) \quad &\leq \bar{\epsilon}\bar{\gamma}\theta_{\bar{\epsilon}\bar{\gamma}}(\bar{t})(\beta)^2, \end{aligned}$$

where the third inequality follows from (3.16).

(a) We have from (3.16) and the hypothesis $\beta < 1/\theta_{\bar{\epsilon}\bar{\gamma}}(\bar{t})$ that $\|\bar{T}^{-1}\Delta t\|^2 \leq \theta_{\bar{\epsilon}\bar{\gamma}}(\bar{t})(\beta)^2 < \beta < 1$, so (3.9) and $\bar{t} > 0$ yields $t = \bar{t} + \Delta t > 0$. Also, $B\bar{t} = d$ together with $B\Delta t = 0$ (see (3.11)) and (3.9) yields $Bt = d$, and (3.18) together with (3.9), (3.10) yields $0 = A(c - t - A^Tp) + \bar{\epsilon}b$. Hence $(t, p) \in \mathcal{Y}_{\bar{\epsilon}}$.

(b) Fix any α satisfying (3.12) and let $\gamma = \alpha\bar{\gamma}$, $\epsilon = \alpha\bar{\epsilon}$. (Note that because $\theta_{\bar{\epsilon}\bar{\gamma}}(\bar{t})\beta < 1$, the left-hand quantity in (3.12) is strictly less than 1, so such an α exists.) Let

$$r = T(c - t - A^Tp - B^Tu) + \epsilon\gamma e.$$

Then the triangle inequality and (3.19) imply

$$\begin{aligned} \|r\|/(\epsilon\gamma) &\leq \|T(c - t - A^Tp - B^Tu) + \bar{\epsilon}\bar{\gamma}e\|/(\epsilon\gamma) + (1 - (\alpha)^2)\sqrt{m}/(\alpha)^2 \\ &\leq \theta_{\bar{\epsilon}\bar{\gamma}}(\bar{t})(\beta)^2/(\alpha)^2 + (1/(\alpha)^2 - 1)\sqrt{m}, \end{aligned}$$

which together with the fact (see (3.12)) $(\theta_{\bar{\epsilon}\bar{\gamma}}(\bar{t})(\beta)^2 + \sqrt{m})/(\beta + \sqrt{m}) \leq (\alpha)^2$, yields

$$(3.20) \quad \|r\|/(\epsilon\gamma) \leq \beta.$$

Let $s = A(c - t - A^T p) + \epsilon b$. By using (3.9), (3.10), and (3.18), we have

$$s = A(c - \bar{t} - \Delta t - A^T \bar{p} - A^T \Delta p) + \alpha \bar{\epsilon} b = (\alpha - 1) \bar{\epsilon} b,$$

which together with the fact (see (3.12))

$$1/(1 + \beta\sqrt{\bar{\gamma}/\bar{\epsilon}}/\|b\|) \leq \alpha \leq 1,$$

yields

$$\|s\|/\sqrt{\epsilon\gamma} = (1/\alpha - 1)\|b\|\sqrt{\bar{\epsilon}/\bar{\gamma}} \leq \beta.$$

This together with (3.20) and the definition of $\rho_{\epsilon,\gamma}(t, p, u)$ (see (3.1)) proves our claim. \square

3.2. Bounds. Lemma 3.2 shows that if the rate α at which the penalty parameters ϵ and γ are decreased is not too small (see (3.12)), then a single Newton step suffices to keep the current iterate close to the optimal solution of the penalized problem $(\mathcal{D}_{\epsilon,\gamma})$. Thus, in order to establish the (linear) convergence of the QLPPF Algorithm, it suffices to bound α away from 1 which, according to (3.12), amounts to bounding $\theta_{\epsilon,\gamma}(t)$ by some quantity independent of t and ϵ, γ . It is not difficult to see that such a bound does not exist for arbitrary t . Fortunately, we need to consider only those t that, together with some p , are close to the optimal solution of $(\mathcal{D}_{\epsilon,\gamma})$, in which case, as we show below, such a bound does exist (provided that a certain primal nondegeneracy assumption also holds). The proof of this is somewhat intricate: For ϵ and γ large, we argue by showing that t cannot be too large, i.e., of the order $\epsilon + \gamma + 1$ (see Lemma 3.3(a)) and, for ϵ and γ small, we argue by showing that, under the primal nondegeneracy assumption, the columns of A corresponding to those components of t which are small (i.e., of the order γ) are of rank n .

LEMMA 3.3. (a) *For all $\epsilon > 0$, all $\gamma > 0$, and all $(t, p) \in \mathcal{Y}_\epsilon$ satisfying $\rho_{\epsilon,\gamma}(t, p, u) \leq 1$ for some u , we have*

$$\|t\| \leq M_1(\epsilon + \gamma + 1),$$

where $M_1 > 0$ is some scalar depending on A, B, b, c , and d only.

(b) *Suppose that (\mathcal{P}) is primal nondegenerate in the sense that, for every optimal solution (x^*, y^*) of (\mathcal{P}) , those columns of A corresponding to the positive components of $x^* + B^T y^*$ have rank n . Then, for all $\epsilon > 0$, all $\gamma > 0$, all $\lambda \geq \epsilon\gamma/2$, and all $(t, p) \in \mathcal{Y}_\epsilon$ satisfying $\rho_{\epsilon,\gamma}(t, p, u) \leq 1$ for some u , we have*

$$\theta_\lambda(t) \leq \psi(\epsilon/\gamma),$$

where we define

$$(3.21) \quad \psi(\omega) = M_2(\sqrt{\omega} + 1/\sqrt{\omega})^4 \quad \forall \omega > 0,$$

with $M_2 \geq 1$ some scalar depending on A, B, b, c , and d only.

Proof. (a) The proof is by contradiction. Suppose the contrary, so that there exists a sequence $\{(t^k, p^k, u^k, \epsilon^k, \gamma^k)\}$ such that $\epsilon^k > 0$ and $\gamma^k > 0$ and

$$(3.22) \quad (t^k, p^k) \in \mathcal{Y}_{\epsilon^k}, \quad \rho_{\epsilon^k, \gamma^k}(t^k, p^k, u^k) \leq 1 \quad \forall k,$$

$$(3.23) \quad \|t^k\|/(\epsilon^k + \gamma^k) \rightarrow \infty, \quad \|t^k\| \rightarrow \infty.$$

By passing into a subsequence if necessary we will assume that $(t^k, p^k)/\|(t^k, p^k)\|$ converges to some limit point, say (t^∞, p^∞) (so $(t^\infty, p^\infty) \neq 0$). We have from (3.22) (also using (3.1) and (3.2)) that

$$Bt^k = d, \quad t^k > 0 \quad \forall k,$$

and from Lemma 3.1 that

$$b^T p^k \geq v^* - 2m\gamma^k, \quad \|t^k + A^T p^k - c\| \leq \sqrt{2(\eta^*(\epsilon^k)^2 + 2m\epsilon^k\gamma^k)} \quad \forall k.$$

Upon dividing both sides of the above four relations by $\|(t^k, p^k)\|$ and letting $k \rightarrow \infty$, we obtain from (3.23) and $(t^k, p^k)/\|(t^k, p^k)\| \rightarrow (t^\infty, p^\infty)$ that

$$Bt^\infty = 0, \quad t^\infty \geq 0, \quad b^T p^\infty \geq 0, \quad \|t^\infty + A^T p^\infty\| = 0.$$

Then, any optimal solution to (\mathcal{D}) would remain optimal when moved along the direction (t^∞, p^∞) , contradicting the boundedness of the optimal solution set of (\mathcal{D}) (via Assumption A(a)).

(b) Fix any $\epsilon > 0$, $\gamma > 0$, $\lambda \geq \epsilon\gamma/2$, and any $(t, p) \in \mathcal{Y}_\epsilon$ satisfying $\rho_{\epsilon, \gamma}(t, p, u) \leq 1$ for some u . Let $T = \text{Diag}(t)$ and let D, E, F be given by, respectively, (3.6), (3.7), and (3.8). Then, $F^{-1} = A(I - D^{1/2}ED^{1/2})A^T$, $\|E\| \leq 1$ and $D = (I + \lambda T^{-2})^{-1}$. From the definition of $\theta_\lambda(t)$ (see (3.5)) we then obtain

$$\begin{aligned} \theta_\lambda(t) &= (\|E + ED^{1/2}A^T FAD^{1/2}E\| + \|ED^{1/2}A^T F\|)^2 \\ &\leq (\|E\| + \|E\|^2\|D^{1/2}\|^2\|A\|^2\|F\| + \|E\|\|D^{1/2}\|\|A\|\|F\|)^2 \\ (3.24) \quad &< (1 + \|A\|^2\|F\| + \|A\|\|F\|)^2, \end{aligned}$$

where the strict inequality follows from the facts $\|D\| < 1$, $\|E\| \leq 1$. Now we bound $\|F\|$. We have

$$\begin{aligned} z^T(F^{-1})z &= z^T A(I - D^{1/2}ED^{1/2})A^T z \\ &\geq z^T A(I - D)A^T z \\ &= \sum_{j=1}^m (A_j^T z)^2 / ((t_j)^2 / \lambda + 1) \\ (3.25) \quad &\geq \lambda \sum_{j=1}^m (A_j^T z)^2 / (t_j)^2 \\ &\geq \lambda \sum_{j=1}^m (A_j^T z)^2 / \|t\|^2 \\ &\geq \lambda \sigma \|z\|^2 / \|t\|^2 \quad \forall z, \end{aligned}$$

where the first inequality follows from $\|E\| \leq 1$ and $\sigma > 0$ denotes the smallest eigenvalue of AA^T . ($\sigma > 0$ because A has full row rank.) Hence, $\lambda \geq \epsilon\gamma/2$ yields

$$(3.26) \quad \|F\| \leq 2\|t\|^2 / (\sigma\epsilon\gamma).$$

For ϵ and γ near zero, we give below a different bound on $\|F\|$. By the primal nondegeneracy assumption, there exists a constant $\delta > 0$ depending on A, B, b, c , and d only such that if (x, y) is any feasible solution of (\mathcal{P}) with $c^T x + d^T y \leq v^* + \delta$,

then the columns $\{A_j \mid j \in \{1, \dots, m\} \text{ with } x_j + B_j^T y \geq \delta\}$ have rank n . Consider the case in which $\eta^* \epsilon + 2m\gamma < \delta$, where η^* is defined as in Lemma 3.1. Since $(t, p) \in \mathcal{Y}_\epsilon$ and $\rho_{\epsilon, \gamma}(t, p, u) \leq 1$, we have from Lemma 3.1 that the columns $\{A_j \mid j \in \{1, \dots, m\} \text{ with } (t_j + A_j^T p + B_j^T u - c_j)/\epsilon \geq \delta\}$ have rank n . Since $(t, p) \in \mathcal{Y}_\epsilon$ and $\rho_{\epsilon, \gamma}(t, p, u) \leq 1$, we have $T(c - t - A^T p - B^T u) \geq -2\epsilon\gamma e$ (cf. (3.1) and (3.2)) so that $(t_j + A_j^T p + B_j^T u - c_j)/\epsilon \geq \delta$ implies $t_j \leq 2\gamma/\delta$. Hence, we obtain from (3.25) that

$$\begin{aligned} z^T(F^{-1})z &\geq \lambda \sum_{j=1}^m (A_j^T z)^2 / (t_j)^2 \\ &\geq \lambda(\delta)^2 \sum_{t_j \leq 2\gamma/\delta} (A_j^T z)^2 / (2\gamma)^2 \\ &\geq \lambda(\delta)^2 \sigma' \|z\|^2 / (2\gamma)^2 \quad \forall z, \end{aligned}$$

where the last inequality follows from the fact that those A_j for which $t_j \leq 2\gamma/\delta$ have rank n , and σ' is some positive scalar depending on A only. Since $\lambda \geq \epsilon\gamma/2$, we then have

$$\|F\| \leq (2\gamma)^2 / (\lambda(\delta)^2 \sigma') \leq 8\gamma / (\epsilon(\delta)^2 \sigma') = 8 / (\omega(\delta)^2 \sigma'),$$

where for convenience we let $\omega = \epsilon/\gamma$. Now, consider the remaining case where $\eta^* \epsilon + 2m\gamma \geq \delta$. Then, $\gamma \geq \delta/(2m)$, so part (a) and (3.26) together yield

$$\begin{aligned} \|F\| &\leq \frac{2(M_1)^2}{\sigma\epsilon\gamma} (\epsilon + \gamma + 1)^2 \\ &= \frac{2(M_1)^2}{\sigma} \left(\sqrt{\omega} + \frac{1}{\sqrt{\omega}} + \frac{1}{\gamma\sqrt{\omega}} \right)^2 \\ &\leq \frac{2(M_1)^2}{\sigma} \left(\sqrt{\omega} + \frac{1}{\sqrt{\omega}} + \frac{2m}{\delta\sqrt{\omega}} \right)^2. \end{aligned}$$

Combining the above two cases and we conclude that

$$\|F\| \leq \begin{cases} K/\omega & \text{if } \eta^* \epsilon + 2m\gamma < \delta; \\ K(\sqrt{\omega} + 1/\sqrt{\omega})^2 & \text{otherwise,} \end{cases}$$

for some positive scalar K depending on A, B, b, c , and d only. Combining the above bound with (3.24) and we conclude that $\theta_\lambda(t) \leq M_2(\sqrt{\omega} + 1/\sqrt{\omega})^4$ for some scalar $M_2 \geq 1$ depending on A, B, b, c , and d only. \square

3.3. Main convergence result. By combining Lemmas 3.1 to 3.3, we obtain the following global convergence result for the QLPPF Algorithm.

THEOREM 3.4. *Suppose that (\mathcal{P}) is primal nondegenerate in the sense of Lemma 3.3(b) and let $\psi(\cdot)$ be given by (3.21). If in the QLPPF Algorithm (t^1, p^1) together with some u^1 satisfies*

$$(3.27) \quad t^1 > 0, \quad Bt^1 = d,$$

$$(3.28) \quad \theta_{\epsilon^1, \gamma^1}(t^1) \leq \psi(\epsilon^1/\gamma^1),$$

$$(3.29) \quad \rho_{\epsilon^1, \gamma^1}(t^1, p^1, u^1) \leq \beta,$$

for some scalar

$$(3.30) \quad 0 < \beta < \frac{1}{\psi(\epsilon^1/\gamma^1)},$$

and if we choose

$$(3.31) \quad \alpha^k = \max \left\{ \sqrt{\frac{\theta_{\epsilon^k, \gamma^k}(t^k)(\beta)^2 + \sqrt{m}}{\beta + \sqrt{m}}}, \frac{1}{1 + \beta\sqrt{\gamma^1/\epsilon^1}/\|b\|} \right\} \quad \forall k,$$

then $\epsilon^k \downarrow 0$, $\gamma^k \downarrow 0$ linearly, and $\{((t^k + A^T p^k - c)/\epsilon^k, u^k/\epsilon^k)\}$, $\{(t^k, p^k)\}$ approach the optimal solution set of, respectively, (\mathcal{P}) and (\mathcal{D}) .

Proof. First note from $\psi(\omega) > 1$ for all $\omega > 0$ (see (3.21) and $M_2 \geq 1$) and (3.30) that $\beta < 1$. Also note from (2.7) that

$$(3.32) \quad \epsilon^k/\gamma^k = \epsilon^1/\gamma^1 \quad \forall k.$$

We claim that

$$(3.33) \quad (t^k, p^k) \in \mathcal{Y}_{\epsilon^{k-1}}, \quad \rho_{\epsilon^{k-1}, \gamma^{k-1}}(t^k, p^k, u^k) \leq \beta, \quad \rho_{\epsilon^k, \gamma^k}(t^k, p^k, u^k) \leq \beta,$$

for all $k \geq 2$. It is easily seen by using (3.27)–(3.31) and (2.5)–(2.7) and Lemma 3.2 that (3.33) holds for $k = 2$. Suppose that (3.33) holds for all $k \leq h$, for some $h \geq 2$. Then, $(t^h, p^h) \in \mathcal{Y}_{\epsilon^{h-1}}$ and $\rho_{\epsilon^{h-1}, \gamma^{h-1}}(t^h, p^h, u^h) \leq \beta < 1$. Since we also have from (2.7) that $\epsilon^h = \alpha^{h-1}\epsilon^{h-1}$ and $\gamma^h = \alpha^{h-1}\gamma^{h-1}$ and from (3.31) that $(\alpha^{h-1})^2 \geq \sqrt{m}/(1 + \sqrt{m}) \geq 1/2$, we can apply Lemma 3.3(b) to conclude that

$$(3.34) \quad \theta_{\epsilon^h, \gamma^h}(t^h) \leq \psi(\epsilon^{h-1}/\gamma^{h-1}) = \psi(\epsilon^1/\gamma^1),$$

where the equality follows from (3.32). Then, by (3.30), $\beta < 1/\theta_{\epsilon^h, \gamma^h}(t^h)$. Since (3.33) holds for $k = h$, we also have $\rho_{\epsilon^h, \gamma^h}(t^h, p^h, u^h) \leq \beta$, so Lemma 3.2 together with (2.5)–(2.7) and (3.31), (3.32) yields

$$(t^{h+1}, p^{h+1}) \in \mathcal{Y}_{\epsilon^h}, \quad \rho_{\epsilon^h, \gamma^h}(t^{h+1}, p^{h+1}, u^{h+1}) \leq \beta, \quad \rho_{\epsilon^{h+1}, \gamma^{h+1}}(t^{h+1}, p^{h+1}, u^{h+1}) \leq \beta.$$

Hence, (3.33) holds for $k = h + 1$.

Since (3.33) holds for all $k \geq 2$, we see that (3.34) holds for all $h \geq 2$. Then, by (3.30), $\theta_{\epsilon^h, \gamma^h}(t^h)\beta$ is less than 1 and bounded away from 1 for all $h \geq 2$, so that, by (3.31), α^k is less than 1 and bounded away from 1 for all k . Hence $\epsilon^k \downarrow 0$, $\gamma^k \downarrow 0$ at the rate of a geometric progression. The remainder of the proof follows from (3.33) and Lemma 3.1. \square

Note that instead of $\theta_{\epsilon^k, \gamma^k}(t^k)$ we can use, for example, the upper bound $1/\psi(\epsilon^1/\gamma^1)$ in the formula (3.31), and linear convergence would be preserved. However, this bound is typically loose and difficult to compute. There is also the issue of finding ϵ^1 , γ^1 , β , (t^1, p^1) and u^1 satisfying (3.27)–(3.30), which we will address in §3.4.

3.4. Algorithm initialization. By Theorem 3.4, if the primal nondegeneracy assumption therein holds and if we can find ϵ , γ , (t, p) and u satisfying

$$(3.35) \quad t > 0, \quad Bt = d,$$

$$(3.36) \quad \theta_{\epsilon, \gamma}(t) \leq \psi(\epsilon/\gamma),$$

$$(3.37) \quad \rho_{\epsilon, \gamma}(t, p, u) < 1/\psi(\epsilon/\gamma),$$

then we can set $\beta = \rho_{\epsilon, \gamma}(t, p, u)$ (assuming $\rho_{\epsilon, \gamma}(t, p, u) \neq 0$) and start the QLPPF Algorithm with ϵ , γ , (t, p) , and we would obtain linear convergence. But how do we find such ϵ , γ , (t, p) , and u ?

One obvious way is to fix any $\epsilon > 0$, any $\gamma > 0$, and then solve the penalized problem $(\mathcal{D}_{\epsilon,\gamma})$. The solution (t, p) obtained satisfies

$$t > 0, \quad Bt = d, \quad \nabla f_{\epsilon,\gamma}(t, p) + \begin{pmatrix} B^T u \\ 0 \end{pmatrix} = 0$$

for some u (see (2.2)) so, by (2.3) and (3.1), (3.2), we have $\rho_{\epsilon,\gamma}(t, p, u) = 0$ and $(t, p) \in \mathcal{Y}_\epsilon$. Hence (3.35) and (3.37) hold and, by Lemma 3.3(b), $\theta_{\epsilon,\gamma}(t) \leq \psi(\epsilon/\gamma)$, so (3.36) also holds. (Of course $(\mathcal{D}_{\epsilon,\gamma})$ need not be solved exactly.) To solve the problem $(\mathcal{D}_{\epsilon,\gamma})$, we can use any method for convex differentiable minimization (e.g., gradient descent, coordinate descent), and we would typically want ϵ small and γ large so that $(\mathcal{D}_{\epsilon,\gamma})$ is well conditioned.

Suppose that there holds $Be = 0$ and $Ae = b$. (This holds, for example, when B is the zero matrix (which corresponds to the case when all equality constraints are penalized), and a change of variable $x' = (\bar{X})^{-1}x$, where \bar{x} is any interior feasible solution of (\mathcal{P}) (i.e., $A\bar{x} = b$, $\bar{x} > 0$) and $\bar{X} = \text{Diag}(\bar{x})$, has been made in (\mathcal{P}) .) Then we can find a usable ϵ , γ , (t, p) , u immediately: Fix any $\epsilon > 2\psi(1)(\|c\| + \|B^T(BB^T)^{-1}d\|)$ and let $\gamma = \epsilon$. Also let $w = B^T(BB^T)^{-1}d$ and

$$\begin{aligned} p &= (AA^T)^{-1}A(c - w), \\ t &= \epsilon e + w, \\ u &= -(BB^T)^{-1}d. \end{aligned}$$

Then $Bw = d$, $A(c - A^T p) = Aw$, $At = \epsilon b + Aw$ and $B^T u = \epsilon e - t$, so that

$$\begin{aligned} Bt &= Bw = d, \\ A(c - t - A^T p) &= -\epsilon b, \\ T(c - t - A^T p - B^T u) + \epsilon \gamma e &= (\epsilon I + W)(c - \epsilon e - A^T p) + (\epsilon)^2 e \\ &= (\epsilon I + W)(c - A^T p) - \epsilon w, \end{aligned}$$

where $T = \text{Diag}(t)$ and $W = \text{Diag}(w)$. Also from $\psi(1) > 1$ and our choice of ϵ we have $\epsilon > \|w\|$, so $t > 0$. Hence, by (3.2), we have $(t, p) \in \mathcal{Y}_\epsilon$ and, by (3.1) and $\epsilon = \gamma$, we have

$$\begin{aligned} (3.38) \quad \rho_{\epsilon,\gamma}(t, p, u) &= \|(\epsilon I + W)(c - A^T p) - \epsilon w\|/(\epsilon)^2 \\ &\leq \|c - w - A^T p\|/\epsilon + \|W\|\|c - A^T p\|/(\epsilon)^2 \\ &= \|(I - A^T(AA^T)^{-1}A)(c - w)\|/\epsilon \\ &\quad + \|W\|\|(I - A^T(AA^T)^{-1}A)c + A^T(AA^T)^{-1}Aw\|/(\epsilon)^2 \\ &\leq \|c - w\|/\epsilon + \|w\|(\|c\| + \|w\|)/(\epsilon)^2, \end{aligned}$$

where the last inequality follows from the triangle inequality and the nonexpansive property of projection matrices. From our choice of ϵ we see that $(\|c\| + \|w\|)/\epsilon < .5/\psi(1)$, so the right-hand side of (3.38) is bounded above by $.5/\psi(1) + (.5/\psi(1))^2 \leq 1/\psi(1) = 1/\psi(\epsilon/\gamma)$, where the inequality follows from $\psi(1) \geq 1$ and the equality follows from $\gamma = \epsilon$. Hence (3.35) and (3.37) hold. Also, since $(t, p) \in \mathcal{Y}_\epsilon$, then (3.37) together with Lemma 3.3(b) shows that (3.36) holds.

4. Numerical results. To study the performance of the QLPPF Algorithm in practice, we have implemented the algorithm to solve the special case of (\mathcal{D}) and (\mathcal{P})

in which B is the zero matrix, i.e., (\mathcal{P}) is of the form

$$(4.1) \quad \begin{aligned} & \text{minimize } c^T x \\ & \text{subject to } Ax = b, \quad x \geq 0. \end{aligned}$$

(This corresponds to penalizing all equality constraints in the corresponding dual problem.) Below we describe our implementation and present our very preliminary numerical experience.

1. Initialization. In our implementation, we set for all problems

$$\epsilon^1 = 10^{-7} \|c\|_1/m, \quad \gamma^1 = 10^4 \|c\|_1/m,$$

and set (somewhat arbitrarily)

$$p^1 = 0, \quad t^1 = \max\{e, c/2\},$$

where “max” is taken componentwise. (Note that since B is the zero matrix, t^1 can be set to any positive vector.) We have chosen t^1 so to minimize $\|T^1(c - t^1 - A^T p^1)\|$ subject to $t^1 \geq e$. Also, care must be exercised in choosing ϵ^1 and γ^1 : if their values are set too low, then the QLPPF Algorithm may fail to converge; if their values are set too high, then the QLPPF Algorithm may require many iterations to converge. (Notice that we set ϵ^1 and γ^1 directly proportional to the average cost $\|c\|_1/m$ so their values scale with c .)

2. Steplength selection. To ensure that the t^k 's remain inside the positive orthant, we employ a backtracking scheme similar to that used by Setiono: whenever $t^k + \Delta t^k$ is outside the positive orthant, we replace the formula for t^{k+1} in (2.6) by

$$(4.2) \quad t^{k+1} = t^k + .98\lambda^k \Delta t^k,$$

where

$$(4.3) \quad \lambda^k = \min_{\Delta t_j^k < 0} -\frac{t_j^k}{\Delta t_j^k}.$$

However, this raises a difficulty, namely, for λ^k much smaller than 1, the vector $(.98\lambda^k \Delta t^k, \Delta p^k)$ may be far from the Newton direction $(\Delta t^k, \Delta p^k)$ and, as a consequence, the iterates may fail to converge. To remedy this, we replace (analogous to (4.2)) the formula for p^{k+1} in (2.6) by

$$p^{k+1} = p^k + .98\lambda^k \Delta p^k,$$

whenever nonconvergence is detected. (The parameter value .98 is chosen somewhat arbitrarily, but it works well in our tests.)

The proper choice of the α^k 's is very important for the QLPPF Algorithm: if the α^k 's are too near 1 (so the penalty parameters decrease slowly), then the algorithm would converge slowly; if the α^k 's are too near 0 (so the penalty parameters decrease rapidly), then the algorithm may fail to converge. In our implementation we adjust the α^k 's dynamically according to the following rule:

$$\alpha^k = \begin{cases} \max\{.3, .95\alpha^{k-1}\} & \text{if } \lambda^k = 1; \\ .6 & \text{if } \lambda^k \leq .2; \\ \alpha^{k-1} & \text{otherwise} \end{cases} \quad \forall k \geq 2,$$

with α^1 set to .5. The rationale for this adjustment rule is that, if $\lambda^k = 1$, then the current iterate is closely following the solution trajectory (so we can decrease the penalty parameters at a faster rate and still retain convergence) and, if $\lambda^k \leq .2$, then the current iterate is unable to follow the solution trajectory (so we must decrease the penalty parameters at a slower rate).

3. Termination. To avoid numerical problems, we stop decreasing the penalty parameters ϵ and γ when they reach some prespecified tolerances ϵ_{\min} and γ_{\min} , respectively. In our tests we set

$$\epsilon_{\min} = 10^{-12} \|c\|_1/m, \quad \gamma_{\min} = 10^{-9} \|c\|_1/m.$$

We terminate the QLPPF Algorithm when the relative duality gap and the violation of primal and dual feasibility are small. More specifically, we terminate whenever the current iterate, denoted by (t, p) , satisfies

$$(4.4) \quad \frac{\|X(A^T p - c)\|_1}{|c^T x|} \leq 10^{-7},$$

$$(4.5) \quad \max\{\|Ax - b\|_\infty, \|[-x]_+\|_\infty\} \leq 10^{-7},$$

$$(4.6) \quad \|[A^T p - c]_+\|_\infty \leq 10^{-7},$$

where $x = (t + A^T p - c)/\epsilon$ (see Lemma 3.1), $X = \text{Diag}(x)$, and $[\cdot]_+$ denotes the orthogonal projection onto the nonnegative orthant. Only for three of our test problems could the above termination criterion not be met (owing to violation of (4.4) and (4.6)) in which case the algorithm is terminated whenever primal feasibility (4.5) is met and $|c^T x - v^*|/|v^*|$ is less than $5 \cdot 10^{-7}$, where v^* denotes the optimal cost of (4.1).

4. Solving for the direction. The most expensive computation at each iteration of the QLPPF Algorithm lies in solving the system of linear equations (2.5). This can be seen to entail solving a single linear system of the form

$$(4.7) \quad AQA^T w = z,$$

for w , where z is some n -vector and Q is some $m \times m$ diagonal matrix whose j th diagonal entry is

$$(4.8) \quad \frac{\epsilon\gamma}{\epsilon\gamma + (t_j)^2},$$

with $\epsilon > 0$, $\gamma > 0$, and t some positive m -vector. (Linear system of the form (4.7) also arise in interior point algorithms, but (4.7) has the nice property that the condition number of Q can be controlled by adjusting the penalty parameters ϵ and γ .) In our implementation, (4.7) is solved using YSMP, a sparse matrix package for symmetric positive semidefinite systems developed at Yale University (see [EGSS79], [EGSS82]) and a precursor to the commercial package SMPAK (Scientific Computing Associates, 1985). YSMP comprises a set of Fortran routines implementing the Cholesky decomposition scheme and, as a preprocessor, the minimum-degree ordering algorithm (see, e.g., [GeL81]). In our implementation, the minimum-degree ordering routine ORDER is called first to obtain a permutation of the rows and columns of the matrix AA^T so that fill-in is reduced during factorization. Then, AA^T is symbolically factored using the routine SSF. (SSF is called only once since the nonzero pattern of AQA^T does not change with Q .) At each iteration, the matrix AQA^T is numerically factored by

the routine SNF (taking advantage of information generated by SSF concerning the location of the nonzeros in the factorization), and the two triangular systems thus generated are solved by the routine SNS to obtain a solution of (4.7). (We also experimented with the public domain version of the sparse matrix package SPARSPAK [GeL81], presently available from Netlib. We found SPARSPAK to be comparable to YSMP in solution time but somewhat inferior in solution accuracy.)

5. Data structure. The data structure used in our implementation is similar to that described in [AKRV89] and [MoM87]. Each matrix is stored in sparse format by row. To compute the nonzero entries of the matrix AQA^T efficiently for any Q , we also store the nonzero entries of the outer products $A_j(A_j)^T$, where A_j denotes the j th column of A . AQA^T is then computed using the formula

$$AQA^T = \sum_{j=1}^m q_j A_j(A_j)^T,$$

where q_j denotes the j th diagonal entry of Q and the product of q_j is taken with each nonzero entry of $A_j(A_j)^T$.

6. Test problems. Our test problems comprise the first 25 of the Netlib linear programming problems (see [Gay86]) used in the test of Monma and Morton [MoM87].² These problems range in size from 27 rows and 51 columns up to 1042 rows and 2869 columns and, for some of them, slack columns must be added and null rows must be removed to transform them into the form (4.1). (We also wrote a routine to convert these problems from their original MPS format to that used by our implementation.) The statistics for the test problems (after problem transformation) are summarized in Table 1.

7. Computing environment. Our implementation was written in Fortran and was compiled and ran on a Decstation 5000 under the Ultrix 4.2 operating system (similar to Berkeley 4.2 with some 4.3 enhancements). The default optimization setting for the compiler was used.

Table 2 summarizes the computational results obtained with our implementation of the QLPPF algorithm. Columns 2 and 3 show, respectively, the total number of iterations and the CPU time. Columns 4 and 6 show, respectively, the cost and the accuracy of the final primal solution (the latter is measured by the left-hand quantity in (4.5)). Analogously, columns 5 and 7 show, respectively, the cost and the accuracy of the final dual solution (the latter is measured by the left-hand quantity in (4.6)). For most of the problems, the primal cost agrees with the optimal cost in the first 7 digits and the accuracy of the primal solution is between 10^{-7} and 10^{-14} . Thus the quality of the computed solutions compares favorably with that of solutions generated by interior point algorithms. The number of iterations varies between 29 and 48 (except for Scagr25 which required 62 iterations) and the CPU time varies between 0.3 and 22 seconds, depending on the problem size and the sparsity of the constraint matrix. For most of the problems, over half of the CPU time is devoted to solving the linear system (4.7) at every iteration. (We also performed tests on a μ VAX-2000 Workstation under the operating system VMS 4.1. The resulting number of iterations is roughly the same; the accuracy of the final solutions improves slightly; and the CPU times are from 10 to 15 times that on the Decstation 5000.)

The number of iterations for the QLPPF Algorithm is comparable to that for the projected Newton barrier method of Gill et al. [GMSTW86], but is typically more

² Possibly due to conversion error, our version of Scorpion has an optimal cost very different from that reported in [Gay86] and hence the problem is excluded.

than that for the affine-scaling algorithm or for Setiono's algorithm. Specifically, by comparing column 3 of [MoM87, Table 5] (also see [BDDW89], [MSSPB89]) with column 2 of Table 2, we see that the number of iterations for the QLPPF Algorithm can be up to $\frac{3}{2}$ times that for the affine-scaling algorithm. Similarly, the number of iterations for the QLPPF Algorithm can be up to $\frac{5}{3}$ times that for Setiono's algorithm (compare column 3 of [Set89, Table 3] with column 2 of Table 2). On the other hand, there are some problems on which the number of iterations is less for the QLPPF Algorithm than for the other algorithms.

In conclusion, our computational results indicate that, for linear programming, a mixed interior point-exterior point penalty method, as exemplified by the QLPPF Algorithm, can perform near the level of interior point algorithms. On the other hand, we caution that these results are very preliminary and thus should be viewed only as encouraging. In particular, the performance of the QLPPF Algorithm can be very sensitive to the choice of the initial parameters and the initial iterate. Of course, this also gives us hope that the performance of the QLPPF Algorithm can be improved with further fine tuning.

Finally, we remark it is typically beneficial to operate the QLPPF Algorithm with a large ratio of γ^k/ϵ^k . An intuitive explanation for this is that, if γ^k/ϵ^k is small, then γ^k is not a sufficiently large penalty (relative to ϵ^k) to maintain $t^k + \Delta t^k$ within the positive orthant. This results in small stepsizes λ^k (cf. (4.3)) and hence slow convergence.

5. Some extensions. We have thus far assumed that the parameters ϵ and γ are decreased at the same rate in the QLPPF Algorithm. Alternatively we can decrease them at different rates. For example, Setiono's algorithm employs the strategy whereby ϵ is first decreased with γ held fixed and, once ϵ reaches a prescribed tolerance, then γ is decreased with ϵ held fixed. (In [Set89], the product $\epsilon\gamma$ is what is referred to as γ .) We can also use different penalty parameters for different coordinates.

Our convergence results very possibly also extend to linear complementarity problems with positive semi-definite matrices—in the same manner that the results in [Tse89] can be extended to these problems (see [Tse92]). This is a topic for further study.

Acknowledgment. I thank Dr. R. Setiono for providing me with a copy of the YSMP code and for helpful discussions regarding implementation. I also thank Professor D. P. Bertsekas for his support of this project and the referees for their helpful comments.

DISCRETE-TIME TRANSITIVITY AND ACCESSIBILITY: ANALYTIC SYSTEMS*

FRANCESCA ALBERTINI[†] AND EDUARDO D. SONTAG[‡]

Abstract. A basic open question for discrete-time nonlinear systems is that of determining when, in analogy with the classical continuous-time “positive form of Chow’s Lemma,” accessibility follows from transitivity of a natural group action.

This paper studies the problem and establishes the desired implication for analytic systems in several cases: (i) compact state space, (ii) under a Poisson stability condition, and (iii) in a generic sense. In addition, the paper studies accessibility properties of the “controllability sets” recently introduced in the context of dynamical systems studies. Finally, various examples and counterexamples are provided relating the various Lie algebras introduced in past work.

Key words. discrete-time, nonlinear systems, transitivity, accessibility

AMS subject classifications. primary 93B03, 93B05; secondary 93C55, 93B29

1. Introduction. This paper continues the study, initiated in [7], of systems of the type

$$(1) \quad x(t+1) = f(x(t), u(t)), \quad t = 0, 1, 2, \dots,$$

where x and u take values in manifolds. The smooth mapping f is assumed to be invertible on x for each fixed u , a restriction that models systems that arise when dealing with continuous-time plants under digital control. See [7] for further motivation for the study of such systems, and [12] for general definitions of systems.

Given the system (1), we may introduce the *reachable* or *forward-accessible set* from a state x^0 , which we will denote by $R(x^0)$. This is the set of states to which we may steer x^0 using arbitrary controls. Clearly, reachable sets are one of the central concepts in control theory.

A mathematically far easier object to deal with is the *orbit* or *forward-backward accessible set* from x^0 , which we will denote by $O(x^0)$. This is defined as the set consisting of all states to which x^0 can be steered using both motions of the system and negative time motions: a state z is in the orbit of x^0 if there exists a sequence of states

$$x_0 = x^0, x_1, \dots, x_k = z$$

such that, for each $i = 1, \dots, k$, either x_i is reachable from x_{i-1} or x_{i-1} is reachable from x_i .

Of course, $R(x^0)$ is always included in $O(x^0)$, but these two sets are in general different. Observe that $O(x^0)$ is the orbit of x^0 under the group action induced by all the diffeomorphisms $f(\cdot, u)$, while the main interest in control theory—since negative time motions are in general not physically realizable—is in $R(x^0)$, the orbit under the corresponding semigroup. One reason that orbits are easier to study is that they have

[‡] SYCON–Rutgers Center for Systems and Control, Department of Mathematics, Rutgers University, New Brunswick, New Jersey 08903 (sontag@hilbert.rutgers.edu).

a natural structure of submanifold of the state space; this induces a decomposition of the state space into invariant submanifolds that integrate a natural distribution of vector fields (see, for instance, [13] and [11]).

One of the central facts in continuous-time controllability is the following property, valid for analytic systems and arbitrary states x^0 :

$$(C) \quad R(x^0) \text{ has nonempty interior in } O(x^0).$$

This property follows directly from the orbit theorem, but it can also be established for general smooth systems, under appropriate Lie-algebraic assumptions; it is often known as the “positive form of Chow’s Lemma.” Thus, for continuous-time, the state space can be partitioned into invariant submanifolds, and inside each submanifold we can reach an open set from each state. In particular, the interior of the reachable set from x^0 is nonempty—we then say that there is *forward accessibility from x^0* —if and only if the orbit is open—i.e., there is *transitivity from x^0* .

In contrast, property (C) may fail in discrete-time, even for systems obtained through the time-sampling of one-dimensional analytic continuous-time systems; see the examples in [7]. There are two known cases where (C) does hold:

(a) When x^0 is an *equilibrium point* (and the system is analytic and the control-value set is connected); this is one of the main results in [7].

(b) If the map f is *rational* on states and controls; see [9].

Both of these properties are quite restrictive; equilibria are in general few, and the rationality assumption is too strong in discrete-time (note that even when sampling very simple—for instance, polynomial—continuous-time systems we do not in general obtain rational equations.)

In this paper we extend the validity of property (C). For analytic systems, we prove that property (C) does hold if the orbit from x^0 is compact (see Remark 4.1), or under certain stability hypotheses related to Hamiltonian dynamics. Another result shows that if there is only one orbit (the system is transitive), then forward accessibility holds from an *open dense* set of states, assuming the state space to have at most finitely many connected components. Building upon the results in this paper, [2] provides further conditions under which property (C) holds.

Low-dimensional cases are of interest because certain special implications hold in those cases, and as sources of examples and counterexamples. For instance, we show that in dimension one transitivity from a given state x^0 implies either forward accessibility from x^0 or backward accessibility (controllability from some open set to x^0), but that this result fails in dimension two.

Recently, Colonius and Kliemann introduced the notion of *controllability subsets* of the state space of continuous-time systems. These are essentially sets where “almost reachability” holds. Controllability sets have proved to be an extremely useful concept; in particular, in [4] these authors established an interesting relationship between such sets and chaotic behavior in subsets of an associated dynamical system. The extension to discrete-time of the results of Colonius and Kliemann depends critically on the better understanding of the forward accessibility properties of controllability sets, so we devote the last part of this paper to that goal. The reader is referred to the conference paper [1] for a detailed explanation of how the results in [4] can indeed be extended when applying the techniques developed here.

2. Basic definitions. In this paper we will deal with discrete-time nonlinear systems Σ of the type (1) where $x(t) \in X$ and $u(t) \in U$. We assume that the

state space X is a connected, second countable, Hausdorff, differentiable manifold of dimension n , except in §5.1, where we wish to study what happens if the connectedness assumption is dropped.

The control-value space U is always assumed to be a subset of \mathbb{R}^m that satisfies the assumptions

$$U \subseteq \text{clos int } U$$

and $0 \in U$. We always assume that U is a connected set, except in §§3.1 and 6 where this assumption can be dropped.

The system is of class C^k , with $k = \infty$ or ω , if the manifold X is of class C^k and the function

$$f : X \times U \rightarrow X$$

is of class C^k (i.e., there exists a C^k extension of f to an open neighbourhood of $X \times U$ in $X \times \mathbb{R}^m$). We call systems of class C^∞ *smooth systems* and those of class C^ω *analytic systems*.

The most restrictive technical assumption to be made is that the system is *invertible*; this means that for each $u \in U$ the map $f_u = f(\cdot, u) : X \rightarrow X$ is a global diffeomorphism of X . Invertibility allows the application of the techniques in [7]; the assumption is satisfied when dealing with systems obtained by sampling a continuous-time one. We will use f_u^{-1} to denote the inverse of the map f_u .

Unless otherwise stated, from now on we assume that a fixed smooth system Σ is given.

2.1. Some notation. If there exists an integer $k \geq 0$ and a k -tuple $(u_k, \dots, u_1) \in U^k$ such that $f_{u_k, \dots, u_1}(x) = z$, we will write

$$x \overset{\sim}{\underset{k}{\rightsquigarrow}} z.$$

As usual, f_{u_k, \dots, u_1} denotes $f_{u_k} \circ \dots \circ f_{u_1}$. For any fixed state x and any nonnegative integer k define:

$$\psi_{k,x}(\mathbf{u}) := f_{u_k, \dots, u_1}(x),$$

where $\mathbf{u} = (u_k, \dots, u_1) \in U^k$. For each \mathbf{u} , let $\rho_{k,x}(\mathbf{u})$ be the rank of $\partial/\partial \mathbf{u} \psi_{k,x}[\mathbf{u}]$, and denote

$$\bar{\rho}_{k,x} := \max_{\mathbf{u} \in U^k} \rho_{k,x}(\mathbf{u}).$$

For each x , let also

$$\bar{\rho}_x := \max_{k \geq 0} \bar{\rho}_{k,x};$$

roughly, this is the largest possible dimension of a manifold reachable from x . Observe that $k' \geq k$ implies

$$(2) \quad \bar{\rho}_{k',x} \geq \bar{\rho}_{k,x}$$

because if $\mathbf{u} \in U^k$ achieves $\rho_{k,x}(\mathbf{u}) = \bar{\rho}_{k,x}$ then also $\rho_{k',x}(\tilde{\mathbf{u}}) \geq \rho_{k,x}(\mathbf{u})$ for any $\tilde{\mathbf{u}} \in U^{k'}$ that extends \mathbf{u} . We define the following sets:

$$R^k(x) := \{z \mid x \overset{\sim}{\underset{k}{\rightsquigarrow}} z\}$$

is the set of states *reachable from x in (exactly) k steps*,

$$\tilde{R}^k(x) := \{\psi_{k,x}(\mathbf{u}) \mid \mathbf{u} \in U^k, \rho_{k,x}(\mathbf{u}) = \bar{\rho}_x\}$$

is the set of states that are *maximal-rank reachable from x in (exactly) k steps*,

$$\bar{R}^k(x) := \{\psi_{k,x}(\mathbf{u}) \mid \mathbf{u} \in U^k, \rho_{k,x}(\mathbf{u}) = n\}$$

is the set of states that are *nonsingularly reachable from x in k steps*. Observe that, clearly,

$$\bar{R}^k(x) \subseteq \tilde{R}^k(x) \subseteq R^k(x).$$

We let

$$R(x) := \bigcup_{k \geq 0} R^k(x)$$

and analogously for $\tilde{R}(x)$ and $\bar{R}(x)$. Recall that Σ is said to be *forward accessible from x* if and only if $\text{int } R(x) \neq \emptyset$.

We also define

$$\begin{aligned} O^0(x) &= x, \\ O^k(x) &= \{z \mid \exists z_1 \in O^{k-1} \text{ and } z_1 \rightsquigarrow_1 z \text{ or } z \rightsquigarrow_1 z_1\}, \end{aligned}$$

and

$$O(x) = \bigcup_{k \geq 0} O^k(x).$$

Thus $O(x)$ is the orbit from x ; Σ is said to be *transitive from x* if and only if $\text{int } O(x) \neq \emptyset$.

Note that, given any state x , there is a well-defined restriction of the system to the orbit $O(x)$. Hence all results can be, in principle, applied in each orbit. The only difficulty is that orbits are often *not* connected, while most results hold only under the blanket assumption that the state space must be connected. In §5.1 we make some further comments about this issue.

Certain Lie algebras of vector fields L , L^+ , Γ , Γ^+ were introduced in [7] (see also [5] and [6] for previous work) we repeat their definitions here for the convenience of the reader.

First we let X_u^+ and X_u^- be the following vector fields:

$$X_{u,i}^+(x) = \left. \frac{\partial}{\partial v_i} \right|_{v=0} f_u^{-1} \circ f_{u+v}(x),$$

$$X_{u,i}^-(x) = \left. \frac{\partial}{\partial v_i} \right|_{v=0} f_u \circ f_{u+v}^{-1}(x),$$

one for each $i = 1, \dots, m$ (for computational aspects associated to these vector fields see [3]). Given a vector field Y and a control value u , we can define another vector field from Y by applying a change of coordinates given by the diffeomorphism f_u ,

$$(\text{Ad}_u Y)(x) = (df_u(x))^{-1} Y(f_u(x)).$$

Here df_u stands for the differential of f_u with respect to x . In the same way, but now using the diffeomorphism f_u^{-1} , we also define Ad_u^{-1} . We let

$$(3) \quad \text{Ad}_{u_k \dots u_1}^{\epsilon_k \dots \epsilon_1} Y = \text{Ad}_{u_1}^{\epsilon_1} \dots \text{Ad}_{u_k}^{\epsilon_k} Y.$$

We will use the abbreviated notation $\text{Ad}_0^k Y$ for $\text{Ad}_{0 \dots 0} Y$ with $u = 0$ repeated k -times, if $k > 0$, and for $\text{Ad}_0^{-1} \dots \text{Ad}_0^{-1} Y$, if $k < 0$. Additionally, $\text{Ad}_0^0 Y = Y$. The Lie algebras Γ^+ and Γ are now defined as

$$\Gamma^+ = \{\text{Ad}_{u_k \dots u_1} X_{u_0, i}^+ \mid k \geq 0, 1 \leq i \leq m, u_0, \dots, u_k \in U\},$$

$$\Gamma = \{\text{Ad}_{u_k \dots u_1}^{\epsilon_k \dots \epsilon_1} X_{u_0, i}^\sigma \mid k \geq 0, 1 \leq i \leq m, u_0, \dots, u_k \in U, \epsilon_1, \dots, \epsilon_k = \pm 1, \sigma = \pm\}.$$

Finally the Lie algebras L^+ and L are as follows:

$$L^+ = \text{Lie} \{\text{Ad}_0^k X_{u, i}^+ \mid k \geq 0, 1 \leq i \leq m, u \in U\},$$

$$L = \text{Lie} \{\text{Ad}_0^k X_{u, i}^+ \mid k \in \mathbb{Z}, 1 \leq i \leq m, u \in U\}.$$

We look at the sets of states in which various rank conditions fail, or forward accessibility fails:

$$\begin{aligned} B^+ &:= \{x \mid \text{int } R(x) = \emptyset\} \\ B_L^+ &:= \{x \mid \dim L^+(x) < n\} \\ B_\Gamma^+ &:= \{x \mid \dim \Gamma^+(x) < n\}. \end{aligned}$$

Although well-defined always, the set B_L^+ will be of interest only when the system is analytic.

2.2. Review of main known facts. With this notation, many of the results obtained in [7] can be visualized by the following diagram, where an arrow “ $A \rightarrow B$ ” indicates inclusion $A \subseteq B$, and the inclusions involving B_L^+ are only valid in the analytic case:

$$\begin{array}{ccccc} \tilde{R}(B^+) & \longrightarrow & B_\Gamma^+ & \longrightarrow & B_L^+ \\ \downarrow & & \downarrow & \swarrow & \\ R(B^+) & \longrightarrow & B^+ & & \end{array}$$

Note. The inclusion

$$(4) \quad \tilde{R}(B^+) \subseteq B_\Gamma^+$$

rephrases the result obtained in Corollary 4.4 of [7]. The inclusion $B_\Gamma^+ \subseteq B^+$ expresses the result in Theorem 6 part (a) of [7]. The inclusion $B_L^+ \subseteq B^+$ represents the result in Theorem 6 part (b) of [7].

3. Some new general properties. In this section we prove a number of general facts that can be conveniently expressed in terms of the sets just defined.

Remark 3.1. If there exists any k_0 such that $\bar{R}^{k_0}(x)$ is nonempty, then for all $k \geq k_0$ we have $\bar{R}^k(x) = \tilde{R}^k(x)$. Indeed, the assumption implies that $\bar{\rho}_x = n$.

PROPOSITION 3.1. *For each $x \in X$, the following properties are equivalent:*

- (a) $\text{int } \bar{R}(x) \neq \emptyset$;
- (b) $\text{int } \tilde{R}(x) \neq \emptyset$;
- (c) $\text{int } R(x) \neq \emptyset$.

Proof. Since $\bar{R}(x) \subseteq \tilde{R}(x) \subseteq R(x)$, it is only necessary to show that (c) implies (a).

We will show the following two properties:

- 1. for each $k \geq 0$ if $\text{int } \bar{R}^k(x) = \emptyset$ then $\bar{R}^k(x) = \emptyset$;
- 2. if $\bar{R}^k(x) = \emptyset$ for all $k \geq 0$ then $\text{int } R(x) = \emptyset$.

Combining (1) and (2) we have that if $\text{int } \bar{R}(x) = \emptyset$ then all $\text{int } \bar{R}^k(x) = \emptyset$ too, so $\text{int } R(x) = \emptyset$, as desired.

We first prove (1). Suppose that $\bar{R}^k(x) \neq \emptyset$, so that there exists some sequence $\bar{\mathbf{u}}$ for which the rank $\rho_{k,x}(\cdot)$ is equal to n at $\bar{\mathbf{u}}$. Since we assume $U \subset \text{clos int } U$, there exists also some $\tilde{\mathbf{u}} \in \text{int } U^k$ so that $\rho_{k,x}(\mathbf{u}) = n$ for each \mathbf{u} in some neighbourhood of $\tilde{\mathbf{u}}$. By the implicit mapping theorem, $\tilde{z} = \psi_{k,x}(\tilde{\mathbf{u}})$ belongs to $\text{int } \bar{R}^k(x)$.

We now prove (2). If $\bar{R}^k(x) = \emptyset$ for all $k \geq 0$ then each $\mathbf{u} \in U^k$ is a singular point of the map $\psi_{k,x}$, for each k . Thus by Sard's theorem $\psi_{k,x}(U^k)$ has measure zero for all $k \geq 0$. It follows that also

$$R(x) = \bigcup_{k \geq 0} R^k(x) = \bigcup_{k \geq 0} \psi_{k,x}(U^k)$$

has measure zero, and hence $\text{int } R(x) = \emptyset$, as desired. \square

PROPOSITION 3.2. *If the system Σ is analytic then, for any $x \in X$:*

$$\text{clos } R^k(x) = \text{clos } \tilde{R}^k(x)$$

for all k sufficiently large.

Proof. Fix $x \in X$, and let k_0 be so that $\bar{\rho}_{k_0,x} = \bar{\rho}_x$. For all $k \geq k_0$, let

$$A_k(x) = \{\mathbf{u} \mid \rho_{k,x}(\mathbf{u}) = \bar{\rho}_x\}.$$

We claim that $A_k(x)$ is an open dense set of U^k . This is because $A_k(x) \neq \emptyset$ by (2) and the complement of $A_k(x)$ is a set defined by the vanishing of certain analytic functions (suitable determinants) of \mathbf{u} .

We claim that

$$R^k(x) \subseteq \text{clos } \tilde{R}^k(x),$$

which implies

$$(5) \quad \text{clos } R^k(x) \subseteq \text{clos } \tilde{R}^k(x) \text{ for each such } k.$$

This will establish the result, the other inclusion being obvious.

Indeed, pick $k \geq k_0$ and take any $z \in R^k(x)$. Then $z = \psi_{k,x}(\mathbf{u})$ for some $\mathbf{u} = (u_k, \dots, u_1)$. Since $A_k(x)$ is dense, we can find a sequence $\{\mathbf{u}_l\}$ such that

$$\mathbf{u}_l = (u_k^{(l)}, \dots, u_1^{(l)}) \rightarrow \mathbf{u} = (u_k, \dots, u_1) \text{ as } l \rightarrow \infty$$

and $\mathbf{u}_l \in A_k(x)$ for each l .

Let $z_l = \psi_{k,x}(\mathbf{u}_l) \in \tilde{R}^k(x)$. By continuity, $z_l \rightarrow z$, which proves (5). \square

Remark 3.2. Assume that the system Σ is analytic, and that there exists an $x_0 \in X$ and a $k_0 \geq 0$ for which $\bar{R}^{k_0}(x_0) \neq \emptyset$. Then the proof of the previous result together with Remark (3.1) imply that

$$\text{clos } R^k(x_0) = \text{clos } \bar{R}^k(x_0)$$

for all $k \geq k_0$.

Moreover, since $\partial/\partial \mathbf{u} \psi_{k,x}[\mathbf{u}]$ is analytic also with respect to the x -variable, this particular k_0 works also for an open dense set of states $x \in X$. Thus, under these assumptions, we have that

$$\text{clos } R^k(x) = \text{clos } \tilde{R}^k(x) = \text{clos } \bar{R}^k(x)$$

for all $k \geq k_0$ and for almost all $x \in X$.

3.1. Regular points. We call x a *regular point* if $\bar{\rho}_x$ is constant in a neighbourhood of x . The following fact will be useful later; it is of course a well-known general fact about smooth mappings.

LEMMA 3.3. *The regular points form an open dense subset of X .*

Proof. Let

$$\bar{\rho} = \max_{x \in X} \bar{\rho}_x.$$

We have $\bar{\rho} \in \{0, \dots, n\}$. We will prove our thesis by induction on $\bar{\rho}$.

If $\bar{\rho} = 0$, then each $x \in X$ is a regular point, thus the statement is true.

Let $\bar{\rho} > 0$. Define

$$\begin{aligned} X_1 &:= \{x \in X \mid x \text{ is a regular point and } \bar{\rho}_x = \bar{\rho}\}, \\ Y_1 &:= \text{int } \{X \setminus X_1\}. \end{aligned}$$

Then X_1 and Y_1 are open. Moreover $X_1 \cup Y_1$ is dense in X , since its complement is the boundary of X_1 which is a nowhere dense set. If we call

$$\bar{\rho}_1 = \max_{x \in Y_1} \bar{\rho}_x$$

we have $\bar{\rho}_1 < \bar{\rho}$.

Thus, applying the inductive assumption to $(\bar{\rho}_1, Y_1)$, we have that the set of regular points in Y_1 , denote it by Y_r , is dense in Y_1 . But since the set of regular points of X is given by $X_1 \cup Y_r$ and $X_1 \cup Y_1$ is dense in X , then $X_1 \cup Y_r$ is also dense in X . \square

Note that, in the particular case in which the system is analytic, then in the above proof the set X_1 is already dense, because the rank is less than $\bar{\rho}$ if and only if certain determinants, which are analytic functions of x , vanish and this can happen only in a nowhere dense set.

4. More results for analytic systems. In this section we always assume the system Σ to be *analytic*.

LEMMA 4.1. *Suppose that for a fixed $x \in X$ there exists a sequence of elements $\{x_{n_k}\}$ and some $y \in X$ so that $\dim L^+(y) = n$, such that*

1. $x_{n_k} \in R^{n_k}(x)$, with $n_k \rightarrow \infty$;
2. $x_{n_k} \rightarrow y$.

Then the system is forward accessible from x (i.e. $x \notin B^+$).

Proof. Since $x_{n_k} \rightarrow y$ and $\dim L^+(y) = n$ there is some integer $k_0 \geq 0$ such that $\dim L^+(x_{n_k}) = n$ for all $k \geq k_0$. But for k sufficiently large we know (by Proposition (3.2)) that $x_{n_k} \in \text{clos } \tilde{R}^{n_k}(x)$. Thus there exists some $z \in X$ such that $z \in \tilde{R}^{n_k}(x)$ and $\dim L^+(z) = n$. So we can conclude forward accessibility from x by (4). \square

Remarks 4.1.

1. The result is also true if the weaker assumption $\dim \Gamma^+(y) = n$ is made, but we will apply it in the above form.

2. If x and y are as in the previous lemma, and U is any open neighbourhood of y , then, in particular, we have that $R(x) \cap U$ is also open.

3. If for a fixed $x \in X$ there exists a sequence of elements $\{x_{n_k}\}$ such that $x_{n_k} \in R^{n_k}(x)$, with $n_k \rightarrow \infty$ and $x_{n_k} \rightarrow x$ then, by the previous lemma, we can conclude that forward accessibility from x is equivalent to $\dim L^+(x) = n$. We will see later that in dimension 1 this equivalence is always true, but it can fail in higher dimensions.

For each $x \in X$, we will denote by $y_{0,x}^k$ the image under $\psi_{k,x}(\cdot)$ of the zero control; i.e.,

$$y_{0,x}^k = \psi_{k,x}(\underbrace{0, \dots, 0}_{k\text{-times}}).$$

LEMMA 4.2. *Suppose that $x, y \in X$ are so that*

1. *the system is transitive from y , (or equivalently, $\dim L(y) = n$),*

2. *there exists a sequence $\{y_{0,x}^{n_k}\}$ with $n_k \rightarrow \infty$ such that $y_{0,x}^{n_k} \rightarrow y$.*

Then $\dim L^+(x) = n$.

Proof. Choose n vector fields v_1, \dots, v_n in L such that

$$\{v_1(y), \dots, v_n(y)\}$$

is a basis for $L(y)$.

As in the proof of Proposition 4.2 in [7], we can assume that the v_i 's involve Lie brackets of a finite numbers of vector fields of the form $Ad_0^{k_j} X_{u_j}^+$, with $k_j \in \mathbb{Z}$. Choose a positive integer k_0 so that $k_j + k_0 \geq 0$ for all such j .

Since the v_i 's are linearly independent at y , they are still linearly independent in some neighbourhood U_y of y . By assumption (2), there is some n_k so that $y_{0,x}^{n_k} \in U_y$ and $n_k \geq k_0$.

Applying the operator $Ad_0^{n_k}$ to the v_i 's, there result n linearly independent vectors in $L^+(x)$, as desired. \square

4.1. Poisson stability. Recall that if Y is a vector field on a manifold M , one says that $x \in M$ is a *positively Poisson stable point* for Y if and only if for each neighbourhood V of x and each $T \geq 0$ there exists some $t > T$ such that $e^{tY}(x) \in V$, where $e^{tY}(\cdot)$ represents the flow of Y .

Analogously, we can define positive Poisson stability in discrete time, as follows.

DEFINITION 4.1. Let $f : X \rightarrow X$ be a global diffeomorphism. The point $x \in X$ is *positively Poisson stable* if and only if for each neighbourhood V of x and each integer $N \geq 0$ there exists some integer $k > N$ such that $f^k(x) \in V$.

THEOREM 4.3. *Let $x \in X$ be a positively Poisson stable point for $f_0 = f(\cdot, 0)$. Then transitivity from x implies forward accessibility from x .*

Proof. Positive Poisson stability from x implies the existence of a sequence $\{y_{0,x}^{n_k}\}$, with $n_k \rightarrow \infty$, convergent to x . Thus the result follows immediately combining Lemmas (4.1), (4.2) (applied with $y = x$). \square

4.2. Compact state space. For each $k \geq 0$ we define the following sets:

$$C^k(x) := \{y \mid y \overset{\sim}{\rightsquigarrow}_k x\},$$

i.e., the set of states *controllable to* x in (exactly) k steps, and

$$C(x) = \bigcup_{k \geq 0} C^k(x).$$

A system is *backward accessible from* x if and only if $\text{int } C(x) \neq \emptyset$.

THEOREM 4.4. *Let Σ be a discrete time, analytic, invertible system, and assume that the state space X is compact.*

Then, Σ is transitive if and only if it is forward accessible.

Proof. By [7], Theorem 3, it will be enough to show that $\dim L^+(x) = n$ for all $x \in X$. Fix any $x \in X$, and consider the sequence

$$y_{0,x}^l = \psi_{l,x}(0, \dots, 0).$$

Then since X is compact (and second countable) there exists a subsequence $\{y_{0,x}^{l_k}\}$ which converges; let y be so that $y_{0,x}^{l_k} \rightarrow y$. Since Σ is transitive, $\dim L(y) = n$, so, by Lemma (4.2), $\dim L^+(x) = n$ as wanted. \square

Remark 4.1. Notice that, in the previous theorem, the blanket assumption of connectedness of the state space X is not needed. In particular, the result holds if the orbit from a state x is compact.

Remark 4.2. Clearly, using the same arguments as in Theorem 4.4, we also have that, if the state space is compact, then transitivity from all $x \in X$ is equivalent to backward accessibility from all $x \in X$. We will not use this fact, however.

Recall that for a space Z with a σ -algebra F and a finite measure μ , we say that a measurable transformation $T: Z \rightarrow Z$ is *measure-preserving* if for every $A \in F$ we have $\mu(T^{-1}A) = \mu(A)$.

The following controllability result is an analogue for discrete-time systems of the result in [8]. The proof is very similar, but it uses the facts just established.

PROPOSITION 4.5. *Assume that the state space X is a compact Riemannian analytic manifold, and that for all $u \in U$ the map f_u is a measure preserving transformation (for the natural measure in X). Then Σ is transitive if and only if Σ is controllable.*

Proof. We need only to prove that transitivity implies controllability.

For each u , since f_u is a measure preserving map, by the Poincaré recurrence theorem the set of positively Poisson stable points for f_u is known to be dense in X .

Let $x, y \in X$; we need $y \in R(x)$. By Theorem 4.4, we know that Σ is both forward and backward accessible from x and y . Choose $\bar{x} \in \text{int } R(x)$ and $\bar{y} \in \text{int } C(y)$; since Σ is transitive there exist k , (u_k, \dots, u_1) , and $(\epsilon_k, \dots, \epsilon_1)$, with each $u_i \in U$ and $\epsilon_i = 1$ or -1 , such that

$$f_{u_k}^{\epsilon_k} \circ \dots \circ f_{u_1}^{\epsilon_1}(\bar{x}) = \bar{y}.$$

Let $l = \text{number of } \epsilon_i = -1$. We will show by induction on l the following fact:

there exist $\tilde{x} \in \text{int } R(x)$ and $\tilde{y} \in \text{int } C(y)$ such that $\tilde{y} \in R(\tilde{x})$.

Clearly the previous statement implies our thesis.

If $l = 0$ then the statement holds with $\tilde{x} = \bar{x}$ and $\tilde{y} = \bar{y}$. So let $l > 0$ and let i be the first index such that $\epsilon_i = -1$. Define

$$x_i = f_{u_{i-1}} \circ \dots \circ f_{u_1}(\bar{x})$$

and

$$y_i = f_{u_i}^{-1}(x_i).$$

Since $\bar{y} \in \text{int } C(y)$, there exists a neighbourhood V of y_i such that

$$f_{u_k}^{\epsilon_k} \circ \dots \circ f_{u_{i+1}}^{\epsilon_{i+1}}(V) \subseteq C(y);$$

let $W = f_{u_i}(V)$. Since $\bar{x} \in \text{int } R(x)$ we can assume (taking V smaller if necessary) that $W \subseteq R(x)$.

Choose $z_i \in W$ positively Poisson stable for f_{u_i} ; then there exists some $n > 1$ such that $f_{u_i}^n(z_i) \in W$ and the following properties hold:

- $f_{u_i}^{n-1}(z_i) = f_{u_i}^{-1} \circ f_{u_i}^n(z_i) \in V$,
- $\hat{y} = f_{u_k}^{\epsilon_k} \circ \dots \circ f_{u_{i+1}}^{\epsilon_{i+1}}(z_i) \in \text{int } C(y)$.

So we have constructed a trajectory joining $z_i \in \text{int } R(x)$ to $\hat{y} \in \text{int } C(y)$ with a number of negative steps strictly less than l ; the statement follows by induction. \square

Remark 4.3. The result obtained in the previous proposition can be applied to any discrete-time system Σ that arises through the time-sampling of a continuous-time system, if the vector fields in the right-hand side of the differential equation are conservative. The latter happens for Hamiltonian systems; see for instance [10] for many examples of such Hamiltonian control systems, and the last section of [11] for conditions under which transitivity is preserved under sampling.

5. Accessibility almost everywhere. For analytic systems, we say here that a property holds for “almost all” $x \in X$ if it holds on a set which is the complement of the set of zeros of a nonzero analytic function; note that such a set is open dense and its complement has zero measure.

LEMMA 5.1. *Let Σ be an n -dimensional, discrete-time, invertible, and analytic system. Then the following are equivalent:*

- (1) Σ is transitive from almost all $x \in X$;
- (2) $\dim L(x) = n$ for almost all $x \in X$;
- (3) Σ is forward accessible from almost all $x \in X$;
- (4) $\dim L^+(x) = n$ for almost all $x \in X$.

Proof. We will show $(1) \rightarrow (2) \rightarrow (4) \rightarrow (3) \rightarrow (1)$.

$(1) \rightarrow (2)$ This is a consequence of Theorem 4 in [7].

$(2) \rightarrow (4)$ Since the system is analytic, and X is connected it will be enough to show that there is at least one x with $\dim L^+(x) = n$, because the set where this property holds is either empty or open and dense. To show that there exists such an x we will use the same procedure used in proving Lemma 4.2.

Fix any $y \in X$ for which $\dim L(y) = n$, and let $v_1, \dots, v_n \in L$ be so that

$$\{v_1(y), \dots, v_n(y)\}$$

is a basis for $L(y)$. Assume that the v_i 's involve vector fields of the form

$$Ad_0^{k_j} X_{u_j}^+,$$

with $k_j \in \mathbb{Z}$, and choose a positive integer k_0 so that $k_j + k_0 \geq 0$ for all such j . Applying the operator $Ad_0^{k_0}$ to the v_i 's, there result n linearly independent vectors in $L^+(x)$, where $x := f_0^{-k_0}(y)$. Thus $\dim L^+(x) = n$.

$(4) \rightarrow (3)$ Again by analyticity, it will be sufficient to find at least one x form which Σ is forward accessible. Choose \bar{x} regular and let k , $\mathbf{u} = (u_k, \dots, u_1)$, and \bar{z} be such that

$$\psi_{k,\bar{x}}(\mathbf{u}) = \bar{z} \quad \text{and} \quad \rho_{k,\bar{x}}(\mathbf{u}) = \bar{\rho}_{\bar{x}}.$$

Let W be some neighbourhood of \bar{x} so that

$$\rho_{k,x}(\mathbf{u}) \geq \rho_{k,\bar{x}}(\mathbf{u}) = \bar{\rho}_{\bar{x}}$$

for each $x \in W$. As \bar{x} is regular

$$\bar{\rho}_{\bar{x}} = \bar{\rho}_x \geq \rho_{k,x}(\mathbf{u}),$$

so there is equality, $\rho_{k,x}(\mathbf{u}) = \rho_{k,\bar{x}}(\mathbf{u})$. Define

$$U = f_{\mathbf{u}}(W);$$

since $f_{\mathbf{u}}$ is a diffeomorphism, U is open. Moreover, by maximality of the rank, we have

$$U \subseteq \tilde{R}^k(W).$$

Since $\dim L^+(x) = n$ for almost all x , we can choose some $z \in U$ for which $\dim L^+(z) = n$. Let

$$y := f_{\mathbf{u}}^{-1}(z) \in W.$$

Note that then $z \in \tilde{R}^k(y)$ and $\dim L^+(z) = n$.

We can conclude forward accessibility from y by (4).

(3) \rightarrow (1) This is clear. \square

Remarks 5.1. (1) Since Σ is analytic, in each of the previous statements we can substitute “there exists $x \in X$ ” instead of “for almost all $x \in X$.”

(2) Note that, in general, the open dense sets in which the previous statements hold are *not* the same, except for those in parts (1) and (2). In particular, if we denote

$$B := \{x \mid \dim L(x) < n\},$$

we have

- $B = \{x \mid x \text{ is not transitive}\};$
- $B \subseteq B_L^+ \subseteq B^+;$

and the previous inclusions can be proper. For example, for the system described in Example 6.1 below we have

$$\begin{aligned} B &= \emptyset \\ B_L^+ &= \{ (k, y) \mid k \geq 1, k \in \mathbb{Z}, -k \leq y \leq k \} \\ B^+ &= \{ (k, y) \mid k \geq 0, k \in \mathbb{Z}, -k \leq y \leq k \} = B_L^+ \cup \{(0, 0)\}. \end{aligned}$$

(3) Let L^- be the Lie algebras defined in the same way as L^+ , but using the vector fields $X_{u,i}^-$ instead of $X_{u,i}^+$, and $k \leq 0$ instead of $k \geq 0$. Given this definition, the conclusions of Lemma 5.1 hold substituting (3) and (4) with the following properties:

- (3') Σ is backward accessible from almost all $x \in X$.
- (4') $\dim L^-(x) = n$ for almost all $x \in X$.

5.1. Nonconnected orbits. Given any system Σ , its state space can be partitioned into invariant submanifolds, the orbits. Since the system restricted to each orbit is transitive, we would like to conclude that relative to each orbit there is forward accessibility from almost every state. Unfortunately, this conclusion is false in general (see Example 5.1 below), because orbits are in general not connected. We can prove this fact, however, in the particular case of orbits with at most finitely many connected components, as follows from the next result.

PROPOSITION 5.2. *Let Σ be an n -dimensional, discrete-time, invertible and analytic system, and assume that the state space X has finitely many connected components. If Σ is transitive then it is forward accessible from almost all $x \in X$.*

Proof. Partition $X = \bigcup_{i=1}^l X_i$ into disjoint nonempty open connected subsets. Note that, if $x \in X_i$ and $f(x, u) \in X_j$, then since $X_i \times U$ is connected we have that

$$(6) \quad f(X_i \times U) \subseteq X_j,$$

by continuity of f . Then for each i there is some $j(i)$ so that

$$f_u(X_i) \subseteq X_{j(i)} \quad i = 1, \dots, l,$$

for every $u \in U$.

Fix now any $u \in U$. Since $f_u(X) = X$, necessarily $\bigcup_{i=1}^l X_{j(i)} = X$. As f_u is a diffeomorphism of X , the $X_{j(i)}$ are all distinct and $f_u(X_i) = X_{j(i)}$. Since Σ is transitive, we can conclude that for any $p = 1, \dots, l-1$, denoting by

$$f_u^p = \underbrace{f_u, \dots, u}_{p\text{-times}},$$

the following holds:

$$(7) \quad f_u^p(X_i) \neq X_i \quad \forall i = 1, \dots, l.$$

If this were not the case and there exists such p and i , then applying (6) p -times we would have

$$f_{u_1, \dots, u_p}(X_i) = X_i$$

for all $(u_1, \dots, u_p) \in U^p$. Thus the set

$$\bigcup_{j=0}^{p-1} f_u^j(X_i)$$

will be an invariant set different from X , which contradicts the assumption that Σ is an orbit. Moreover, from (7), since l is finite, we can conclude that

$$(8) \quad f_{u_1, \dots, u_l}(X_i) = X_i \quad \forall i.$$

By repeating the arguments used in the proof of the Lemma 5.1 ((2) \rightarrow (4)) we conclude that there exists $x \in X$ such that $\dim L^+(x) = n$. Assume that $x \in X_i$. Since X_i is connected we have

$$\dim L^+(y) = n \quad \text{from almost all } y \in X_i.$$

Choose $\bar{x} \in X_i$, \bar{x} regular and let k , $\mathbf{u} = (u_k, \dots, u_1)$, and \bar{z} be such that

$$\psi_{k,\bar{x}}(\mathbf{u}) = \bar{z} \quad \text{and} \quad \rho_{k,\bar{x}}(\mathbf{u}) = \bar{\rho}_{\bar{x}}.$$

By inequality (2) we can assume that k is a multiple of l . Thus, by (7), we get that $\bar{z} \in X_i$. Now, we can repeat the arguments used in the proof of the Lemma 5.1 ((4) \rightarrow (3)) and conclude that Σ is forward accessible from almost all $x \in X_i$.

To conclude that Σ is forward accessible from almost all $x \in X$ it is enough to note that, for any $j \neq i$, (7) implies that there exists p such that

$$f_{u_1, \dots, u_p}(X_j) = X_i. \quad \square$$

Example 5.1. Consider the following analytic system, with $X = \mathbb{R}^2$, $U = \mathbb{R}$, and equations:

$$\begin{aligned} x^+ &= x + 1, \\ y^+ &= y + uh(x), \end{aligned}$$

where $h(x)$ is any analytic function whose zeros are exactly at the positive integers $\{1, 2, 3, \dots\}$. This system is easily seen to be invertible. Let $z_0 = (0, 0)$. Then it is easy to verify that the orbit $O(z_0)$ is as follows:

$$O(z_0) = \bigcup_{i \in \mathbb{Z}} R_i,$$

$$R_i = \{ (i, y) \mid y \in \mathbb{R} \}.$$

If we restrict the system to this orbit, the restricted system is not forward accessible from any the points in R_i , for each $i = 1, 2, 3, \dots$. This is because there it holds that $h(x) = 0$, so z^+ and z must have the same y -coordinate.

6. Low-dimensional cases. In this section we make some remarks about one- and two-dimensional systems.

6.1. Dimension one. There we consider systems for which the state space X is of dimension one. The pointwise versions of [7, Thm. 3] hold for these systems as follows.

LEMMA 6.1. *Let Σ be as above, and pick $x \in X$. Then*

1. *if Σ is smooth then*
- Σ *is forward accessible from x if and only if $\dim \Gamma^+(x) = 1$;*
2. *if Σ is analytic and U is connected then*
- Σ *is forward accessible from x if and only if $\dim L^+(x) = 1$.*

Proof. (1) The necessary part follows from part (a) of Theorem 6 in [7], so we will prove sufficiency. If Σ is not forward accessible from x then $f(x, u)$ must be independent of u . Moreover if $y = f_{u_k, \dots, u_1}(x)$, since Σ is also not forward accessible from y , also

$$f(y, u) = f(f_{u_k, \dots, u_1}(x), u)$$

must be independent of u . Thus

$$Ad_{u_k, \dots, u_1} X_{u_0}^+(x) = \frac{\partial}{\partial v} \bigg|_{v=0} f_{u_k, \dots, u_1}^{-1} \circ f_{u_0}^{-1} \circ f_{u_0+v} \circ f_{u_k, \dots, u_1}(x) = 0,$$

which implies $\dim \Gamma^+(x) = 0$.

(2) The necessary part follows from part (b) of Theorem 6 in [7]. Sufficiency is a consequence of (1), since $L^+(x) \subseteq \Gamma^+(x)$. \square

LEMMA 6.2. *Let Σ be a one-dimensional, discrete-time, invertible system, and pick any $x \in X$ so that Σ is transitive from x . Then, either Σ is forward accessible from x or Σ is backward accessible from x .*

Proof. Suppose that neither conclusion holds.

We claim that, for each $u \in U$, Σ is not forward nor backward accessible from $y = f_u(x)$. Since x is not forward accessible, $f(x, u)$ is independent of u . Thus $y = f_u(x)$ for all $u \in U$, so also

$$f_u^{-1}(y) = x \quad \text{for all } u \in U.$$

It follows that $C^1(y) = x$, which implies that

$$C^k(y) = C^{k-1}(x) \quad \text{for all } k \geq 1.$$

Thus if Σ would be backward accessible from y also Σ would be backward accessible from x . Clearly, forward accessibility from y would imply forward accessibility from x (in any dimension). So the claim is proved.

With the same arguments we can prove that Σ is not forward nor backward accessible from $z = f_u^{-1}(x)$ for all $u \in U$.

Now we want to prove that $\dim \Gamma(x) = 0$, which implies that Σ is not transitive from x . In order to do that, we will show that

$$Ad_{u_k, \dots, u_1}^{\epsilon_k, \dots, \epsilon_1} X_{u_0}^\sigma(x) = 0$$

for all $k \geq 0$, (u_k, \dots, u_1) , $\epsilon_i = 1$ or -1 , $\sigma = 1$ or -1 , and for all x which are neither forward nor backward accessible.

We will use induction on k . Take first $k = 0$.

- If $\sigma = 1$

$$X_{u_0}^+(x) = \left. \frac{\partial}{\partial v} \right|_{v=0} f_{u_0}^{-1} \circ f_{u_0+v}(x) = 0$$

since $f(x, \cdot)$ is independent of u (Σ is not forward accessible from x).

- If $\sigma = -1$

$$X_{u_0}^-(x) = \left. \frac{\partial}{\partial v} \right|_{v=0} f_{u_0} \circ f_{u_0+v}^{-1}(x) = 0$$

since $f^{-1}(x, \cdot)$ is independent of u (Σ is not backward accessible from x).

Take now any $k > 0$ and note that

$$Ad_{u_k, \dots, u_1}^{\epsilon_k, \dots, \epsilon_1} X_{u_0}^\sigma(x) = (df_{u_k}^{\epsilon_k}(x))^{-1} Ad_{u_{k-1}, \dots, u_1}^{\epsilon_{k-1}, \dots, \epsilon_1} X_{u_0}^\sigma(f_{u_k}^{\epsilon_k}(x)).$$

From the first part of the proof, we have that Σ is also neither forward nor backward accessible from $f_{u_k}^{\epsilon_k}(x)$, so, by inductive assumption, this last vector is zero. \square

Remark 6.1. A consequence of the two previous lemmas is that, for each x :

1. $\dim L(x) = 1$ if and only if $\dim L^+(x) = 1$ or $\dim L^-(x) = 1$.
2. $\dim \Gamma(x) = 1$ if and only if $\dim \Gamma^+(x) = 1$ or $\dim \Gamma^-(x) = 1$.

The result in Lemma 6.2 is true only pointwise. In fact we can find a one-dimensional, analytic system Σ that is transitive but is neither forward nor backward accessible. One example of such a system is as follows.

Consider the following system:

$$(9) \quad x^+ = 1 + x + \frac{u}{2}[g(x) + g(x-1)]$$

with $X = \mathbb{R}$, $U = [-1, 1]$, and where $g(x)$ is the following function:

$$(10) \quad g(x) = \frac{\sin(\pi x)}{\pi x}.$$

It is easy to verify that $|g'(x)| \leq 1$ for all $x \in \mathbb{R}$. Moreover, $g(x) = 0$ if and only if $x \in \mathbb{Z} \setminus \{0\}$. Since $|g'(x)| \leq 1$, this system is invertible. Moreover the following properties hold and are easily verified:

1. Σ is transitive;
2. if $x = 2, 3, \dots$ then Σ is backward accessible but not forward accessible from x ;
3. if $x = -1, -2, -3, \dots$ then Σ is forward accessible but not backward accessible from x .

6.2. Dimension two. We now show that both the results in Lemmas 6.1 and 6.2 are false if the dimension of the state space X is greater than one, even if the system is invertible, analytic and with a connected control space U .

The following example illustrates these facts.

Example 6.1. Consider the discrete-time, analytic system with $X = \mathbb{R}^2$, $U = [-1, 1]^2$, and equations:

$$\begin{aligned} x^+ &= x + 1 + \frac{u}{2} \sin(y)g(x), \\ y^+ &= y + v, \end{aligned}$$

where $g(x)$ is the function in (10).

This system is invertible. In fact, the determinant of the Jacobian matrix of the map $f_{u,v}(x, y)$ is given by

$$1 + \frac{u}{2} \sin(y)g'(x).$$

Since $u \in [-1, 1]$, $|\sin(y)| \leq 1$ and $|g'(x)| \leq 1$,

$$|\frac{u}{2} \sin(y)g'(x)| < 1$$

so the determinant is nonzero for all x, y . Moreover it is easy to verify that for each $(u, v) \in U$, the map $f_{u,v}(\cdot, \cdot)$ is bijective.

We wish to study the behavior of this system when starting from $x = 0$, $y = 0$. Let $z_0 = (0, 0)$. We prove the following properties:

- (1) the system is not forward accessible from z_0 ;
- (2) the system is not backward accessible from z_0 ;
- (3) $\dim L^+(z_0) = 2$;
- (4) the system is transitive from z_0 .

Proof.

(1) This follows from the equality

$$R^k(z_0) = \{ (k, y) \mid -k \leq y \leq k \},$$

which holds for each $k \geq 1$ and it is clear from the equations.

(2) It will be sufficient to show that

$$(11) \quad C^k(z_0) = \{ (-k, y) \mid -k \leq y \leq k \}.$$

First note that if $(x_k, y_k) \in C^k(z_0)$ then we can write $y_k + v_1 + \dots + v_k = 0$ with all $|v_i| \leq 1$, so $|y_k| \leq k$.

To prove (11), it is now sufficient to note the following. For any fixed $u \in [-1, 1]$ and any $y \in \mathbb{R}$, the function

$$x \mapsto x + 1 + \frac{u}{2} \sin(y)g(x)$$

is invertible. Moreover

$$h^{-1}(-k+1) = -k \quad \text{for all } k \geq 1,$$

independently of u and y . Thus $x = -k$ is the only solution of $h(x) = -k+1$, for all u, y , and we have proved

$$C^k(z_0) \subseteq \{ (-k, y) \mid -k \leq y \leq k \}.$$

The other inclusion is obvious.

(3) Consider the vector fields

$$X_{(u,v),1}^+(z) = (df_{(u,v)}(z))^{-1} \frac{\partial}{\partial \epsilon} \Big|_{\epsilon=0} f_{(u+\epsilon,v)}(z)$$

and

$$X_{(u,v),2}^+(z) = (df_{(u,v)}(z))^{-1} \frac{\partial}{\partial \epsilon} \Big|_{\epsilon=0} f_{(u,v+\epsilon)}(z).$$

Fix $(u, v) = (0, 0)$. Then

$$df_{(0,0)}(z) = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$$

for all $z \in \mathbb{R}^2$,

$$X_{(0,0),1}^+(z) = \begin{pmatrix} \frac{\sin(y)g(x)}{2} \\ 0 \end{pmatrix},$$

and

$$X_{(0,0),2}^+(z) = \begin{pmatrix} 0 \\ 1 \end{pmatrix}.$$

So

$$\left[X_{(0,0),1}^+, X_{(0,0),2}^+ \right](z) = \begin{pmatrix} \frac{\cos(y)g(x)}{2} \\ 0 \end{pmatrix}.$$

In particular,

$$X_{(0,0),2}^+(z_0) = \begin{pmatrix} 0 \\ 1 \end{pmatrix}$$

and

$$\left[X_{(0,0),1}^+, X_{(0,0),2}^+ \right] (z_0) = \begin{pmatrix} 1/2 \\ 0 \end{pmatrix},$$

so $\dim L^+(z_0) = 2$ as desired.

(4) Transitivity at z_0 is a consequence of (3) since $\dim L^+(z_0) = 2$ implies $\dim L(z_0) = 2$. \square

7. Controllability sets. The next definition is a discrete-time analogue of that in [4], except that we make the assumption of nonempty interior.

DEFINITION 7.1. A set $D \subseteq X$ is called a *precontrollability set* if

$$D \subseteq \text{clos } R(x) \quad \text{for all } x \in D$$

and $\text{int } D \neq \emptyset$. A precontrollability set which is maximal with respect to set inclusion is called a *controllability set*.

Note that if D is a precontrollability set, then in D the system Σ is “almost” controllable, in the sense that if $x, y \in D$ then from x it is possible to reach any neighbourhood of y .

LEMMA 7.1. Let $D \subseteq X$ be a controllability set. Pick any two elements \bar{x}, \bar{y} in $\text{int } D$. Then, for each sequence $(u_0, \dots, u_T) \in U^{T+1}$ such that

$$f_{u_T} \circ \dots \circ f_{u_0}(\bar{x}) = \bar{y}$$

we have that, necessarily, also

$$f_{u_k} \circ \dots \circ f_{u_0}(\bar{x}) \in \text{int } D \quad \text{for } k = 0, \dots, T-1.$$

Proof. Let $\bar{x}, \bar{y}, u_0, \dots, u_T$ be as in the statement and let E be the following set:

$$E := \{ f_{u_k} \circ \dots \circ f_{u_0}(\bar{x}), \quad k = 0, \dots, T-1 \}.$$

We will first prove that $E \subseteq D$, by showing that $D' = D \cup E$ is again a precontrollability set and using that D is maximal. For this, we must prove that

$$D' \subseteq \text{clos } R(x) \quad \text{for each } x \in D'.$$

Observe that $E \subseteq R(\bar{x}) \subseteq \text{clos } R(\bar{x})$ and $\bar{y} \in R(y) \subseteq \text{clos } R(y)$ for all $y \in E$. Thus

- $E \subseteq \text{clos } R(\bar{x}) \subseteq \text{clos } R(\text{clos } R(x)) = \text{clos } R(x) \quad \forall x \in D$;
- $D \subseteq \text{clos } R(x) \quad \forall x \in D$;
- If $y \in E$ then $D \subseteq \text{clos } R(\bar{y}) \subseteq \text{clos } R(\text{clos } R(y)) = \text{clos } R(y)$
and $E \subseteq \text{clos } R(\bar{x}) \subseteq \text{clos } R(\text{clos } R(\bar{y})) \subseteq \text{clos } R(y)$.

Thus $D \cup E = D' \subseteq \text{clos } R(x) \quad \forall x \in D'$.

So we have proved that, for any two points \bar{x}, \bar{y} in $\text{int } D$ and any trajectory joining them, all the intermediate states must be in D . We now prove that such intermediate points must be in $\text{int } D$.

Pick any $\bar{x}, \bar{y}, u_0, \dots, u_T$ as above. Let $k \in \{0, \dots, T-1\}$ and $\bar{z} = f_{u_k} \circ \dots \circ f_{u_0}(\bar{x})$. By continuity of $f_{u_0}^{-1} \circ \dots \circ f_{u_k}^{-1}$ and of $f_{u_{k+1}} \circ \dots \circ f_{u_T}$, there exists some open neighbourhood V of \bar{z} such that

$$f_{u_0}^{-1} \circ \dots \circ f_{u_k}^{-1}(V) \subseteq \text{int } D \quad \text{and} \quad f_{u_{k+1}} \circ \dots \circ f_{u_T}(V) \subseteq \text{int } D.$$

Pick any $z \in V$. For such a z ,

$$z = f_{u_k} \circ \dots \circ f_{u_0}(x)$$

for some $x \in \text{int } D$ and

$$y = f_{u_{k+1}} \circ \dots \circ f_{u_T}(z) \in \text{int } D.$$

Thus, applying the first part of the proof to x and y (rather than to \bar{x} and \bar{y}), it follows that $z \in D$. We conclude that $V \subseteq D$, so \bar{z} is in $\text{int } D$, as desired. \square

LEMMA 7.2. *Let $D \subseteq X$ be a precontrollability set. Then we have*

$$D \subseteq \text{clos } F_k(\text{int } D) \quad \text{for all } k = 0, 1, 2, \dots,$$

where

$$F_k(\text{int } D) = \bigcup_{l \geq k} R^l(\text{int } D).$$

Proof. We proceed by induction on k . The case $k = 0$ follows directly from the definition of controllability set. So let $k \geq 1$ and pick any $x \in D$.

Choose $y \in \text{int } D$, $y \neq x$. By inductive assumption there exists a sequence $y_n \rightarrow y$ with

$$y_n \in F_k(\text{int } D).$$

For \bar{n} sufficiently large, $y_{\bar{n}} \in D$ (since $y \in \text{int } D$) and $y_{\bar{n}} \neq x$ (since $y \neq x$), where each $y_{\bar{n}}$ is of the form

$$y_{\bar{n}} = \psi_{l,z}(\mathbf{u})$$

with $z \in \text{int } D$, $l \geq k$, for some $\mathbf{u} \in U^l$. Pick one such \bar{n} . Since $x \in \text{clos } R(y_{\bar{n}})$, there exist a sequence $\{t_n\}$ and a sequence $\{z_n\}$ so that

$$z_n \in R^{t_n}(y_{\bar{n}}) \quad \text{and} \quad z_n \rightarrow x.$$

Since $y_{\bar{n}} \neq x$ we can assume $t_n \geq 1$ for all n . Thus

$$z_n \in R^{l+t_n}(z) \subseteq F_{k+1}(\text{int } D),$$

which implies $x \in \text{clos } F_{k+1}(\text{int } D)$. \square

Remark 7.1. The conclusion of the previous lemma can be rephrased by saying that

$$D \subseteq \overline{\lim}_k R^k(\text{int } D),$$

where for any family of sets E_k , $\overline{\lim}_k E_k = \bigcap_{k=0}^{\infty} \bigcup_{l \geq k} E_l$.

LEMMA 7.3. *Let $D \subseteq X$ be a controllability set. Then*

$$\text{clos } D = \text{clos int } D.$$

Proof. Let $x \in D$. We only need to prove that for any neighbourhood W of x ,

$$W \cap \text{int } D \neq \emptyset.$$

Pick any such W and choose any $y \in \text{int } D$. Since $y \in \text{clos } R(x)$, we can find $z = \psi_{k,x}(\mathbf{u})$ for some $k \geq 0$ and some $\mathbf{u} \in U^k$, such that $z \in \text{int } D$. Let U_z be a neighbourhood of z contained in D . Then, by continuity, there exists a neighbourhood U_x of x such that for all $y \in U_x$, $\psi_{k,y}(\mathbf{u})$ is in U_z and so, in particular, in $\text{int } D$.

Let $W_x = U_x \cap W$. Choose $y' \in \text{int } D$. Since $x \in \text{clos } R(y')$, we can find k', \mathbf{u}' such that

$$\bar{x} := \psi_{k',y'}(\mathbf{u}') \in W_x.$$

Let $\bar{\mathbf{u}}$ be the concatenation of \mathbf{u}' and \mathbf{u} . Since $\bar{x} \in U_x$,

$$\psi_{k,\bar{x}}(\mathbf{u}) \in \text{int } D.$$

Thus

$$\psi_{k+k',y'}(\bar{\mathbf{u}}) \in \text{int } D,$$

so by Lemma (7.1), $\bar{x} \in \text{int } D$. Hence

$$W_x \cap \text{int } D \neq \emptyset,$$

so $W \cap \text{int } D \neq \emptyset$ as wanted. \square

DEFINITION 7.2. Let $x \in X$ and $S \subseteq X$. We say that x is *forward accessible in S* (respectively, *backward accessible in S*) if

$$\text{int}(R(x) \cap S) \neq \emptyset$$

(respectively, $\text{int}(C(x) \cap S) \neq \emptyset$).

If we simply say that x is forward (backward) accessible, we mean forward (backward) accessible in X .

LEMMA 7.4. *Let $S \subseteq X$ and define*

$$S_f = \{ x \in M \mid x \text{ is forward accessible in } S \},$$

then S_f is open.

Proof. If $S_f = \emptyset$, then it is trivially open; thus assume $S_f \neq \emptyset$. Pick any $x \in S_f$.

By assumption there exists $W \subseteq S$ open such that $W \subseteq R(x)$; therefore there exists k such that $W \cap R^k(x)$ has nonzero measure. Let

$$U_W^k = \{ \mathbf{u} \mid \mathbf{u} \in U^k, \text{ and } \psi_{k,x}(\mathbf{u}) \in W \},$$

then U_W^k is open and the image of

$$\psi_{k,x}|_{U_W^k}$$

has nonzero measure. It follows, by Sard's theorem, that there exists $\mathbf{u} \in U^k$ such that $\rho_{k,x}(\mathbf{u}) = n$. We may assume, without loss of generality, that $\mathbf{u} \in \text{int } U^k$.

Now pick any neighbourhood V of x such that $\psi_{k,V}(\mathbf{u}) \subseteq W$ and still $\rho_{k,y}(\mathbf{u}) = n$ for all $y \in V$. By the implicit mapping theorem, $V \subseteq S_f$; therefore S_f is open. \square

We assume from now on that the system Σ to be *analytic* and *transitive*. In this case, we can conclude the following important property of precontrollability sets.

THEOREM 7.5. *Let $D \subseteq X$ be a precontrollability set. Then every point of D is forward accessible in D .*

Proof. Since Σ is transitive and analytic, by Lemma 5.1 we have that there exists an open dense set of points for which $\dim L^+(x) = n$. If we intersect this set with $\text{int } D$ then this intersection, which we denote by W , is open.

Pick any $x \in D$, and y in W , with $x \neq y$. Now, we will construct a sequence of elements y_n such that

$$y_n \rightarrow y, \quad y_n \in R^{k_n}(x) \quad \text{and} \quad k_n \rightarrow \infty \quad \text{as} \quad n \rightarrow \infty.$$

Then, using Lemma 4.1 and its successive remarks, we can conclude that from x it is possible to reach an open set within any neighbourhood of y , i.e., since $y \in \text{int } D$, x is forward accessible in D , as desired.

To construct the y_n 's we proceed as follows. Let's denote by W_n a neighbourhood of y . Since $y \in \text{clos } R(x)$, we can find $y_1 \in W_1$, $y_1 \neq y$, and $y_1 \in R^{k_1}(x)$ where (since $y \neq x$) we can assume $k_1 \geq 1$.

Now we proceed by induction. Suppose that we have found y_1, \dots, y_n such that

$$y_i \in W_i, \quad y_i \neq y, \quad y_i \in R^{k_i}(x) \quad \text{and} \quad k_i \geq i \quad \text{for} \quad i = 1, \dots, n.$$

Since $y \in \text{clos } R(y_n)$ we can find $y_{n+1} \in W_{n+1}$ such that

$$y_{n+1} \neq y, \quad y_{n+1} \in R^l(y_n)$$

with $l \geq 1$. Since $y_n \in R^{k_n}(x)$,

$$y_{n+1} \in R^{k_n+l}(x)$$

and $k_{n+1} = k_n + l \geq n + 1$. Thus $k_n \rightarrow \infty$ as $n \rightarrow \infty$; moreover, we can choose the W_i 's in such a way that $y_n \rightarrow y$. \square

The definition of precontrollability set is not reversible in time, so we cannot conclude backward accessibility from every point. However, the next result provides backward accessibility from a dense subset.

PROPOSITION 7.6. *Let $D \subseteq X$ be a controllability set. Then there exists some (necessarily nonempty) open subset $E \subseteq D$ such that*

- (1) $\text{clos } E = \text{clos } D$;
- (2) if $y \in E$ then y is backward accessible in D .

Proof. Since Σ is transitive and analytic, by Lemma 5.1 applied to the "inverse" system

$$x(t+1) = f_u^-(x(t)),$$

we know that there exists an open dense set from which we have backward accessibility. Moreover, there exists some integer k_0 such that the set G of states $x \in X$ for which $\text{int } C^{k_0}(x) \neq \emptyset$ and

$$\text{clos int } C^k(x) = \text{clos } C^k(x)$$

for all $k \geq k_0$ is itself open dense (Remark 3.2). Consider first the open set

$$E' = \text{int } D \cap G.$$

We claim that E' is open and

$$\text{clos } E' = \text{clos int } D.$$

To show this, it is enough to establish that $\text{int } D \subseteq \text{clos } E'$. So take any $x \in \text{int } D$. By density of G , there exists some sequence $\{y_n\}$ with $y_n \in G$ for all n , $y_n \rightarrow x$. Thus

$$y_n \in \text{int } D \cap G$$

for all large enough n , and this shows that $x \in \text{clos } E'$. Finally, let

$$E = E' \cap F_{k_0}(\text{int } D),$$

where $F_{k_0}(\text{int } D)$ is defined as in Lemma (7.2). Then E is also open, since $F_k(\text{int } D)$ is open for any k . Moreover, using the result in Lemma (7.2) (i.e., $D \subseteq \text{clos } F_{k_0}(\text{int } D)$) and the same arguments used before we have

$$\text{clos } E = \text{clos } E' = \text{clos int } D.$$

Thus, by Lemma (7.3),

$$\text{clos } E = \text{clos } D.$$

So E satisfies property (1). We prove next that it also satisfies (2).

Pick $y \in E$. Since $y \in F_{k_0}(\text{int } D)$ then there exists $x \in \text{int } D$ so that $y \in R^k(x)$ for some $k \geq k_0$. This means that $x \in C^k(y)$. Since $y \in G$,

$$x \in \text{clos int } C^k(y).$$

Thus, since $x \in \text{int } D$, we can find some $z \in \text{int } D \cap \text{int } C^k(y)$, which means that y is backward accessible in D . Thus (2) is proved. \square

LEMMA 7.7. *Let $D \subseteq X$ be a controllability set and let E be any set as in the conclusion of the previous proposition. Then*

$$E \subseteq R(x) \quad \text{for each } x \in D.$$

Proof. Take any $y \in E$ and $x \in D$. By the previous proposition, there exists some nonempty open set $W \subseteq D \cap C(y)$. Choose any $z \in W$. Since D is a controllability set, $z \in \text{clos } R(x)$, so there exists also $\tilde{z} \in R(x) \cap W$. Thus $\tilde{z} \in R(x)$ and $y \in R(\tilde{z})$ (since $\tilde{z} \in C(y)$) imply $y \in R(x)$. \square

DEFINITION 7.3. For any set $S \subseteq X$, define

$$\text{Core}(S) := \{ x \in \text{int } S \mid x \text{ is forward and backward accessible in } S \}.$$

Using Lemma 7.4 twice (once for Σ and another time for the “inverse” system $x(t+1) = f_u^-(x(t))$), we can conclude the following.

LEMMA 7.8. *For any subset $S \subseteq X$, $\text{Core}(S)$ is open.*

For a controllability set D , we proved (see results in Theorem 7.5 and Proposition (7.6)) that $\text{Core}(D) \supseteq E$ for some $E \subseteq D$ such that $\text{clos } E = \text{clos } D$. Thus we have

$$(12) \quad \boxed{\text{clos Core}(D) = \text{clos } D \quad \text{for a controllability set } D.}$$

Moreover, the result in Lemma (7.7) can be rephrased as follows.

PROPOSITION 7.9. *If D is a controllability set, and $E = \text{Core}(D)$, then $E \subseteq R(x)$ for all $x \in D$.*

If D is a controllability set, then, by the previous results, $\text{Core}(D)$ is a dense subset of D in which we have exact controllability. Note that if Σ was a continuous time system then $\text{Core}(D)$ would have been equal to $\text{int } D$. However for discrete-time systems there are controllability sets D for which $\text{Core}(D)$ is strictly contained in $\text{int } D$, as it is shown in the next example.

Example 7.1. Let us consider the discrete-time, analytic system with $X = \mathbb{R}^2$, $U = [-1, 1]^2$, and equations

$$\begin{aligned}x^+ &= x + 1 + uy, \\y^+ &= y + \frac{v}{2}g(x),\end{aligned}$$

where $g(x)$ is the function in (10).

This system is invertible. In fact the determinant of the Jacobian matrix of the map $f_{u,v}(x, y)$ is given by

$$1 - \frac{uv}{2}g'(x).$$

Since $u, v \in [-1, 1]$, and $|g'(x)| \leq 1$,

$$\left| \frac{uv}{2}g'(x) \right| \leq \frac{1}{2}$$

so the determinant is nonzero for all x, y . Moreover it is easy to verify that for each $(u, v) \in U$, the map $f_{u,v}(\cdot, \cdot)$ is bijective. It is also easy to prove that this system is transitive.

For this system we can see that for all $k \in \mathbb{N}$ with $k \geq 1$ the following hold:

1. the points of the type $(-k, 0)$ are not backward accessible;
2. the points of the type $(k, 0)$ are not forward accessible.

Let

$$B = \{ (k, 0) \mid k \in \mathbb{N}, \ k \geq 1 \}.$$

Next we want to show that $D = \mathbb{R}^2 \setminus B$ is a controllability set.

Note that D is certainly maximal; in fact, no points in B could belong to a controllability set, since they are not forward accessible. To prove that D satisfies

$$(13) \quad D \subseteq \bar{R}(\xi) \quad \text{for all } \xi \in D$$

we will prove the following:

$$(14) \quad \mathbb{R}^2 \setminus \{ (k, y) \mid k \in \mathbb{Z}, \ y \in \mathbb{R} \} \subseteq R(\xi),$$

which, by taking the closure in both sides, implies (13). Let $F = \{ (k, y) \mid k \in \mathbb{Z}, \ y \in \mathbb{R} \}$.

First we note that, since $|\sin(\pi(x+1))| = |\sin(\pi x)|$, if we apply to any (x, y) a control sequence of the following form:

$$(15) \quad u_l = 0, \quad v_l = \text{sign}(g(x+l-1)),$$

then, after k steps, we will reach the following point:

$$x_k = x + k$$

$$y_k = y + \frac{|\sin(\pi x)|}{2\pi} \sum_{l=0}^{k-1} \frac{1}{|x+l|}.$$

Using this fact and the divergence of the series $\sum_n 1/n$ we will prove (14).

Fix $(\bar{x}, \bar{y}) \in D$ and $(\tilde{x}, \tilde{y}) \in \mathbb{R}^2 \setminus F$. Note that, since $(\bar{x}, \bar{y}) \notin B$, it is not restrictive to assume

$$g(\bar{x}) \neq 0 \quad \text{and} \quad \bar{y} \neq 0.$$

First we choose u_l, v_l as in (15). Since $g(\bar{x}) \neq 0$ there exists k such that $y_k > 1$. Next we apply a control sequence with all $v_l = 0$ so as to reach a state (x', y') of the type

$$x' = \tilde{x} - n \quad \text{and} \quad y' = y_k,$$

where n is a positive integer that will be chosen later. Note that we can assume $\tilde{y} < y'$.

Now we want to find a sequence of controls $(0, v_l)$ such that we get the state (\tilde{x}, \tilde{y}) in exactly n steps. It is clear that this is possible if and only if

$$(16) \quad y' - \frac{|\sin(\pi \tilde{x})|}{2\pi} \sum_{l=0}^{n-1} \frac{1}{|\tilde{x} - n + l|} \leq \tilde{y}.$$

So we just have to choose n large enough such that (16) is satisfied. This is possible since $\sin(\pi \tilde{x}) \neq 0$ and

$$\sum_{l=0}^{n-1} \frac{1}{|\tilde{x} - n + l|} = \sum_{m=1}^n \frac{1}{|\tilde{x} - m|}$$

is divergent. Thus D is a controllability set.

Note that, for this controllability set D , $\text{Core}(D)$ is strictly contained in $D = \text{int } D$. In fact, none of the points of the type $(-k, 0)$ with k a strictly positive integer belongs to $\text{Core}(D)$.

INFINITE DETERMINISTIC GRAPHICAL GAMES*

V. J. BASTON[†] AND F. A. BOSTOCK[†]

Abstract. A deterministic graphical game is a two-person zero-sum game with perfect information played on a directed graph. Nodes with no successor are called terminal nodes and have a payoff associated with them. The other nodes are labelled to indicate which of the players chooses the successor node. Play starts at a specific node and only stops when a terminal node is reached at which point player 1 obtains the payoff corresponding to that node; if play never ends the payoff is zero. The paper shows that such games have a solution even when the graph has an infinite number of nodes.

Key words. recursive game, two-person zero-sum game, game with perfect information, graphical game

AMS subject classifications. 90D20, 90D05

1. Introduction. Two-person zero-sum games with perfect information have attracted considerable attention over the years. They were defined by von Neumann and Morgenstern [10], who proved that they have a value and that the players in them have pure strategies that are optimal. Gale and Stewart [5] considered infinite games with perfect information in which a play of the game gives rise to a sequence of digits that determines a real number x leading to a payoff $f(x)$. They demonstrated that not all such games have a solution and found sufficient conditions for them to do so. Davis [2] and Mycielski [6] obtained further results on these games while Oxtoby [8] investigated a very general game of a similar type. Ehrenfeucht and Mycielski [3] studied games with perfect information in which the two players move alternately along the edges of a finite directed graph having weights attached to its edges. More recently, Washburn [11] considered a class of perfect information games played on a finite graph and his results have been supplemented by Baston and Bostock [1]. Washburn called his games deterministic graphical games and defined them as follows.

A *deterministic graphical game* is a two-person zero-sum game played on a directed graph with $n > 0$ nodes. Nodes with no successor are called terminal nodes and have a payoff to player 1 associated with them. The other nodes are called continuing nodes and are labelled to indicate which player chooses the successor node. Play starts at a specific node and only stops when a terminal node is reached at which point player 1 obtains the payoff corresponding to that node; if play never ends, the payoff is by convention zero.

Washburn pointed out that special cases of these games had previously occurred in the literature but, that up to then, the class had remained nameless. He also commented that they are special cases of recursive games with the consequence that every deterministic graphical game has a value and, what is more, attention can be restricted to stationary strategies for the players. In this paper we consider the corresponding game in which the number of nodes can be infinite; since it is still an open question whether all countably infinite recursive games have a solution, the position

*Received by the editors October 16, 1991; accepted for publication (in revised form) July 15, 1992.

[†]Faculty of Mathematical Studies, University of Southampton, Southampton SO9 5NH, United Kingdom.

in this case is not so straightforward. However, we show that even uncountably infinite deterministic graphical games always have a value and that the players have pure stationary strategies that are essentially ϵ -optimal (with an appropriate interpretation when a component game has an infinite value). In recursive games, knowing the starting component is regarded as part of the history and, in this context, the strategies we present are very simple history remembering (namely semistationary) ones. An example is provided to show that infinite recursive games with perfect information need not have a solution if the players are restricted to Markov strategies which were the strategies used by Everett in his paper [4] introducing finite recursive games.

2. Notation and preliminary ideas. Let W be the set of nodes that we consider to be well-ordered; the well-ordering is used when we select certain elements in the proof of Theorem 3.1. Let T be the set of terminal nodes, I the set of continuing nodes at which player 1 chooses the successor, and J the set of continuing nodes at which player 2 chooses the successor. For $k \in W$, let

$$U_k = \begin{cases} \{i \in W : i \text{ is a successor of } k\} & \text{if } k \in I; \\ \{1\} & \text{if } k \in W \setminus I, \end{cases}$$

and

$$V_k = \begin{cases} \{i \in W : i \text{ is a successor of } k\} & \text{if } k \in J; \\ \{1\} & \text{if } k \in W \setminus J. \end{cases}$$

Note that U_k and V_k are effectively the control sets of players 1 and 2 at node k ; since player 1 has no control over which successor is chosen at nodes k in $W \setminus I$, we have, in such cases, defined U_k arbitrarily as $\{1\}$. Analogous comments apply to the V_k .

For $k \in W$, $u \in U_k$, $v \in V_k$ let

$$f(k, u, v) = \begin{cases} u & \text{if } k \in I; \\ v & \text{if } k \in J; \\ k & \text{if } k \in T, \end{cases}$$

and

$$c(k, u, v, f(k, u, v)) = \begin{cases} P(f(k, u, v)) & \text{if } k \notin T, f(k, u, v) \in T; \\ 0 & \text{otherwise,} \end{cases}$$

where, for $w \in T$, $P(w)$ is the payoff to player 1 at w .

We now define our strategy spaces for the players. In a deterministic graphical game each player knows the node at which the game starts. However, in a multistage game, it is usual for a strategy to provide instructions for all starting nodes and this is the approach we will adopt. A *history* h_k at stage $k \geq 0$ is defined as a sequence

$$(1) \quad (x_0; u_0, v_0), (x_1; u_1, v_1), \dots, (x_{k-1}; u_{k-1}, v_{k-1}), x_k,$$

where $x_i \in W$, $u_i \in U_{x_i}$, and $v_i \in V_{x_i}$. Note that a history at stage $k = 0$ is not empty but comprises of the starting node. Our definition of history corresponds to that of, for instance, Nowak and Raghavan [7] in stochastic games. Let \mathcal{H}_k be the set of all histories at stage $k \geq 0$. A *history remembering strategy* F for player 1 is a sequence F^0, F^1, \dots , where F^k is a function from \mathcal{H}_k to $\bigcup_{i \in W} U_i$, where $F^k(h_k) \in U_{x_k}$ when h_k is given by (1). A history remembering strategy for player 2 is defined similarly.

If, for all k and for all h_k of the form (1), $F^k(h_k)$ depends solely on the starting node x_0 and the node x_k that play has reached, F is called *semistationary*. When, in addition, $F^k(h_k)$ is independent of the starting node x_0 for all k the

strategy is said to be *stationary*. Given a starting node x_0 and strategies F and G for player 1 and player 2, respectively, it is easily seen that an infinite sequence $(x_0, u_0, v_0, x_1), (x_1, u_1, v_1, x_2), \dots$ is defined recursively where $f(x_r, u_r, v_r) = x_{r+1}$; the payoff $C(x_0, F, G)$ is now given by $C(x_0, F, G) = \sum_{k=0}^{\infty} c(x_k, u_k, v_k, x_{k+1})$. Player 1 seeks to maximize $C(x_0, F, G)$ and player 2 seeks to minimize it.

A deterministic graphical game has been modelled as a system evolving in W according to $x_{t+1} = f(x_t, u_t, v_t)$ starting at a given node $x_0 \in W \setminus T$ at stage $t = 0$; we are ignoring the trivial case when play starts at a terminal node. The ϵ -optimal strategies we will give for the players are semistationary strategies. Note that, in the system, play effectively terminates if and when play first enters a terminal node since the only possible nonzero term of the infinite sum is one that corresponds to play first entering a terminal node.

For the example in §4 it is convenient to use the notation of recursive games (see [4] or, on a more elementary level, [9]). Note that our system can be put as a recursive game $\Gamma = (\Gamma_i)_{i \in W}$, where Γ_i has matrix $M_i : U_i \times V_i \rightarrow W$ given for $u \in U_i, v \in V_i$ by

$$M_i(u, v) = \begin{cases} \Gamma_{f(i, u, v)} & \text{if } i \notin T; \\ P(i) & \text{if } i \in T. \end{cases}$$

For all nonnegative integers n and all positive real numbers x we now define a subset $H_n(x)$ of the set of nodes W . For a positive real number x put

$$H_0(x) = \{t \in T : P(t) \geq x\}.$$

Let $n \geq 1$ be a positive integer and suppose that $H_r(x)$ has been defined for all $x > 0$ and for all nonnegative integers $r < n$. For $x > 0$ define

$$H_n(x) = \{i \in I : U_i \cap H_r(x) \text{ is nonempty for some } r < n\} \\ \cup \{i \in J : \text{for each } \xi \in V_i \text{ there is an } r < n \text{ such that } \xi \in H_r(x)\}.$$

Clearly $r < n$ implies $H_r(x) \subseteq H_n(x)$. Further, using induction, it is easy to see that $x < y$ implies $H_n(y) \subseteq H_n(x)$.

Let $H(x) = \bigcup_{n=0}^{\infty} H_n(x)$. Intuitively, if play starts at a node $i \in H(x)$, then player 1 will be able to ensure himself of at least x . Now define $p(i) = \max\{0, \sup\{x : i \in H(x)\}\}$. Note that we write $p(i) = \infty$ when $\{x : i \in H(x)\}$ is not bounded above. For $x > 0$ define $m_j(x)$ as follows; if $j \in H(x) \cap I$, then $m_j(x)$ is the least integer n such that $U_j \cap H_n(x)$ is nonempty; otherwise $m_j(x) = 0$.

In an analogous fashion, for a negative real number y , put

$$K_0(y) = \{t \in T : P(t) \leq y\}$$

and, for positive integers $n \geq 1$,

$$K_n(y) = \{i \in J : V_i \cap K_r(y) \text{ is nonempty for some } r < n\} \\ \cup \{i \in I : \text{for each } \xi \in U_i \text{ there is an } r < n \text{ such that } \xi \in K_r(y)\}.$$

Let $K(y) = \bigcup_{r=0}^{\infty} K_r(y)$ and define $n(i) = \min\{0, \inf\{y : i \in K(y)\}\}$, where possibly $n(i) = -\infty$.

3. Main result. In this section we show that an infinite deterministic graphical game has a value and obtain an expression for it in terms of the $p(i)$ and $n(i)$. In coping with the fact that the game may have an infinite value, we remind the reader that, in a game with an infinite value, a strategy X^* is said to be ϵ -optimal for player

1 if the expectation $E(X^*, Y) > 1/\epsilon$ for all strategies Y for player 2. A corresponding definition applies for player 2.

THEOREM 3.1. *The value v_i of the deterministic graphical game starting at node i is given by*

$$v_i = \begin{cases} p(i) & \text{if } p(i) \neq 0; \\ n(i) & \text{otherwise.} \end{cases}$$

Furthermore, for this particular game that starts at the node i , the players possess pure ϵ -optimal stationary strategies for all positive numbers ϵ .

Proof. Let $\epsilon > 0$. For the game starting at node i we now define a pure stationary strategy $X^*(i)$ for player 1.

If $p(i) \neq 0$ then $p(i) > 0$ or $p(i) = \infty$ by the definition of $p(i)$. Choose a positive number x_i such that $p(i) - \epsilon < x_i < p(i)$ if $p(i) \neq \infty$ and $x_i > 1/\epsilon$ if $p(i) = \infty$. It is easy to see that $i \in H(x_i)$. Now let $X^*(i)$ be the stationary strategy which, for each $j \in I$, selects the first element in U_j belonging to $H_{m_j(x_i)}(x_i)$ if $j \in H(x_i)$, and the first element in U_j otherwise.

Now suppose $p(i) = 0$. If $n(i) = -\infty$ let $X^*(i)$ be the strategy that chooses the first element in U_j for every j satisfying $j \in I$ (in maintaining $-\infty$ player 1 can be as careless as he likes!). If $n(i) \neq -\infty$ then $n(i) \leq 0$ so choose $y_i < 0$ such that $n(i) - \epsilon < y_i < n(i)$. Thus $i \notin K(y_i)$. Now, for each $j \in I$ satisfying $j \notin K(y_i)$, there is an element in U_j not belonging to $K_r(y_i)$ for any positive integer r (and therefore not in $K(y_i)$) and so we can let $X^*(i)$ select the first such element in U_j . Otherwise let $X^*(i)$ select the first element in U_j .

We now show that $X^*(i)$ is ϵ -optimal. Suppose player 1 uses strategy $X^*(i)$, player 2 the strategy Y .

(I) Assume $p(i) \neq 0$ then $i \in H(x_i)$. Suppose at stage $t \geq 1$ under $X^*(i)$ and Y that either play has reached a terminal node with a payoff to player 1 of at least x_i or play has been sent through the nodes $i = i(1), i(2), \dots, i(t)$ where $i(j) \in H_{n(j)}(x_i)$ for $j = 1, 2, \dots, t$ and $n(1) > n(2) > \dots > n(t)$. Suppose the latter holds; note that this is the position for $t = 1$ if i is not a terminal node.

If $i(t) \in I$ then under $X^*(i)$ player 1 chooses the first element in $U_{i(t)}$ belonging to $H_{m_{i(t)}(x_i)}(x_i)$. Thus either play reaches a terminal node giving player 1 a payoff of at least x_i or play is sent to a node $i(t+1) \in H_{n(t+1)}(x_i)$ where $n(t+1) < n(t)$.

If $i(t) \in J$ then the fact that $i(t) \in H_{n(t)}(x_i)$ implies that, whatever the strategy Y , play has to be sent to a node that is in an $H_{n(t+1)}(x_i)$, where $n(t+1) < n(t)$. Thus again either play reaches a terminal node giving player 1 a payoff of at least x_i or play is sent to a node $i(t+1) \in H_{n(t+1)}(x_i)$, where $n(t+1) < n(t)$.

Hence at stage $t+1$ we have similar conditions to those at stage t and the process can be repeated if play has not reached a terminal node. The process must clearly reach a terminal node after at most $n(1)$ steps and so player 1 is ensured of a payoff of at least x_i .

(II) Now assume $p(i) = 0$ and $n(i) \neq -\infty$ then $i \notin K(y_i)$. Suppose at stage $t \geq 1$ under $X^*(i)$ and Y that either play has reached a terminal node with a payoff to player 1 of at least y_i or play has been sent through the nodes $i = i(1), i(2), \dots, i(t)$, where $i(j) \notin K(y_i)$ for $j = 1, 2, \dots, t$. Assume the latter holds; note that this is the case for $t = 1$ if i is not a terminal node.

If $i(t) \in I$ then, since $i(t) \notin K(y_i)$, player 1 under $X^*(i)$ chooses the first element not belonging to $K(y_i)$. Thus either play reaches a terminal node giving player 1 a payoff greater than y_i or play is sent to a node $i(t+1) \notin K(y_i)$.

If $i(t) \in J$ then the fact that $i(t) \notin K(y_i)$ implies that, whatever the strategy Y ,

play must either reach a terminal node giving a payoff greater than y_i to player 1 or be sent to a node $i(t+1) \notin K(y_i)$.

Hence at stage $t+1$ we have similar conditions to those at stage t and the process can be repeated. Note that if play never reaches a terminal node the payoff is zero, which is greater than y_i . Hence when $p(i) = 0$ and $n(i) \neq -\infty$ player 1 can ensure himself of a payoff of at least $n(i) - \epsilon$.

Applying similar arguments to the corresponding strategy to $X^*(i)$ for player 2 shows that player 1's payoff can be restricted to at most $p(i) + \epsilon$ if $p(i) \neq 0$, $n(i) + \epsilon$ if $p(i) = 0$ and $n(i)$ is finite and $-1/\epsilon$ when $n(i) = -\infty$. The theorem now follows.

Note. It is not difficult to adapt the proof to show that, if $p(i) > 0$ and $\sup\{x : i \in H(x)\}$ is attained, then player 1 actually has a pure *optimal* stationary strategy in the game starting at node i . Similarly, when $n(i) < 0$ and $\inf\{y : i \in K(y)\}$ is attained, player 2 has a pure *optimal* stationary strategy in the game starting at node i .

4. An example. In this section we present an example of a countably infinite deterministic graphical game expressed in recursive game notation that demonstrates a fundamental difference between finite and infinite deterministic graphical games. In the former, a player possesses a pure stationary strategy that is optimal wherever the game starts whereas, in the latter, this does not necessarily hold.

The following example also shows that, when players are restricted to using Markov strategies, a countably infinite recursive game of perfect information need not have a solution. (A strategy F is said to be Markov if, for all k and all h_k of the form (1), $F^k(h_k)$ depends only on the stage k and the node x_k that play has reached). Strictly speaking, we do not present it in the form of a countably infinite recursive matrix game $\Gamma_1, \Gamma_2, \dots$, but it can clearly be put into this form.

Let Γ be the recursive game given for $n = 1, 2, \dots$ and $i = 1, 2, \dots$ by

$$\begin{aligned} \Gamma_1^{(n)} : (n), \quad \Gamma_{2i}^{(n)} : \left(\begin{array}{c} n-1 \\ \Gamma_{2i-1}^{(n)} \end{array} \right), \\ \Gamma_{2i+1}^{(n)} : (\Gamma_1^{(n)}, \Gamma_2^{(n)}, \dots, \Gamma_{2i}^{(n)}, \Gamma_2^{(n+1)}, \Gamma_4^{(n+1)}, \Gamma_6^{(n+1)}, \dots). \end{aligned}$$

We first use Theorem 3.1 to show that, when play starts in $\Gamma_i^{(n)}$ the value is n . In the deterministic graphical game formulation the nodes $W_i^{(n)}$ are identified with the $\Gamma_i^{(n)}$ in the recursive game formulation, where we also identify $W_1^{(n)}$ with the number entry n in the matrix of $\Gamma_1^{(n)}$. Nodes of the form $W_1^{(n)}$ are seen to be terminal nodes with payoff n . It is easily verified that

$$\begin{aligned} H_0(x) &= \{W_1^{(n)} : n \geq x\}, \\ H_1(x) &= H_0(x) \cup \{W_{2i}^{(n)} : n \geq x+1\} \cup \{W_2^{(n)} : n \geq x\}, \\ H_r(x) &= H_1(x) \cup \bigcup_{j=3}^{r+1} \{W_j^{(n)} : n \geq x\} \cup \bigcup_{j=3}^{2r-1} \{W_j^{(n)} : n \geq x+1\} \quad \text{for } r \geq 2, \end{aligned}$$

so that

$$H(x) = \bigcup_{i \geq 1} \bigcup_{n \geq x} W_i^{(n)}.$$

Hence $p(W_i^{(n)}) = n$ and the value of the game is n .

We assert that Γ does not have a solution in Markov strategies. Let $\epsilon > 0$ and X be a Markov strategy for player 1; we let $x_{2i}^{(n)}(t)$ denote the probability under X of choosing the first row when in $\Gamma_{2i}^{(n)}$ at time t . Let $\delta_1, \delta_2, \dots$ be a decreasing sequence of probabilities such that

$$\delta_1 + 2\delta_2 + 3\delta_3 + \dots < \frac{1}{2}.$$

Let $k_i = \lceil \ln(1 - \epsilon) / \ln(1 - \delta_i) \rceil + 1$ for $i \geq 1$, $t_2 = 1$, and $t_{r+1} = t_r + 2k_r$ for $r \geq 2$. Note that $(1 - \delta_i)^{k_i} < 1 - \epsilon$ for $i \geq 1$ and k_1, k_2, \dots is an increasing sequence.

(i) Suppose there is a positive integer $n \geq 2$ such that $x_{6k_{n+1}+2k_n-2j}^{(n)}(t_n + 2j + 1) \geq \delta_n$ for $j = 0, 1, \dots, k_n - 1$. Consider the Markov strategy Y for player 2 which, for all positive integers r and i , chooses $\Gamma_{2i-1}^{(r)}$ when in $\Gamma_{2i+1}^{(r)}$ at time $t < t_n$ and chooses $\Gamma_{2i}^{(r)}$ when in $\Gamma_{2i+1}^{(r)}$ at time $t \geq t_n$. Under the strategies X and Y , when play starts at $t = 1$ in $\Gamma_{6k_{n+1}+2k_n+2t_n-1}^{(n)}$, play will be in $\Gamma_{6k_{n+1}+2k_n}^{(n)}$ at time $t_n + 1$ and it follows that the expectation is at most

$$(1 - \delta_n)^{k_n} n + \{1 - (1 - \delta_n)^{k_n}\}(n - 1) = n - 1 + (1 - \delta_n)^{k_n} < n - \epsilon.$$

Hence in this case X is not an ϵ -optimal strategy.

(ii) Now suppose (i) does not hold then, for every positive integer $n \geq 2$, we may choose an integer j_n satisfying $0 \leq j_n < k_n$ and $x_{6k_{n+1}+2k_n-2j_n}^{(n)}(t_n + 2j_n + 1) \leq \delta_n$. Consider the Markov strategy Y for player 2 whereby, for all positive integers i and n , he chooses $\Gamma_{6k_{n+2}+2k_{n+1}-2j_{n+1}}^{(n+1)}$ when in $\Gamma_{2i+1}^{(n)}$ at time $t_{n+1} + 2j_{n+1}$ and $\Gamma_{2i-1}^{(n)}$ when in $\Gamma_{2i+1}^{(n)}$ at other times.

Consider play under X and Y when play starts at $t = 1$ in $\Gamma_{6k_2+3}^{(1)}$. At time $t_2 + 2j_2 = 1 + 2j_2$ play is in $\Gamma_{6k_2+3-4j_2}^{(1)}$ so play at time $t_2 + 2j_2 + 1$ is in $\Gamma_{6k_3+2k_2-2j_2}^{(2)}$. Suppose, for $n \geq 2$, at time $t_n + 2j_n + 1$ play is in $\Gamma_{6k_{n+1}+2k_n-2j_n}^{(n)}$.

(a) With probability $x_{6k_{n+1}+2k_n-2j_n}^{(n)}(t_n + 2j_n + 1) \leq \delta_n$ play will terminate giving player 1 a payoff of $n - 1$.

(b) With probability $1 - x_{6k_{n+1}+2k_n-2j_n}^{(n)}(t_n + 2j_n + 1)$ play goes to

$$\Gamma_{6k_{n+1}+2k_n-2j_n-1}^{(n)}$$

at time $t_n + 2j_n + 2 \leq t_n + 2k_n = t_{n+1}$. Hence, for $i = 1, 2, \dots, 2k_n + 2j_{n+1} - 2j_n - 2 = t_{n+1} + 2j_{n+1} - t_n - 2j_n - 2$, at time $t_n + 2j_n + 2 + i$ play is in $\Gamma_{6k_{n+1}+2k_n-2j_n-1-2i}^{(n)}$.

In particular, play is in $\Gamma_{6k_{n+1}-2k_n+2j_n-4j_{n+1}+3}^{(n)}$ at time $t_{n+1} + 2j_{n+1}$; we note that $6k_{n+1} - 2k_n + 2j_n - 4j_{n+1} + 3 \geq 3$. Hence at time $t_{n+1} + 2j_{n+1} + 1$ play is in $\Gamma_{6k_{n+2}+2k_{n+1}-2j_{n+1}}^{(n+1)}$ and the process is repeated. It follows that the expectation is at most

$$\delta_2 + 2\delta_3 + 3\delta_4 + \dots \leq \delta_1 + 2\delta_2 + 3\delta_3 + \dots < \frac{1}{2}$$

and X is not ϵ -optimal when $\epsilon < \frac{1}{2}$.

5. Conclusions. When the restriction that the nodes in a deterministic graphical game be finite is removed, our results show that not only does the corresponding game have a solution but also its solution inherits many of the characteristics of the original game. There is the natural difference that the players may have to be content with ϵ -optimal strategies. The more fundamental change is that a player's ϵ -optimal

strategy may need to depend on the starting node. However once he has this information, the player will be able to employ a pure stationary strategy.

In [11] Washburn briefly considered the possibility of introducing random moves into deterministic graphical games and pointed out that they still have solutions with stationary strategies. In the infinite case such a game need not even have a solution as the following example (given in recursive form) clearly shows when play starts in Γ_1 .

Example. Let $\Gamma = (\Gamma_1, \Gamma_2, \dots)$ be given by

$$\Gamma_1 : ((1/2)\Gamma_2 + (1/2)\Gamma_3), \quad \Gamma_{2n} : \begin{pmatrix} n \\ \Gamma_{2n+2} \end{pmatrix}, \quad \Gamma_{2n+1} : (-n \quad \Gamma_{2n+3}) \text{ for } n \geq 1.$$

AVERAGING IN LAGRANGE AND MINIMAX PROBLEMS OF OPTIMAL CONTROL*

E. N. BARRON†

This paper is dedicated to Avner Friedman on the occasion of his 60th birthday.

Abstract. The perturbed test function method of Evans [*Proc. Royal Soc. Edinburgh*, 111A (1989), pp. 359–375] is applied to two optimal control problems with fast variables. In the classical problem of Lagrange, which has been considered by Chaplais [*SIAM J. Control. Optim.*, 25 (1987), pp. 767–780], a new and simpler proof of convergence to the averaged problem is given. In addition, it is shown that an entirely different limit problem is obtained when the controls have inertia, i.e., are Lipschitz. The optimal control problem with minimax cost and fast variables is studied in section 2. In this problem the cost functional is not the integral of a running cost, which is smooth, but the max in time of a function of the state, the control, and time. The limit problem is derived in this case also.

Key words. optimal control, minimax problem, averaging of fast variables, viscosity solutions, perturbed test functions

AMS subject classifications. 49C20, 49L25, 35B05

Introduction. An important problem in optimal control theory is the modeling of systems that have at least one component that oscillates rapidly. For example, flight systems subject to weather and other disturbances are of this type. The problem considered in this paper is the determination of the limit problem as the oscillations occur infinitely fast. The limit problem is then used as a macroscopic approximation to the rapidly vibrating system. In the first section the classical problem of Lagrange with a fast time variable, say $\varphi(t, t/\varepsilon, x, z)$, is studied. For simplicity we will assume that the dynamics are 1-periodic in the fast variable although this is not necessary—assuming an average exists in the fast variable is enough. The class of controls is, as usual, the class of Lebesgue measurable functions. This problem was first studied by Chaplais [11] (see also Peng [15]) but by completely different methods and with more stringent assumptions in some cases. Chaplais proved that the optimal control limit problem involves the averaged dynamics $\int_0^1 \varphi(t, s, x, z(t, s)) ds$. The important point discovered by Chaplais is that the control z must also involve the fast variable, and an example is given proving that this is indeed necessary. In the dynamic programming approach we take in this paper it becomes very clear why the control must depend on s .

When we are considering problems with fast variables, we must also consider very carefully the class of control functions. The result of Chaplais requires measurable control functions that have the property that they can switch quickly enough (instantaneously) to keep up with the fast variables. It is known, however, that real controls are rarely, if ever, capable of instantaneous changes. Real controls are, in the terminology of Berkovitz, inertial. Consequently, practical controls must be chosen out of the class of Lipschitz-continuous functions. The problem arises as to whether

† Department of Mathematical Sciences, Loyola University of Chicago, Chicago, Illinois, 60626.

Lipschitz controls can keep up with the fast variables and thus achieve the same value for the limit problem with measurable controls. The answer given in §1.1 is negative. The limit problem with Lipschitz controls involves the averaged dynamics of the form $\int_0^1 \varphi(t, s, x, z) ds$, where the z control does *not* depend on s .

In §1 we rederive the result of Chaplais (actually only one of his results) using the very powerful and simple perturbed test function method of Evans [13]. This method is intimately connected with another very powerful idea—the idea of viscosity solutions for fully nonlinear partial differential equations [12]. Chaplais also uses viscosity solution theory to prove convergence of the value functions but he resorts to second-order approximations, which are not, in fact, necessary.

The perturbed test function method of Evans is connected with the older known method of expansion in ε , i.e., looking at $V^\varepsilon(t, x) = V^0(t, x) + \varepsilon V^1(\frac{t}{\varepsilon}, x) + \dots$. This looks at perturbing the *solution*, which is usually not smooth enough. Evans instead looks at perturbing the (smooth) test function in the definition of viscosity solution in an appropriate way. Then we can apply the usual tricks associated with the older method. Therein lies the utility of the method. His method is very successfully applied in [13] for second-order problems. However, for first-order problems, the equation for the perturbation does not generally have a smooth enough solution to generate a test function that can be used in the viscosity definition. This is, in fact, the case for homogenization (see §1.3), but is not true for a fast time variable. In that case, a smooth perturbation can be constructed (see (1.13)).

In §2 we study the optimal control problem in which the cost is of the form $P(\zeta) = \sup_{t \leq \tau \leq T} h(\tau, \xi(\tau), \zeta(\tau))$. When the ζ controls are chosen to minimize the cost, this is called the minimax problem.

The minimax control problem was first considered from the dynamic programming point of view in [6]. (It later came to our attention that Aronsson in [1] had considered the minimax calculus of variations problem from the point of view of the Euler equation). After seeing [1] and [6], the reader will understand why this criterion is not widely used, even though it is usually more realistic than an integral running cost. In fact, for some problems the minimax cost is the only realistic formulation. A recent example of this appears in [10], in which the problem of landing an aircraft in the presence of windshear is studied. For minimax problems, the necessary conditions are much more difficult to solve in virtually all cases. Also, the Bellman equation requires a minimization over a set that involves the solution function (see (2.1) and (2.5)). Nevertheless, the results for this problem are not beyond the scope of numerical methods.

The question we pose in §2 is the determination of the limit of the rapidly oscillating minimax optimal control problem. The limit problem is discovered using the usual L^p approximations to the L^∞ norm. Evans' technique is then used to actually prove the convergence and is presented in Theorem 2.2. The cost function h in this problem is not allowed to depend on the fast variable because it is not clear that such dependence leads to convergence. In fact, looking at the Bellman equation as a nonlinear variational inequality (see (2.1a)), the lower obstacle for the ε -value function, assuming fast variable dependence, is given by $\beta(t, t/\varepsilon, x) \equiv \min_{z \in Z} h(t, t/\varepsilon, x, z)$. The function β does converge in some sense, for example, weakly to the average, or epi-convergence [2] to an infimum, or hypo-convergence to a supremum. None of these seems to be strong enough to give convergence of the value functions. This is an open problem.

When oscillations occur in the spatial parameters of a system the limit equations are known as the homogenized version (see Bensoussan, Lions, and Papanicolaou [9] for the basic results concerning homogenization). Lions, Papanicolaou, and Varadhan in [14] study the asymptotic problems for first-order Hamilton–Jacobi equations of the form $H(x, x/\varepsilon, u, Du) = 0$. This problem is much more difficult than the problem considered in this paper. While a limit problem is proved to exist, the characterization of the limit Hamiltonian is known only in special cases. To show where the difficulties with the perturbed test function method arise, we will consider in §1.2 a simple one-dimensional control problem. This example also establishes that the controls for the homogenized problem must depend on the fast spatial parameter, just as they depend on the fast time parameter for the problems in this paper.

1. The Lagrange optimal control problem. In this section we formulate precisely the standard free endpoint problem of Lagrange in optimal control. The dynamics are

$$(1.1) \quad \frac{d\xi}{d\tau} = f\left(\tau, \frac{\tau}{\varepsilon}, \xi(\tau), \zeta(\tau)\right) \quad \text{if } t < \tau \leq T,$$

$$(1.2) \quad \xi(t) = x \in R^n.$$

The control functions ζ are chosen from the class of functions

$$\mathcal{Z}[t, T] = \{\zeta : [t, T] \rightarrow Z \mid \zeta(\cdot) \text{ is Lebesgue measurable}\},$$

where Z is a compact subset of some R^p , $p \geq 1$. The objective will be to minimize on $\mathcal{Z}[t, T]$ the following payoff:

$$(1.3) \quad P_{t,x}(\zeta) = g(\xi(T)) + \int_t^T h\left(r, \frac{r}{\varepsilon}, \xi(r), \zeta(r)\right) dr.$$

We define the value function $V^\varepsilon : [0, T] \times R^n \rightarrow R^1$ as follows:

$$V^\varepsilon(t, x) = \inf_{\zeta \in \mathcal{Z}[t, T]} P_{t,x}(\zeta).$$

The following assumptions regarding the given functions f , g , and h will be used throughout this paper.

(A). For $\varphi = f, h, \varphi : [0, T] \times R^1 \times R^n \times Z \rightarrow R^1$ is uniformly continuous in all arguments. $\varphi(\cdot, s, \cdot, \cdot)$ is periodic with period 1. There is a generic constant $K > 0$ such that

$$|f(t, s, x, z)| \leq K(1 + |x|), \quad |h(t, s, x, z)| \leq K,$$

for $(t, s, x, z) \in [0, T] \times R^1 \times R^n \times Z$ and

$$|\varphi(t, s, x, z) - \varphi(t', s, x', z)| \leq K(|x - x'| + |t - t'|).$$

Further, $|g(x)| \leq K(1 + |x|)$, and g is also uniformly Lipschitz continuous.

Assumption (A) is sufficient to guarantee that for each control $\zeta \in \mathcal{Z}[t, T]$ there will be a unique trajectory $\xi_\varepsilon = \xi(\cdot)$ on the interval $[t, T]$ with $\xi(t) = x$. The hypotheses can be weakened to allow h to have quadratic growth in x for the Lagrange problem.

To simplify notation, let Ω denote the set $(0, T) \times R^n$.

For the convenience of the reader we recall the precise definition of viscosity solution. In general, both the solution and the Hamiltonian may be discontinuous. The notation is that for any function f , f^* is the upper semicontinuous envelope and f_* is the lower semicontinuous envelope: $f^*(x) = \limsup_{y \rightarrow x} f(y)$, and $f_*(x) = \liminf_{y \rightarrow x} f(y)$.

DEFINITION 1.1. A function $u : \bar{\Omega} \rightarrow R^1$ is a viscosity solution of

$$(1.4) \quad u_t + F(t, x, u, D_x u) = 0$$

if the following two conditions are satisfied:

(1) u is a viscosity subsolution, i.e., for any function $\varphi \in C^1(\Omega)$ for which $u^* - \varphi$ achieves a maximum at the point $(t_0, x_0) \in \Omega$ we have that

$$(1.5) \quad \varphi_t(t_0, x_0) + F^*(t_0, x_0, u^*(t_0, x_0), D_x \varphi(t_0, x_0)) \geq 0 \quad \text{at } (t_0, x_0).$$

(2) u is a viscosity supersolution, i.e., for any function $\varphi \in C^1(\Omega)$ for which $u_* - \varphi$ achieves a minimum at the point $(t_0, x_0) \in \Omega$ we have that

$$(1.6) \quad \varphi_t(t_0, x_0) + F_*(t_0, x_0, u_*(t_0, x_0), D_x \varphi(t_0, x_0)) \leq 0 \quad \text{at } (t_0, x_0).$$

As was established in [12], we may always arrange to have unique strict extrema and $0 < t_0 < T$. Furthermore, it is not necessary to have $\varphi \in C^1$. In fact, differentiability of φ at the point of contact with u^* or u_* is sufficient.

If the Hamiltonian $F(t, x, r, p)$ is continuous in all variables and concave in p then it was established in [8] that a continuous function u is a viscosity solution of (1.4) if and only if the condition " $u - \varphi$ achieves a minimum at (t_0, x_0) " implies that

$$(1.6a) \quad \varphi_t(t_0, x_0) + F(t_0, x_0, u(t_0, x_0), D_x \varphi(t_0, x_0)) = 0 \quad \text{at } (t_0, x_0).$$

That is, the fact that u is a supersolution in this stronger sense is sufficient.

In several places we will use a lemma of Barles and Perthame [3], which we will reproduce here for the convenience of the reader. It will be stated only for subsolutions but is also true for supersolutions, suitably modified.

LEMMA A.3 (see [3]). Let $u(t, x) = \limsup_{(n, \sigma, y) \rightarrow (\infty, t, x)} u_n(\sigma, y)$, where, for all n , u_n is a subsolution of $u_t + F_n(t, x, u, D_x u) = 0$. Assume that u_n and u are locally bounded. Let $\varphi \in C^1(\Omega)$ and (t_0, x_0) the unique maximum of $u - \varphi$ in $B_\varrho(t_0, x_0)$ for some $\varrho > 0$. For each n , let $(t_n, x_n) \in \overline{B_\varrho(t_0, x_0)}$ be a maximum of $u_n - \varphi$. Then $(t_n, x_n) \rightarrow (t_0, x_0)$ and $u_n(t_n, x_n) \rightarrow u(t_0, x_0)$ as $n \rightarrow \infty$.

As pointed out by the reviewer, certain modifications of the test function φ in Lemma A.3 may be necessary so as to keep $(t_n, x_n) \in \overline{B_\varrho(t_0, x_0)}$. The details are to be found in [3].

The next lemma gives the dynamic programming result for the fast problem.

LEMMA 1.2. The value function V^ε is the unique continuous viscosity solution of the problem

$$(1.7) \quad \frac{\partial V}{\partial t} + \min_{z \in Z} \left\{ D_x V \cdot f \left(t, \frac{t}{\varepsilon}, x, z \right) + h \left(t, \frac{t}{\varepsilon}, x, z \right) \right\} = 0 \quad \text{on } \Omega,$$

with terminal condition

$$(1.8) \quad V^\varepsilon(T, x) = g(x) \quad \text{on } R^n.$$

Further, there exists a Lipschitz continuous function $W : \bar{\Omega} \rightarrow R^1$ such that (at least) on a subsequence of $\{\varepsilon\}$ we have

$$(1.9) \quad \lim_{\varepsilon \rightarrow 0} V^\varepsilon(t, x) = W(t, x).$$

Define the Hamiltonian $H : [0, T] \times R^1 \times R^n \times R^n \rightarrow R^1$ by

$$(1.10) \quad H(t, s, x, p) = \min_{z \in Z} \{p \cdot f(t, s, x, z) + h(t, s, x, z)\}.$$

Proof. The fact that V^ε is the unique continuous viscosity solution of the Bellman equation (1.7) is well known (e.g., [7]). Now we secure a convergent subsequence by showing that V^ε is uniformly Lipschitz continuous. Since this is rather standard we will only sketch the proof, needing to make sure that the estimates are uniform in ε .

Let $x, x' \in R^n$ and fix $0 \leq t < T$ and $\zeta \in \mathcal{Z}[t, T]$. Denote the solution of (1.1) with initial condition x or x' by ξ_x and $\xi_{x'}$. Then, using condition (A),

$$|\xi_x(\tau) - \xi_{x'}(\tau)| \leq |x - x'| + \int_t^\tau K |\xi_x(s) - \xi_{x'}(s)| ds.$$

Gronwall's inequality then gives

$$\sup_{t \leq \tau \leq T} |\xi_x(\tau) - \xi_{x'}(\tau)| \leq K|x - x'|.$$

This immediately gives uniform Lipschitz continuity of V^ε in x , and since g is uniformly Lipschitz, this is true on $[0, T]$.

Let $0 \leq t_1 < t_2 \leq T$ and fix $x \in R^n$ and $\zeta \in \mathcal{Z}[0, T]$. Denote the solution of (1.1) with initial condition $\xi_i(t_i) = x, i = 1, 2$. Then, since f is uniformly Lipschitz in x , we easily see that $|\xi_1(t_2) - x| \leq K(t_2 - t_1)$, with K independent of ε . Then

$$\begin{aligned} |\xi_1(\tau) - \xi_2(\tau)| &\leq |\xi_1(t_2) - x| + \int_{t_2}^\tau K |\xi_1(s) - \xi_2(s)| ds \\ &\leq K(t_2 - t_1) + \int_{t_2}^\tau K |\xi_1(s) - \xi_2(s)| ds. \end{aligned}$$

Another application of Gronwall's inequality yields the result that the trajectories cannot separate by more than $K(t_2 - t_1)$ on $[t_2, T]$. Consequently, this is true on $[t_1, T]$. Using now the boundedness and Lipschitz continuity of h and g , Lipschitz continuity of V^ε in t , uniformly in ε is immediate.

We see that $\|V^\varepsilon\|$ and $\|DV^\varepsilon\| \leq K$ in the uniform norm, uniformly in ε . Therefore, a subsequence converges uniformly to a Lipschitz function W . \square

Remarks. 1. Chaplais obtains a convergent subsequence in the following way. Let V_α^ε denote the (classical) solution of

$$\frac{\partial V_\alpha^\varepsilon}{\partial t} + \alpha \Delta V_\alpha^\varepsilon + H\left(t, \frac{t}{\varepsilon}, x, D_x V_\alpha^\varepsilon\right) = 0, \quad (t, x) \in \Omega,$$

with $V_\alpha^\varepsilon(T, x) = g(x)$. It is not hard to show that V_α^ε and its first derivatives are uniformly bounded in an appropriate norm. Since V^ε satisfies the property that

$$\|V^\varepsilon - V_\alpha^\varepsilon\|_{L^\infty(\bar{\Omega})} \leq K\alpha^{1/2},$$

we see that $\{V^\varepsilon\}_\varepsilon$ has a convergent subsequence, to W say, and W is a continuous function. See Chaplais [11, p. 777] for complete details.

2. Observe that in (1.10) any minimizer in Z will depend on t, x, p , and $s \in [0, 1]$. Consequently, it is clear that there must be s dependence of the controls for the limit problem.

Thus is secured a convergent sequence to a nice function W . To describe the equation satisfied by W , introduce the averaged dynamics

$$(1.11a) \quad \bar{f}(t, x, z(\cdot)) = \int_0^1 f(t, s, x, z(s)) \, ds,$$

$$(1.11b) \quad \bar{h}(t, x, z(\cdot)) = \int_0^1 h(t, s, x, z(s)) \, ds,$$

where

$$z(\cdot) \in \mathcal{A} \equiv \{z : [0, 1] \rightarrow Z \mid z \text{ is Lebesgue measurable}\}.$$

Define the averaged Hamiltonian

$$(1.12) \quad \bar{H}(t, x, p) = \min_{z(\cdot) \in \mathcal{A}} \{p \cdot \bar{f}(t, x, z(\cdot)) + \bar{h}(t, x, z(\cdot))\}.$$

The first goal of this section is to provide a new proof of the following result of Chaplais [11] by using the perturbed test function method of Evans [13].

THEOREM 1.3. *The function W is the unique continuous viscosity solution of*

$$(HJB) \quad \frac{\partial W}{\partial t} + \min_{z(\cdot) \in \mathcal{A}} \{D_x W \cdot \bar{f}(t, x, z(\cdot)) + \bar{h}(t, x, z(\cdot))\} = 0, \quad (t, x) \in [0, T] \times R^n,$$

with $W(T, x) = g(x)$.

Remark. Chaplais proves the interesting and useful result that if the limit problem has an optimal control, say $\zeta(t, s)$, then $\zeta(t, t/\varepsilon)$ is near optimal for the ε -oscillation problem.

Proof. This can be done by simply showing (1.6a), but we will go through both (1.5) and (1.6). First, we need the lemma.

LEMMA 1.3a. *For $(t, x, p) \in [0, T] \times R^n \times R^n$, we have that*

$$\int_0^1 H(t, s, x, p) \, ds = \bar{H}(t, x, p).$$

Proof. Fix (t, x, p) . By Fillipov's lemma, since Z is compact, there exists a measurable function $\zeta : [0, 1] \rightarrow Z$ such that

$$H(t, s, x, p) = p \cdot f(t, s, x, \zeta(s)) + h(t, s, x, \zeta(s)).$$

Integrating both sides we get

$$\begin{aligned} \int_0^1 H(t, s, x, p) \, ds &= \int_0^1 p \cdot f(t, s, x, \zeta(s)) + h(t, s, x, \zeta(s)) \, ds \\ &\geq \min_{z(\cdot) \in \mathcal{A}} \{p \cdot \bar{f}(t, x, z(\cdot)) + \bar{h}(t, x, z(\cdot))\} = \bar{H}(t, x, p). \end{aligned}$$

On the other hand, for fixed (t, x, p) , for any $\delta > 0$ there exists $z_\delta \in \mathcal{A}$ such that

$$\begin{aligned}\overline{H}(t, x, p) &\geq p \cdot \bar{f}(t, x, z_\delta(\cdot)) + \bar{h}(t, x, z_\delta(\cdot)) - \delta \\ &= \int_0^1 p \cdot f(t, s, x, z_\delta(s)) + h(t, s, x, z_\delta(s)) \, ds - \delta \\ &\geq \int_0^1 H(t, s, x, p) \, ds - \delta. \quad \square\end{aligned}$$

Now, suppose that $W - \varphi$ has a strict maximum at a point $(t_0, x_0) \in \Omega$, where $\varphi \in C^2(\Omega)$. Consider the function $\gamma : R^1 \rightarrow R^1$ given as the 1-periodic solution of

$$\begin{aligned}(1.13) \quad \frac{d\gamma}{ds} &= \overline{H}(t_0, x_0, D_x \varphi(t_0, x_0)) - H(t_0, s, x_0, D_x \varphi(t_0, x_0)) \\ &= \min_{z(\cdot) \in \mathcal{A}} \{D_x \varphi(t_0, x_0) \cdot \bar{f}(t_0, x_0, z(\cdot)) + \bar{h}(t_0, x_0, z(\cdot))\} \\ &\quad - \min_{z \in Z} \{D_x \varphi(t_0, x_0) \cdot f(t_0, s, x_0, z) + h(t_0, s, x_0, z)\}\end{aligned}$$

if $0 \leq s \leq 1$. A periodic solution is guaranteed to exist because of Lemma 1.3a. Note that the right-hand side of (1.14) is continuous in $s \in [0, 1]$ and, since f and h are periodic in s , $\gamma'(0) = \gamma'(1)$. Therefore, $\gamma \in C^1(R^1)$.

Since $V^\varepsilon \rightarrow W$ uniformly, there exists a sequence $(t_\varepsilon, x_\varepsilon)$ such that $V^\varepsilon(t, x) - (\varphi(t, x) + \varepsilon\gamma(t/\varepsilon))$ achieves a maximum at $(t_\varepsilon, x_\varepsilon)$ and $(t_\varepsilon, x_\varepsilon) \rightarrow (t_0, x_0)$ as $\varepsilon \rightarrow 0$.

Since V^ε is a viscosity solution of (1.7), we apply the definition for subsolution to get that

$$(1.14) \quad \varphi_t(t_\varepsilon, x_\varepsilon) + \frac{d\gamma(\frac{t_\varepsilon}{\varepsilon})}{dt} + H\left(t_\varepsilon, \frac{t_\varepsilon}{\varepsilon}, x_\varepsilon, D_x \varphi(t_\varepsilon, x_\varepsilon)\right) \geq 0,$$

with H given in (1.10). Using the definition (1.13) for γ evaluated at $s = t_\varepsilon/\varepsilon$, we obtain from (1.14) and the continuity of H ,

$$\begin{aligned}0 &\leq \varphi_t(t_\varepsilon, x_\varepsilon) + \frac{d\gamma(\frac{t_\varepsilon}{\varepsilon})}{dt} + H\left(t_\varepsilon, \frac{t_\varepsilon}{\varepsilon}, x_\varepsilon, D_x \varphi(t_\varepsilon, x_\varepsilon)\right) \\ &= \varphi_t(t_\varepsilon, x_\varepsilon) + \overline{H}(t_0, x_0, D_x \varphi(t_0, x_0)) - \\ &\quad H\left(t_0, \frac{t_\varepsilon}{\varepsilon}, x_0, D_x \varphi(t_0, x_0)\right) + H\left(t_\varepsilon, \frac{t_\varepsilon}{\varepsilon}, x_\varepsilon, D_x \varphi(t_\varepsilon, x_\varepsilon)\right) \\ &\leq \varphi_t(t_0, x_0) + \overline{H}(t_0, x_0, D_x \varphi(t_0, x_0)) + o_\varepsilon(1)\end{aligned}$$

as $\varepsilon \rightarrow 0$, since $(t_\varepsilon, x_\varepsilon) \rightarrow (t_0, x_0)$ and φ is smooth. We conclude that

$$(1.15) \quad \varphi_t(t_0, x_0) + \min_{z(\cdot) \in \mathcal{A}} \{D_x \varphi(t_0, x_0) \cdot \bar{f}(t_0, x_0, z(\cdot)) + \bar{h}(t_0, x_0, z(\cdot))\} \geq 0$$

and so W is a subsolution of (HJB).

Next we prove in a similar way that W is a supersolution.

Suppose that $W - \varphi$ has a strict minimum at (t_0, x_0) . Let $\gamma : R^1 \rightarrow R^1$ be the 1-periodic solution of (1.13). $V^\varepsilon - (\varphi(t, x) + \varepsilon\gamma(t/\varepsilon))$ achieves a minimum at

$(t_\varepsilon, x_\varepsilon) \rightarrow (t_0, x_0)$, and since V^ε is a supersolution of (1.7) we have from (1.13) with $s = t_\varepsilon/\varepsilon$

$$\begin{aligned} 0 &\geq \varphi_t(t_\varepsilon, x_\varepsilon) + \frac{d\gamma(\frac{t_\varepsilon}{\varepsilon})}{dt} + H\left(t_\varepsilon, \frac{t_\varepsilon}{\varepsilon}, x_\varepsilon, D_x\varphi(t_\varepsilon, x_\varepsilon)\right) \\ &= \varphi_t(t_\varepsilon, x_\varepsilon) + \bar{H}(t_0, x_0, D_x\varphi(t_0, x_0)) - \\ &\quad H\left(t_0, \frac{t_\varepsilon}{\varepsilon}, x_0, D_x\varphi(t_0, x_0)\right) + H\left(t_\varepsilon, \frac{t_\varepsilon}{\varepsilon}, x_\varepsilon, D_x\varphi(t_\varepsilon, x_\varepsilon)\right) \\ &\geq \varphi_t(t_0, x_0) + \bar{H}(t_0, x_0, D_x\varphi(t_0, x_0)) - o_\varepsilon(1) \end{aligned}$$

as $\varepsilon \rightarrow 0$. Consequently,

$$(1.16) \quad \varphi_t(t_0, x_0) + \min_{z(\cdot) \in \mathcal{A}} \{D_x\varphi(t_0, x_0) \cdot \bar{f}(t_0, x_0, z(\cdot)) + \bar{h}(t_0, x_0, z(\cdot))\} \leq 0.$$

This says that W is a supersolution of (HJB) as well.

Since $V^\varepsilon(T, x) = g(x)$ for all $\varepsilon > 0$, $W(T, x) = g(x)$, $x \in R^n$. Combining this with (1.15) and (1.16) we have established the theorem. \square

Remarks. As a general remark, the critical property of the perturbed test function γ is that it is bounded, smooth, and periodic.

Another proof of Lemma 1.3a using control theory is the following. Consider the optimal control problem: Minimize over controls $z(\cdot) \in \mathcal{A}$ the cost functional $p \cdot \int_0^1 f(t, r, x, z(r)) + h(t, r, x, z(r)) \, dr$, where $t \in [0, T]$, $p, x \in R^n$ are fixed. Let $y \in [0, 1]$ and define the value function

$$(1.17) \quad U(y) = \min_{z(\cdot) \in \mathcal{A}} p \cdot \int_y^1 f(t, r, x, z(r)) + h(t, r, x, z(r)) \, dr.$$

Then U is the unique viscosity solution of

$$(1.18) \quad \frac{dU}{dy} + \min_{z \in Z} \{p \cdot f(t, y, x, z) + h(t, y, x, z)\} = 0, \quad U(1) = 0.$$

However, the $(C^1(0, 1))$ solution of this ordinary differential equation is obviously $\int_y^1 \min_{z \in Z} \{p \cdot f(t, r, x, z) + h(t, r, x, z)\} \, dr$. Uniqueness then says that

$$\min_{z(\cdot) \in \mathcal{A}} p \cdot \int_y^1 f(t, r, x, z(r)) + h(t, r, x, z(r)) \, dr = \int_y^1 \min_{z \in Z} \{p \cdot f(t, r, x, z) + h(t, r, x, z)\} \, dr,$$

for all $y \in [0, 1]$.

Finally, it is straightforward to verify that the simple integral problem in (1.17) always has an optimal control and it can be found in feedback form from (1.18). Consequently, the averaged Hamiltonian \bar{H} is always well defined, i.e., the minimum is attained.

The following corollary is a consequence of the fact that W is the unique viscosity solution of (HJB) and the fact that the value function for the optimal control problem (1.19)-(1.20) also is a viscosity solution of (HJB).

COROLLARY 1.4. *The function W in Theorem 1.3 is the value function for the optimal control problem with dynamics*

$$(1.19) \quad \frac{d\xi}{d\tau} = \int_0^1 f(\tau, s, \xi(\tau), \zeta(\tau, s)) ds, t < \tau \leq T, \quad \xi(t) = x \in R^n,$$

and cost

$$(1.20) \quad \bar{P}_{t,x}(\zeta) = g(\xi(T)) + \int_t^T \int_0^1 h(r, s, \xi(r), \zeta(r, s)) ds dr,$$

where $\zeta(\tau, \cdot) \in \mathcal{Z}[t, T], \zeta(\cdot, s) \in \mathcal{A}$. We have

$$W(t, x) = \inf_{\zeta(\cdot, \cdot)} \bar{P}_{t,x}(\zeta(\cdot, \cdot)).$$

Consequently, we have established that the limit of the fast optimal control problem is the control problem associated with (1.19), (1.20) by using the uniqueness of viscosity solutions. This avoids the technical complexities of a direct proof.

Remark. The result of this section can be extended to differential games. For example, the fast upper value function $V^{\varepsilon+}$ (assuming that $h = 0$) is the viscosity solution of the Isaacs equation

$$\frac{\partial V^{\varepsilon+}}{\partial t} + \min_{z \in Z} \max_{y \in Y} \left(D_x V^{\varepsilon+} f\left(t, \frac{t}{\varepsilon}, x, y, z\right) \right) = 0.$$

Using the perturbed test function

$$\frac{d\gamma}{ds} = \min_{z(\cdot)} \max_{y(\cdot)} (\varphi_x \bar{f}(t, x, y(\cdot), z(\cdot))) - \min_{z \in Z} \max_{y \in Y} (\varphi_x f(t, s, x, y, z))$$

we prove that $V^{\varepsilon+} \rightarrow W$ and W satisfies

$$W_t + \min_{z(\cdot)} \max_{y(\cdot)} (W_x \bar{f}(t, x, y(\cdot), z(\cdot))) = 0.$$

A similar statement holds for the lower value. In the differential game case, both players z , the minimizer, and y , the maximizer, must depend on the fast variable, in general.

Remark. If we are concerned with the stochastic optimal control problem

$$\frac{d\xi}{d\tau} = f\left(\tau, \frac{\tau}{\varepsilon}, \xi(\tau), \zeta(\tau)\right) d\tau + \sigma\left(\tau, \frac{\tau}{\varepsilon}, \xi(\tau), \zeta(\tau)\right) dw(\tau), \quad \xi(t) = x \in R^1,$$

$$V^\varepsilon(t, x) = \inf_{\zeta} E_{t,x}[g(\xi(T))],$$

where $w(\cdot)$ is Brownian motion, under suitable assumptions on f , g , σ , it is not difficult to show that $V^\varepsilon \rightarrow W$ on a subsequence, and W is Lipschitz continuous. Then, by the same method of proof of theorem 1.3 using the perturbation γ which solves

$$\begin{aligned} \frac{d\gamma}{ds} = \min_{z(\cdot)} \left[\frac{1}{2} \int_0^1 \sigma^2(t_0, r, x_0, z(r)) \varphi_{xx}(t_0, x_0) dr + \int_0^1 f(t_0, r, x_0, z(r)) \varphi_x(t_0, x_0) dr \right] \\ - \min_{z \in Z} \left[\frac{1}{2} \sigma^2(t_0, s, x_0, z) \varphi_{xx}(t_0, x_0) + f(t_0, s, x_0, z) \varphi_x(t_0, x_0) \right], \\ 0 \leq s \leq 1, \end{aligned}$$

with γ 1-periodic, it is easily proved that W solves, in the viscosity sense,

$$W_t + \min_{z(\cdot)} \left[\frac{1}{2} W_{xx}(t, x) \int_0^1 \sigma^2(t, s, x, z(s)) ds + W_x(t, x) \int_0^1 f(t, s, x, z(s)) ds \right] = 0,$$

and $W(T, x) = g(x)$. This is also true in R^n . Note that σ^2 is the averaged diffusion, not σ . Also note that the perturbation γ is continuously differentiable and that this is sufficient for a test function against W in time.

1.1 What happens if we use Lipschitz Controls?. In virtually any real problem, measurable controls cannot actually be implemented since most systems are inertial. That is, instantaneous changes in the control and the state are impossible. In effect, this says that practical problems involve the use of Lipschitz-continuous controls, not measurable controls. If that is the case, then it is intuitive that the Lipschitz control cannot keep up with rapidly oscillating dynamics. The question then arises as to exactly what can be achieved. The answer is contained in Theorem 1.5.¹

For simplicity, assume that the control set $Z = [0, 1]^p$ and extend the dynamics f and h so that they are 1-periodic in the z variable. We need to do something like this because of the following.

When the control $\zeta : [0, T] \rightarrow Z$ is Lipschitz, say with Lipschitz constant $L > 0$, we can consider the derivative of ζ to be the real control. Thus we have the dynamics

$$\begin{aligned} \frac{d\xi}{d\tau} &= f\left(\tau, \frac{\tau}{\varepsilon}, \xi(\tau), \zeta(\tau)\right), \\ \frac{d\zeta}{d\tau} &= \beta(\tau) \quad \text{if } t < \tau \leq T, \\ \xi(t) &= x \in R^n, \quad \zeta(t) = z \in Z. \end{aligned}$$

The control functions β are chosen from the class of functions

$$B_L[t, T] = \{\beta : [t, T] \rightarrow [-L, L]^p \mid \beta(\cdot) \text{ is Lebesgue measurable}\}.$$

First, note that we must impose an initial condition on ζ . When the controls ζ are merely measurable, this is irrelevant because the control can instantaneously jump to any desired point. However, when they are Lipschitz this is impossible. On the other hand, when the Lipschitz constant becomes arbitrarily large, it seems reasonable, and is indeed true, that the dependence on the initial condition $z \in Z$ goes away.

Second, in this formulation of the Lipschitz control problem, ζ becomes a state variable. This is, therefore, a state constrained problem due to the fact that we require $\zeta \in Z[t, T]$. By making the dynamics periodic in z , however, we can remove the state constraint because the action of any control ζ that leaves Z can be obtained via a control that does not exit via reflection at the boundaries of $Z = [0, 1]^p$. In this way, if we start in Z we will stay in Z .

Even though periodic extension may destroy continuity of the dynamics, this does not cause a problem. On the other hand, if we do not extend the dynamics, we would need to impose conditions on the value function at the boundary of Z . These conditions are, of course, unknown in general.

Complete details and further results regarding the Lipschitz control problem can be found in [4], [5], [7].

Now we turn to our interest in Lipschitz controls in the context of this paper.

¹This is the outcome of a fruitful conversation with Bob Jensen.

THEOREM 1.5. *For each $L > 0$, $\varepsilon > 0$, let $V^{\varepsilon,L} = V^{\varepsilon,L} : [0, T] \times R^n \times Z \rightarrow R^1$ be the value function for the optimal control problem (1.1)–(1.4) when the controls ζ must be chosen from*

$$\mathcal{Z}_z^L[t, T] = \{\zeta \in \mathcal{Z}[t, T] \mid |\zeta(\tau) - \zeta(\tau')| \leq L|t - t'|, \forall \tau, \tau' \in [t, T], \zeta(t) = z\}.$$

Then

- (1) $\lim_{\varepsilon \rightarrow 0} \lim_{L \rightarrow \infty} V^{\varepsilon,L}(t, x, z) = W(t, x)$ where W is the solution of (HJB).
- (2) $\lim_{L \rightarrow \infty} \lim_{\varepsilon \rightarrow 0} V^{\varepsilon,L}(t, x, z) = U(t, x)$ where U is the value function for the optimal control problem with dynamics

$$\frac{d\xi}{d\tau} = \int_0^1 f(\tau, s, \xi(\tau), \zeta(\tau)) ds, \quad t < \tau \leq T, \quad \xi(t) = x \in R^n,$$

and cost

$$P_{t,x}(\zeta) = g(\xi(T)) + \int_t^T \int_0^1 h(r, s, \xi(r), \zeta(r)) dr, \quad \zeta \in \mathcal{Z}[t, T].$$

U is the viscosity solution of

$$(HJB^*) \quad U_t + \min_{z \in Z} \{D_x U \cdot \int_0^1 f(t, s, x, z) ds + \int_0^1 h(t, s, x, z) ds\} = 0,$$

and $U(T, x) = g(x)$.

Note that the controls in the limit problem yielding U do *not* depend on the fast variable s .

Proof. A special case of [7, Thm. 4.1] says that for each fixed $L > 0$, $\varepsilon > 0$, $V^{\varepsilon,L}$ is the unique continuous viscosity solution of

$$(1.21) \quad \begin{aligned} V_t^{\varepsilon,L} + D_x V^{\varepsilon,L} \cdot f\left(t, \frac{t}{\varepsilon}, x, z\right) + h\left(t, \frac{t}{\varepsilon}, x, z\right) - L|D_z V^{\varepsilon,L}| &= 0, \quad (t, x) \in \Omega, z \in Z \\ V^{\varepsilon,L}(T, x, z) &= g(x). \end{aligned}$$

Now, to prove (1) we use the fact ([7]) that for fixed ε , as $L \rightarrow \infty$, $V^{\varepsilon,L}(t, x, z) \rightarrow V^\varepsilon(t, x)$, where V^ε is the unique viscosity solution of (1.7) and is the same as the value function of Lemma 1.2. Then, as $\varepsilon \rightarrow 0$, $V^\varepsilon \rightarrow W$, according to Theorem 1.3. Thus (1) is proved. This says that if we first let the Lipschitz constant be arbitrarily large then the controls can keep up with the oscillations. This is the measurable control case. This will be in sharp distinction to part (2) in which we first take the fast oscillations for a fixed Lipschitz constant and then let the Lipschitz constant become arbitrarily large.

To prove (2), write (1.21) as

$$V_t^{\varepsilon,L} + \min_{|a| \leq L} \left\{ D_x V^{\varepsilon,L} \cdot f\left(t, \frac{t}{\varepsilon}, x, z\right) + h\left(t, \frac{t}{\varepsilon}, x, z\right) + a D_z V^{\varepsilon,L} \right\} = 0.$$

Fix $L > 0$ and let $\varepsilon \rightarrow 0$. Using Theorem 1.3, we obtain $V^{\varepsilon,L}(t, x, z) \rightarrow U^L(t, x, z)$, where U^L satisfies

$$U_t^L + \min_{|a(\cdot)| \leq L} \left\{ D_x U^L \cdot \int_0^1 f(t, s, x, z) ds + \int_0^1 h(t, s, x, z) ds + D_z U^L \cdot \int_0^1 a(s) ds \right\} = 0.$$

The min is taken over functions $|a(\cdot)| \leq L$. However, this is the same as

$$U_t^L + D_x U^L \cdot \int_0^1 f(t, s, x, z) ds + \int_0^1 h(t, s, x, z) ds - L|D_z U^L| = 0.$$

Now let $L \rightarrow \infty$. Using again [7, Thm. 4.2], we get $U^L(t, x, z) \rightarrow U(t, x)$, where U is the unique viscosity solution of (HJB*). Since the value function in the statement of (2) is known to be the viscosity solution of this equation, U must be the value function. This completes the proof. \square

COROLLARY 1.6. $W(t, x) \leq U(t, x)$ on $[0, T] \times R^n$.

Proof. The corollary follows immediately from the fact that

$$\begin{aligned} \min_{z(\cdot) \in \mathcal{A}} \left\{ p \cdot \int_0^1 f(t, s, x, z(s)) ds + \int_0^1 h(t, s, x, z(s)) ds \right\} \\ \leq \min_{z \in Z} \left\{ p \cdot \int_0^1 f(t, s, x, z) ds + \int_0^1 h(t, s, x, z) ds \right\}. \quad \square \end{aligned}$$

Remark. The result is that in practical problems we should not expect to achieve the averaged value W . The best we should expect is the value U .

1.2. A Homogenized problem in one dimension. In this section we will discuss the homogenized problem for a fast variable in the state, not in time. Specifically, the fast control problem is

$$\begin{aligned} \frac{d\xi}{d\tau} &= f\left(\tau, \frac{\xi}{\varepsilon}, \xi(\tau), \zeta(\tau)\right) \quad \text{if } t < \tau \leq T, \\ \xi(t) &= x \in R^1. \end{aligned}$$

We will assume that (A) holds and that the real valued function $f(\cdot, y, \cdot, \cdot)$ is uniformly Lipschitz and 1-periodic. Also assume that $\min_{z \in Z} f(t, y, x, z) \geq \alpha > 0$. The control functions for the fast problem ζ are chosen from the class $Z[t, T]$. For simplicity, the objective will be to minimize on $Z[t, T]$ the Mayer payoff $P_{t,x}(\zeta) = g(\xi(T))$. The fast value function is $V^\varepsilon(t, x) = \inf_{\zeta \in Z[t, T]} P_{t,x}(\zeta)$.

We will see that the perturbed test function method does not seem to work here because of a lack of smooth solutions to an equation for the perturbation. Instead we will apply the result of [14].

PROPOSITION 1.7. V^ε converges uniformly on Ω to a function W that is bounded and uniformly continuous and which is the unique viscosity solution of

$$\frac{\partial W}{\partial t} + \min_{z(\cdot) \in \mathcal{A}} W_x \cdot \left(\int_0^1 \frac{1}{f(t, y, x, z(y))} dy \right)^{-1} = 0$$

for $(t, x) \in \Omega$, and $W(T, x) = g(x)$.

Proof. Lions, Papanicolaou, and Varadhan [14] prove that V^ε converges uniformly to a bounded, continuous function W that is the viscosity solution of

$$\frac{\partial W}{\partial t} + \overline{H}(t, x, W_x) = 0,$$

where \overline{H} , the so-called *effective Hamiltonian*, is given via the solution of a *cell problem*

$$\min_{z \in Z} \{(p + \gamma'(y)) \cdot f(t, y, x, z)\} = \lambda, \quad y \in (0, 1), \quad p \in R^1,$$

for a function $\gamma \in W^{1,\infty}(R^1)$ which is 1-periodic. The pair (λ, γ) with $\lambda = \overline{H}(t, x, p)$, is unique. The problem is to compute λ .

We claim that

$$\overline{H}(t, x, p) = \min_{z(\cdot) \in \mathcal{A}} p \cdot \left(\int_0^1 \frac{1}{f(t, y, x, z(y))} dy \right)^{-1}.$$

To verify this, let $\zeta \in \mathcal{A}$ be arbitrary. Then

$$\lambda \leq (p + \gamma'(y)) \cdot f(t, y, x, \zeta(y)), \quad \text{for a.e. } y \in [0, 1],$$

so that $\lambda/f - p \leq \gamma'$. Integrating both sides on y from 0 to 1, we get

$$\lambda \int_0^1 \frac{1}{f(t, y, x, \zeta(y))} dy - p \leq \gamma(1) - \gamma(0) = 0.$$

Consequently,

$$\lambda \leq \min_{z(\cdot) \in \mathcal{A}} p \cdot \left(\int_0^1 \frac{1}{f(t, y, x, z(y))} dy \right)^{-1}.$$

For the opposite inequality, let $\zeta \in \mathcal{A}$ satisfy almost everywhere (note that ζ also depends on (t, x, p))

$$\min_{z \in Z} \{(p + \gamma'(y)) \cdot f(t, y, x, z)\} = (p + \gamma'(y)) \cdot f(t, y, x, \zeta(y)) = \lambda.$$

So, $\lambda/f - p = \gamma'$, which, by integration on y , periodicity of γ , and rearrangement, yields

$$\lambda = p \cdot \left(\int_0^1 \frac{1}{f(t, y, x, \zeta(y))} dy \right)^{-1} \geq \min_{z(\cdot) \in \mathcal{A}} p \cdot \left(\int_0^1 \frac{1}{f(t, y, x, z(y))} dy \right)^{-1}$$

and we are done. \square

The terminology in the proof seems to be due to Bensoussan, Lions, and Papanicolaou [9]. The uncontrolled analogue of this problem appears in [9, p. 8]. Note that the limit problem involves controls that depend on y . The limit optimal control problem has the dynamics

$$\frac{d\xi}{d\tau} = \left(\int_0^1 \frac{1}{f(\tau, y, \xi(\tau), \zeta(\tau, y))} dy \right)^{-1},$$

where the controls are $\zeta = \zeta(t, x)$.

The difficulty in using the perturbed test function method to prove convergence for this problem is the fact that the cell problem, while it has a Lipschitz-continuous viscosity solution, does not necessarily have a smooth classical solution.

The proposition does not seem to extend to higher dimensions.

2. The minimax problem. In this section we study the limiting behavior of the optimal control problem with dynamics (1.1), (1.2) but with cost functional given by

$$P_{t,x}^\varepsilon(\zeta) = \|h(r, \xi(r), \zeta(r))\|_{L^\infty[t,T]}.$$

The assumptions on f and h are the same as in §1, but note that here we assume that h is independent of the fast variable. The value function is defined as

$$V^\varepsilon(t, x) = \inf_{\zeta \in Z[t, T]} P_{t, x}^\varepsilon(\zeta).$$

Define the point to set map

$$Z(t, x, r) \equiv \{z \in Z \mid h(t, x, z) \leq r\},$$

and the Hamiltonian

$$H(t, s, x, r, p) \equiv \min\{p \cdot f(t, s, x, z) ; z \in Z(t, x, r)\},$$

If $Z(t, x, r)$ is empty, H is defined as $+\infty$.

The next lemma is the main result from [6] and gives the Bellman equation for the fast minimax problem.

LEMMA 2.1. *The value function V^ε is the unique continuous viscosity solution of the problem*

$$(2.1) \quad \frac{\partial V}{\partial t} + H\left(t, \frac{t}{\varepsilon}, x, V, D_x V\right) = 0 \quad \text{on } \Omega.$$

V^ε satisfies the terminal condition

$$(2.2) \quad V^\varepsilon(T, x) = \min_{z \in Z} h(T, x, z) \quad \text{on } R^n.$$

Remarks. We will also have need of the following results from [6]. It was established in [6, Prop. 4.1] that (2.1) is equivalent to the following nonlinear variational inequality on Ω

$$(2.1a) \quad \max \left\{ \frac{\partial V}{\partial t} + H\left(t, \frac{t}{\varepsilon}, x, V, D_x V\right), \min_{z \in Z} h(t, x, z) - V(t, x) \right\} = 0.$$

Equation (2.1) is an implicit obstacle problem that is made explicit in (2.1a), especially when h is independent of z . It is usually better to work with (2.1a) rather than (2.1) since (2.1a) explicitly shows that when we are dealing with supersolutions the set $Z(t, x, r)$ is not empty.

According to [6, Lemma 2.4], if $r \leq r'$ $H(t, s, x, r, p) \geq H(t, s, x, r', p)$. If $r < r'$ there exists $\varrho > 0$ depending only on r and r' such that

$$(2.3a) \quad H(\tau, s, \xi, r, p) \geq H(t, s, x, r', p) \text{ for any } (\tau, \xi) \in B_\varrho(t, x).$$

Proposition 2.5 of [6] establishes that

$$(2.3b) \quad H^*(t, s, x, r, p) = H(t, s, x, r - 0, p), \quad H_*(t, s, x, r, p) = H(t, s, x, r + 0, p).$$

Consequently, $H(t, s, x, r - 0, p)$ is upper semicontinuous and $H(t, s, x, r + 0, p)$ is lower semicontinuous in all variables. But, for fixed (t, x, r, p) , H is continuous in s .

Finally, it was shown that the essential supremum in time of h can be replaced by the supremum in the definition of V^ε . We will do so in referring to the norm in L^∞ .

Now we proceed formally to determine the limit problem in this case. We use L^p approximations to the L^∞ norm. Indeed, for fixed $\varepsilon > 0, p \geq 1$ let

$$V_p^\varepsilon(t, x) = \inf_{\zeta} \|h(r, \xi(r), \zeta(r))\|_{L^p[t, T]}.$$

Then, according to [6, Lemma 1.1], V_p^ε is the unique continuous viscosity solution of $V(T, x) = \min_{z \in Z} h(T, x, z)$ and

$$\frac{\partial V}{\partial t} + \min_{z \in Z} \left\{ D_x V \cdot f\left(t, \frac{t}{\varepsilon}, x, z\right) + \frac{1}{p} (h(t, x, z))^p V(t, x)^{1-p} \right\} = 0.$$

For $p \geq 1$ fixed, we let $\varepsilon \rightarrow 0$ and use Theorem 1.3 to obtain that $V_p = \lim_{\varepsilon \rightarrow 0} V_p^\varepsilon$ satisfies

$$\frac{\partial V}{\partial t} + \min_{z(\cdot) \in \mathcal{A}} \left\{ D_x V \cdot \bar{f}(t, x, z(\cdot)) + \frac{1}{p} V(t, x)^{1-p} \int_0^1 (h(t, x, z(s)))^p ds \right\} = 0.$$

Reasoning as in [6], by looking at the term $V^{1-p} \int h^p ds$, if a limit as $p \rightarrow \infty$ is going to exist, it must be the case that the controls $z(\cdot) \in \mathcal{A}$ must be chosen so that, for all large p

$$V_p(t, x)^p \geq \int_0^1 (h(t, x, z(s)))^p ds$$

and so

$$V_p(t, x) \geq \left(\int_0^1 (h(t, x, z(s)))^p ds \right)^{1/p},$$

which implies that

$$V(t, x) = \lim_{p \rightarrow \infty} V_p(t, x) \geq \sup_{0 \leq s \leq 1} h(t, x, z(s)).$$

Consequently, we see that the controls in the minimum must be chosen out of \mathcal{A} but that also satisfy

$$V(t, x) \geq \sup_{0 \leq s \leq 1} h(t, x, z(s)).$$

This argument can be made rigorous to yield that

$$\lim_{p \rightarrow \infty} \lim_{\varepsilon \rightarrow 0} V_p^\varepsilon(t, x) \equiv W(t, x)$$

and W satisfies, in the viscosity sense, the equation

$$\begin{aligned} & \max\{W_t + \min\{D_x W \cdot \bar{f}(t, x, z(\cdot)); z(\cdot) \in \mathcal{A}, \sup_{0 \leq s \leq 1} h(t, x, z(s)) \leq W(t, x)\}, \\ (2.4) \quad & \min_{z(\cdot) \in \mathcal{A}} \sup_{0 \leq s \leq 1} h(t, x, z(s)) - W(t, x)\} = 0, \end{aligned}$$

and the terminal condition $W(T, x) = \min_{z(\cdot) \in \mathcal{A}} \sup_{0 \leq s \leq 1} h(T, x, z(s))$. In fact, this is even true when $h = h(t, s, x, z)$, i.e., there is dependence on the fast variable. Unfortunately, it is certainly not clear that the iterated limit can be reversed (it probably cannot). Furthermore, the L^p approximations are monotone nondecreasing, actually

this is true of $(T-t)^{-p}V_p$, so that we are in fact getting a form of variational convergence ([2, Thm. 2.40]). (As an aside, for any periodic function f , $f(y/\varepsilon)$ epi-converges to $\inf_y f(y)$ and hypo-converges to $\sup_y f(y)$.) We can see that the terminal condition $V^\varepsilon(T, x) = \min_{z \in Z} h(T, T/\varepsilon, x, z)$ would cause a great deal of difficulty when there is fast variable dependence. In fact, whenever V^ε hits the obstacle $\min_{z \in Z} h(t, t/\varepsilon, x, z)$ it is not clear that there will be convergence in a strong enough sense. However, without s dependence for h , (2.4) is the correct limit equation. We will prove this fact directly using Evans' method. The case when h depends on the fast variable will be left open.

We are grateful to a reviewer for spotting a subtle, and seemingly minor error in an earlier version of this paper in which we included fast dependence for h . This point led to our realization that dependence of the obstacle on the fast variable is probably not allowed. At least we do not see how to do it.

Now we turn to the main theorem of this section.

THEOREM 2.2. *There exists a continuous function $W : [0, T] \times R^n \rightarrow R^1$ such that (at least) on a subsequence of $\{\varepsilon\}$ we have*

$$\lim_{\varepsilon \rightarrow 0} V^\varepsilon(t, x) = W(t, x).$$

The function W is the minimax value function for the optimal control problem with dynamics

$$\frac{d\xi}{d\tau} = \bar{f}(\tau, \xi(\tau), \zeta(\tau, \cdot)), \quad t < \tau \leq T, \quad \xi(t) = x,$$

and cost functional

$$\bar{P}_{t,x}(\zeta(\cdot, \cdot)) \equiv \sup_{t \leq \tau \leq T} \sup_{0 \leq s \leq 1} h(\tau, \xi(\tau), \zeta(\tau, s)).$$

where the controls $\zeta : [t, T] \times [0, 1] \rightarrow Z$ satisfy $\zeta(\tau, \cdot) \in \mathcal{Z}[t, T]$, and $\zeta(\cdot, s) \in \mathcal{A}$. Furthermore, W is the unique continuous viscosity solution of

$$(2.5) \quad \frac{\partial W}{\partial t} + \bar{H}(t, x, W, D_x W) = 0, \quad (t, x) \in [0, T] \times R^n,$$

where

$$\begin{aligned} \bar{H}(t, x, r, p) &\equiv \min\{p \cdot \bar{f}(t, x, z(\cdot)) \mid z(\cdot) \in \mathcal{A}_\infty(t, x, r)\}, \\ \mathcal{A}_\infty(t, x, r) &\equiv \{z : [0, 1] \rightarrow Z \mid \sup_{0 \leq s \leq 1} h(t, x, z(s)) \leq r\} \end{aligned}$$

\bar{H} is defined as $+\infty$ if \mathcal{A}_∞ is empty. Finally, W satisfies the terminal condition

$$W(T, x) = \min_{z \in Z} h(T, x, z).$$

Remarks. 1. It is important to distinguish the notation from §1 that $\mathcal{A} = \{z : [0, 1] \rightarrow Z \mid z \text{ is Lebesgue measurable}\}$ while in the minimax case $\mathcal{A}_\infty(t, x, r) \equiv \{z : [0, 1] \rightarrow Z \mid \sup_{0 \leq s \leq 1} h(t, x, z(s)) \leq r\}$.

2. Using the same proofs as in [6] it is established that

$$\bar{H}^*(t, x, r, p) = \bar{H}(t, x, r - 0, p), \quad \bar{H}_*(t, x, r, p) = \bar{H}(t, x, r + 0, p)$$

Also, (2.5) is equivalent to

$$(2.5a) \quad \max\left\{\frac{\partial W}{\partial t} + \overline{H}(t, x, W, D_x W), \min_{z \in Z} h(t, x, z) - W(t, x)\right\} = 0.$$

3. Let us dispense with a small technicality. Note that for each fixed $t \in [0, T]$, $x \in R^n$

$$\min_{z(\cdot) \in \mathcal{A}} \sup_{0 \leq s \leq 1} h(t, x, z(s)) = \min_{z \in Z} h(t, x, z).$$

Indeed, by taking $z(s) \equiv z$, $0 \leq s \leq 1$, where $z \in Z$ is arbitrary,

$$\min_{z(\cdot) \in \mathcal{A}} \sup_{0 \leq s \leq 1} h(t, x, z(s)) \leq \min_{z \in Z} h(t, x, z).$$

On the other hand, for any $\delta > 0$ there is a function ζ such that

$$\begin{aligned} \min_{z(\cdot) \in \mathcal{A}} \sup_{0 \leq s \leq 1} h(t, x, z(s)) &\geq h(t, x, \zeta(s, t, x)) - \delta \quad \forall 0 \leq s \leq 1 \\ &\geq \min_{z \in Z} h(t, x, z) - \delta. \end{aligned}$$

The claim is proved.

4. It is clear that $\mathcal{A}_\infty(t, x, r)$ is nonempty if and only if $\mathcal{Z}(t, x, r)$ is nonempty.

Proof of Theorem 2.2. Set

$$W^u(t, x) = \limsup_{(\varepsilon, s, y) \rightarrow (0, t, x)} V^\varepsilon(s, y)$$

and

$$W_d(t, x) = \liminf_{(\varepsilon, s, y) \rightarrow (0, t, x)} V^\varepsilon(s, y).$$

W^u is upper semicontinuous and W_d is lower semicontinuous.

We begin by showing that W^u is a subsolution of (2.5a). As usual, let $W^u - \varphi$ achieve a strict maximum at $(t_0, x_0) \in \Omega$, with φ a smooth function. If

$$(2.6) \quad \min_{z \in Z} h(t_0, x_0, z) \geq W^u(t_0, x_0)$$

then obviously,

$$\max\left\{\frac{\partial \varphi}{\partial t} + \overline{H}(t_0, x_0, W^u(t_0, x_0) - 0, D_x \varphi(t_0, x_0)), \min_{z \in Z} h(t_0, x_0, z) - W^u(t_0, x_0)\right\} \geq 0.$$

Consequently, W^u is a subsolution of (2.5a) immediately. We may therefore assume that

$$(2.7) \quad \min_{z \in Z} h(t_0, x_0, z) < W^u(t_0, x_0).$$

This implies that $\mathcal{A}_\infty(t_0, x_0, W^u(t_0, x_0) - 0)$ is not empty.

Define $\gamma : R^1 \rightarrow R^1$ as the solution of the ordinary differential equation

$$\frac{d\gamma(s)}{ds} = \overline{H}(t_0, x_0, W^u(t_0, x_0) - 0, D_x \varphi(t_0, x_0)) - H(t_0, s, x_0, W^u(t_0, x_0) - 0, D_x \varphi(t_0, x_0)),$$

if $0 \leq s \leq 1$, with γ 1-periodic. To guarantee that a periodic solution of this problem exists we need the following lemma.

LEMMA 2.2a. *For any fixed (t, x, r, p)*

$$(2.8) \quad \int_0^1 H(t, s, x, r, p) ds = \overline{H}(t, x, r, p).$$

Proof. Since $\mathcal{A}_\infty(t, x, r)$ and $Z(t, x, r)$ are either both nonempty or both empty, we may as well assume that both are nonempty and therefore that both Hamiltonians are finite. For fixed (t, x, r, p) , since $Z(t, x, r)$ is compact, we have the existence of a measurable function $\zeta(s) \equiv \zeta(t, s, x, p)$ that satisfies $\zeta \in \mathcal{A}_\infty(t, x, r)$ such that

$$\begin{aligned} \int_0^1 \min_{z \in Z(t, x, r)} p \cdot f(t, s, x, z) ds &= \int_0^1 p \cdot f(t, s, x, \zeta(s)) ds \\ &\geq \min_{z(\cdot) \in \mathcal{A}_\infty(t, x, r)} p \cdot \int_0^1 f(t, s, x, z(s)) ds. \end{aligned}$$

The other side follows from the existence for each $\delta > 0$ of a function $\zeta \in \mathcal{A}_\infty(t, x, r)$ such that

$$\begin{aligned} \min_{z(\cdot) \in \mathcal{A}_\infty(t, x, r)} p \cdot \int_0^1 f(t, s, x, z(s)) ds &\geq p \cdot \int_0^1 f(t, s, x, \zeta(s)) ds - \delta \\ &\geq \int_0^1 \min_{z \in Z(t, x, r)} p \cdot f(t, s, x, z) ds - \delta. \end{aligned}$$

So (2.8) is proved. \square

Returning to the proof of the theorem, we have that γ is a periodic function that is continuously differentiable. The derivative of γ is continuous because the constraint set in

$$H(t_0, s, x_0, W^u(t_0, x_0) - 0, D_x \varphi(t_0, x_0)) = \min_{z \in Z(t_0, x_0, W^u(t_0, x_0) - 0)} D_x \varphi(t_0, x_0) \cdot f(t_0, s, x_0, z)$$

is independent of s . Furthermore, $\gamma(0) = \gamma(1)$ by Lemma 2.1a, and, since f is periodic in s , $\gamma'(0) = \gamma'(1)$. Consequently, γ may be used as a perturbed test function. That is, for all sufficiently small $\varepsilon > 0$, $V^\varepsilon(t, x) - (\varphi + \varepsilon\gamma(t/\varepsilon))$ achieves a maximum at $(t_\varepsilon, x_\varepsilon)$ and, by Lemma A.3, $(t_\varepsilon, x_\varepsilon) \rightarrow (t_0, x_0)$, and $V^\varepsilon(t_\varepsilon, x_\varepsilon) \rightarrow W^u(t_0, x_0)$ as $\varepsilon \rightarrow 0$. Using (2.7) and condition (A), it is easy to see that for all sufficiently small ε ,

$$(2.9) \quad \min_{z \in Z} h(t_\varepsilon, x_\varepsilon, z) < V^\varepsilon(t_\varepsilon, x_\varepsilon).$$

Of course this implies that $Z(t_\varepsilon, x_\varepsilon, V^\varepsilon(t_\varepsilon, x_\varepsilon))$ is nonempty for all small ε . Therefore, using the fact that V^ε is a (continuous) subsolution of (2.1), we conclude that

$$\begin{aligned} 0 &\leq \varphi_t(t_\varepsilon, x_\varepsilon) + \frac{d\gamma(\frac{t_\varepsilon}{\varepsilon})}{ds} + H\left(t_\varepsilon, \frac{t_\varepsilon}{\varepsilon}, x_\varepsilon, V^\varepsilon(t_\varepsilon, x_\varepsilon) - 0, D_x \varphi(t_\varepsilon, x_\varepsilon)\right) \\ &= \varphi_t(t_\varepsilon, x_\varepsilon) + \overline{H}(t_0, x_0, W^u(t_0, x_0) - 0, D_x \varphi(t_0, x_0)) \\ &\quad - H\left(t_0, \frac{t_\varepsilon}{\varepsilon}, x_0, W^u(t_0, x_0) - 0, D_x \varphi(t_0, x_0)\right) \\ &\quad + H\left(t_\varepsilon, \frac{t_\varepsilon}{\varepsilon}, x_\varepsilon, V^\varepsilon(t_\varepsilon, x_\varepsilon) - 0, D_x \varphi(t_\varepsilon, x_\varepsilon)\right) \\ &\leq \varphi_t(t_0, x_0) + \overline{H}(t_0, x_0, W^u(t_0, x_0) - 0, D_x \varphi(t_0, x_0)) + o_\varepsilon(1), \end{aligned}$$

as $\varepsilon \rightarrow 0$. We have used here the upper semicontinuity in all variables of $H(t, s, x, r + 0, p)$, the smoothness of φ and the facts $(t_\varepsilon, x_\varepsilon) \rightarrow (t_0, x_0)$, $V^\varepsilon(t_\varepsilon, x_\varepsilon) \rightarrow W^u(t_0, x_0)$. The conclusion, using (2.7), is that W^u is a subsolution of (2.5).

Next, we will prove that W_d is a supersolution. The proof is very similar to the subsolution case.

Let $W_d - \varphi$ achieve a strict minimum at (t_0, x_0) . For any $\varepsilon > 0$ let $V^\varepsilon - \varphi$ achieve a minimum at $(t_\varepsilon, x_\varepsilon)$ with $(t_\varepsilon, x_\varepsilon) \rightarrow (t_0, x_0)$, $V^\varepsilon(t_\varepsilon, x_\varepsilon) \rightarrow W_d(t_0, x_0)$. Since V^ε is a supersolution of (2.1), or equivalently, (2.1a), we have

$$(2.10) \quad V^\varepsilon(t_\varepsilon, x_\varepsilon) \geq \min_{z \in Z} h(t_\varepsilon, x_\varepsilon, z).$$

From (2.10) and the continuity of h , letting $\varepsilon \rightarrow 0$, we get

$$(2.11) \quad W_d(t_0, x_0) \geq \min_{z \in Z} h(t_0, x_0, z).$$

This implies that $\mathcal{A}_\infty(t_0, x_0, W_d(t_0, x_0) + 0)$ is not empty.

Define $\gamma: R^1 \rightarrow R^1$ as the solution of the ordinary differential equation

$$(2.12) \quad \frac{d\gamma(s)}{ds} = \overline{H}(t_0, x_0, W_d(t_0, x_0) + 0, D_x \varphi(t_0, x_0)) - H(t_0, s, x_0, W_d(t_0, x_0) + 0, D_x \varphi(t_0, x_0)),$$

if $0 \leq s \leq 1$, with γ 1-periodic. Again, a periodic solution is guaranteed to exist by Lemma 2.1a. Furthermore, since $H(t, s, x, r + 0, p)$ is continuous in s , $d\gamma/ds$ will be continuous, and $\gamma(0) = \gamma(1)$, $\gamma'(0) = \gamma'(1)$. Note also that $H(t_0, s, x_0, W_d(t_0, x_0) + 0, D_x \varphi(t_0, x_0))$ is finite because of (2.11).

Again using Lemma A.3, expressed for supersolutions, for all $\varepsilon > 0$ sufficiently small, the function $V^\varepsilon(t, x) - (\varphi(t, x) + \varepsilon \gamma(\frac{t}{\varepsilon}))$ achieves a minimum at $(t_\varepsilon, x_\varepsilon)$, $(t_\varepsilon, x_\varepsilon) \rightarrow (t_0, x_0)$ and $V^\varepsilon(t_\varepsilon, x_\varepsilon) \rightarrow W_d(t_0, x_0)$ as $\varepsilon \rightarrow 0$. Since V^ε is a continuous supersolution of (2.1) we obtain from (2.12) evaluated at $s = t_\varepsilon/\varepsilon$ and the fact that (2.10) implies that $Z(t_\varepsilon, x_\varepsilon, V^\varepsilon(t_\varepsilon, x_\varepsilon) + 0)$ is nonempty,

$$\begin{aligned} 0 &\geq \varphi_t(t_\varepsilon, x_\varepsilon) + \frac{d\gamma(\frac{t_\varepsilon}{\varepsilon})}{ds} + H_*\left(t_\varepsilon, \frac{t_\varepsilon}{\varepsilon}, x_\varepsilon, V^\varepsilon(t_\varepsilon, x_\varepsilon), D_x \varphi(t_\varepsilon, x_\varepsilon)\right) \\ &= \varphi_t(t_\varepsilon, x_\varepsilon) + \frac{d\gamma(\frac{t_\varepsilon}{\varepsilon})}{ds} + H\left(t_\varepsilon, \frac{t_\varepsilon}{\varepsilon}, x_\varepsilon, V^\varepsilon(t_\varepsilon, x_\varepsilon) + 0, D_x \varphi(t_\varepsilon, x_\varepsilon)\right) \\ &= \varphi_t(t_\varepsilon, x_\varepsilon) + \overline{H}(t_0, x_0, W_d(t_0, x_0) + 0, D_x \varphi(t_0, x_0)) \\ &\quad - H\left(t_0, \frac{t_\varepsilon}{\varepsilon}, x_0, W_d(t_0, x_0) + 0, D_x \varphi(t_0, x_0)\right) \\ &\quad + H\left(t_\varepsilon, \frac{t_\varepsilon}{\varepsilon}, x_\varepsilon, V^\varepsilon(t_\varepsilon, x_\varepsilon) + 0, D_x \varphi(t_\varepsilon, x_\varepsilon)\right) \end{aligned}$$

By letting $\varepsilon \rightarrow 0$ and using the lower semicontinuity of $H(t, s, x, r + 0, p)$, we conclude that

$$\varphi_t(t_0, x_0) + \overline{H}(t_0, x_0, W_d(t_0, x_0) + 0, D_x \varphi(t_0, x_0)) \leq 0.$$

Therefore, W_d is a supersolution of (2.5).

Since $V^\varepsilon(T, x) = \min_{z \in Z} h(T, x, z)$, it is an immediate consequence of the definitions of W^u and W_d and continuity of h that

$$W^u(T, x) = W_d(T, x) = \min_{z \in Z} h(T, x, z).$$

We have shown that W^u is a subsolution and W_d is a supersolution of (2.5), both satisfying the same terminal condition. If we can establish that $W^u \leq W_d$ then convergence to a continuous function will be shown. However, this fact is a comparison principle on which uniqueness of solutions of (2.5) is based. The statements we need are in the next theorem, the first part of which is essentially Theorem 4.2 in [6].

THEOREM 2.3. a) Let $u : [0, T] \times R^n \rightarrow R^1$ ($v : [0, T] \times R^n \rightarrow R^1$) be an upper (lower) semicontinuous subsolution (supersolution) of (2.5) both satisfying the terminal condition $u(T, x) = v(T, x) = \min_{z \in Z} h(T, x, z)$. Then, $u \leq v$ on $[0, T] \times R^n$.

b) The unique continuous viscosity solution of (2.5) is given by

$$W(t, x) = \inf_{\zeta(\cdot, \cdot)} \sup_{t \leq \tau \leq T, 0 \leq s \leq 1} h(\tau, \xi(\tau), \zeta(\tau, s)),$$

where

$$\frac{d\xi}{d\tau} = \int_0^1 f(\tau, s, \xi(\tau), \zeta(\tau, s)), \quad \xi(t) = x.$$

Assuming that Theorem 2.3 is true, let us complete the proof of Theorem 2.1. We have shown that W^u is an upper semicontinuous subsolution and W_d is a lower semicontinuous supersolution, which agree at time $t = T$. By Theorem 2.3, $W^u \leq W_d$, but then, $W(t, x) \equiv W^u(t, x) = W_d(t, x)$ is a continuous viscosity solution of (2.5) and we are done.

Proof of Theorem 2.3(a). We will only sketch the proof of the theorem since it is very similar to [6, Thm. 4.2]. Refer to that proof for complete details.

First, we may assume that $u(t, x) > \min_{z \in Z} h(t, x, z)$ because otherwise, since v is a supersolution, $v(t, x) \geq \min_{z \in Z} h(t, x, z) \geq u(t, x)$ and there is nothing to prove. Set

$$v'(t, x) = v(t, x) + \frac{\beta}{t},$$

where $\beta > 0$. Then $v' \geq v$ and it is easy to check that v' is a lower semicontinuous viscosity supersolution of

$$v'_t + \bar{H}(t, x, v', D_x v') + \frac{\beta}{t^2} = 0.$$

Set $w(t, x, y) = u(t, x) - v'(t, y)$. Since u is an upper semicontinuous subsolution, it is immediate that w is an upper semicontinuous subsolution of the equation

$$w_t + \bar{H}^*(t, x, w + v'(t, y), D_x w) - \bar{H}_*(t, y, -w + u(t, x), -D_y w) - \frac{\beta}{t^2} \geq 0.$$

Now consider $M_\alpha \equiv \sup_{[0, T] \times R^{2n}} (w(t, x, y) - \alpha/2 |x - y|^2)$, for $\alpha > 0$. Then $M_\alpha < \infty$ for large α and if $(t_\alpha, x_\alpha, y_\alpha)$ satisfies

$$\lim_{\alpha \rightarrow \infty} (M_\alpha - w(t_\alpha, x_\alpha, y_\alpha) + \frac{\alpha}{2} |x_\alpha - y_\alpha|^2) = 0,$$

then (i) $\alpha|x_\alpha - y_\alpha|^2 \rightarrow 0$, and (ii) $M_\alpha \rightarrow u(t', x') - v'(t', y') = \max(u - v')$.

Assume that $\max(u - v') > 0$. Then $0 < t' < T$ and from the definition of viscosity subsolution, with the test function $\alpha/2|x - y|^2$ we have that

$$\begin{aligned} & \bar{H}^*(t_\alpha, x_\alpha, w(t_\alpha, x_\alpha, y_\alpha) + v'(t_\alpha, y_\alpha), \alpha(x_\alpha - y_\alpha)) \\ & - \bar{H}_*(t_\alpha, y_\alpha, -w(t_\alpha, x_\alpha, y_\alpha) + u(t_\alpha, x_\alpha), \alpha(x_\alpha - y_\alpha)) - \frac{\beta}{t^2} \geq 0. \end{aligned}$$

Since we may assume that $w(t_\alpha, x_\alpha, y_\alpha) > 0$ for large α , we have that

$$u(t_\alpha, x_\alpha) = w(t_\alpha, x_\alpha, y_\alpha) + v'(t_\alpha, y_\alpha) > v'(t_\alpha, y_\alpha).$$

Using the formulas for the upper and lower semicontinuous envelopes of \bar{H} and monotonicity properties of $\bar{H}(\cdot, \cdot, r, \cdot)$ we obtain

$$\bar{H}^*(t_\alpha, x_\alpha, u(t_\alpha, x_\alpha), \alpha(x_\alpha - y_\alpha)) = \bar{H}(t_\alpha, x_\alpha, u(t_\alpha, x_\alpha) - 0, \alpha(x_\alpha - y_\alpha))$$

and, for large enough α ,

$$\begin{aligned} \bar{H}^*(t_\alpha, y_\alpha, v'(t_\alpha, y_\alpha), \alpha(x_\alpha - y_\alpha)) &= \bar{H}(t_\alpha, y_\alpha, v'(t_\alpha, y_\alpha) + 0, \alpha(x_\alpha - y_\alpha)) \\ &\geq \bar{H}(t_\alpha, y_\alpha, u(t_\alpha, x_\alpha) - 0, \alpha(x_\alpha - y_\alpha)). \end{aligned}$$

Consequently,

$$\begin{aligned} 0 &\leq \bar{H}(t_\alpha, x_\alpha, u(t_\alpha, x_\alpha) - 0, \alpha(x_\alpha - y_\alpha)) - \bar{H}(t_\alpha, y_\alpha, v'(t_\alpha, y_\alpha) + 0, \alpha(x_\alpha - y_\alpha)) - \frac{\beta}{t_\alpha^2} \\ &\leq \bar{H}(t_\alpha, x_\alpha, u(t_\alpha, x_\alpha) - 0, \alpha(x_\alpha - y_\alpha)) - \bar{H}(t_\alpha, y_\alpha, u(t_\alpha, x_\alpha) - 0, \alpha(x_\alpha - y_\alpha)) - \frac{\beta}{t_\alpha^2} \\ &\leq \bar{H}(t', y_\alpha, u(t_\alpha, x_\alpha) - 0, \alpha(x_\alpha - y_\alpha)) \\ &\quad - \bar{H}(t', y_\alpha, u(t_\alpha, x_\alpha) - 0, \alpha(x_\alpha - y_\alpha)) - \frac{\beta}{t'^2} + o_{1/\alpha}(1) \end{aligned}$$

where we have used the analogue of (2.3a) for \bar{H} in the last line. Therefore, $-\beta/t'^2 \geq 0$ which is clearly a contradiction. Since $\beta > 0$ was arbitrary, we conclude that $u \leq v$.

Details which remain consist of guaranteeing that the maxima in the proof are actually achieved. This is done by penalizing large x values (see [6]).

For the proof of part (b) we need only state that the value function W in the statement of (b) is the, unique viscosity solution of (2.5) satisfying the terminal condition $W(T, x) = \min_{z \in Z} h(T, x, z)$. The proof of this is virtually identical to [6, Thm. 4.2]. Therefore, the limit of the fast minimax problem must be this solution, and thus the value function of (b). \square

Remark. We used the uniqueness theorem to establish convergence of V^ε to a continuous function W . When h is independent of the fast variable this is not necessary since uniform convergence can be established in a way similar to Lemma 1.2. When h is independent of t/ε , the proof of [6, Prop. 1.5] along with (A) shows that $\|V^\varepsilon\| \leq K$ and $\|DV^\varepsilon\| \leq K$ in the uniform norm, with K independent of ε . Therefore, V^ε has a uniformly convergent subsequence to a Lipschitz continuous function W . The proof of [6, Prop. 1.5] is a direct proof and does not involve second-order partial differential equation approximations. When h depends on t/ε , we should *not* expect uniform convergence.

We conclude this paper by stating the result for the minimax problem when the controls are inertial. Again, assume that $Z = [0, 1]^p$ and the dynamics f and h are 1-periodic in the z variable.

THEOREM 2.3. Let $V^{\varepsilon,L}(t, x, z)$ denote the value function for the fast minimax problem when the controls ζ must be chosen from $Z_z^L[t, T]$. Then

$$U(t, x) = \lim_{L \rightarrow \infty} \lim_{\varepsilon \rightarrow 0} V^{\varepsilon,L}(t, x, z)$$

is the unique continuous viscosity solution of

$$\max \left\{ U_t + \min \left\{ D_x U \cdot \int_0^1 f(t, s, x, z) ds : z \in Z(t, x, U(t, x)) \right\}, \right. \\ \left. \min_{z \in Z} h(t, x, z) - U(t, x) \right\} = 0,$$

on Ω and $U(T, x) = \min_{z \in Z} h(T, x, z)$. Further,

$$U(t, x) = \inf_{\zeta \in Z[t, T]} \sup_{t \leq \tau \leq T} h(\tau, \xi(\tau), \zeta(\tau)),$$

where

$$\frac{d\xi}{d\tau} = \int_0^1 f(\tau, s, \xi(\tau), \zeta(\tau)) d\tau, \quad t < \tau \leq T, \quad \xi(t) = x.$$

Finally, $W(t, x) = \lim_{\varepsilon \rightarrow 0} \lim_{L \rightarrow \infty} V^{\varepsilon,L}(t, x, z)$, where W is given in Theorem 2.2, and $W(t, x) \leq U(t, x)$ on $\bar{\Omega}$.

The proof of this theorem is similar to that of Theorem 1.5 if we use the results concerning Lipschitz controls for minimax control problems from [4]. Once again we see that Lipschitz controls cannot keep up with rapid oscillations.

Remark. The results of this section are true for the more general fast minimax cost

$$V^{\varepsilon}(t, x) = \inf_{\zeta \in Z[t, T]} \sup_{t \leq \tau \leq T} \left\{ \int_t^{\tau} k\left(r, \frac{r}{\varepsilon}, \xi(r), \zeta(r)\right) dr + h(\tau, \xi(\tau), \zeta(\tau)) \right\},$$

where k is a given function satisfying a condition like (A). In this case $W(t, x) = \lim_{\varepsilon \rightarrow 0} V^{\varepsilon}(t, x)$ satisfies

$$W_t + \min_{z(\cdot) \in \mathcal{A}_{\infty}(t, x, W(t, x))} \{D_x W \cdot \bar{f}(t, x, z(\cdot)) + \bar{k}(t, x, z(\cdot))\} = 0,$$

where $\bar{k}(t, x, z(\cdot)) = \int_0^1 k(t, s, x, z(s)) ds$.

Acknowledgments. I am grateful to the reviewers for their careful reading of this paper. One comment led to a substantial simplification of the proofs and another comment led to a revision of Theorem 2.1. I also thank L. C. Evans for sending me a preprint of [14].
